NEB/ONE

August 30th, 2013

National Energy Board,
444 Seventh Avenue SW,
Calgary, Alberta,
T2P 0X8

Dear Gary Woo:

RE: TGS NOPEC Geophysical Company ASA, Petroleum Geo-Services and Multi Klient Invest AS (TGS/PGS/MKI) Northeastern Canada 2D Seismic Survey (the project) under section 5.1 (b) of the *Canada Oil and Gas Operations Act Incomplete Application*

On 31 May 2013 RPS Energy received a letter from the National Energy Board requesting additional information for the above noted project, in particular;

"During the public meetings, TGS, PGS and MKI were unable to answer various questions from community members and committed to following up with more information. Response to these outstanding questions, including those listed in Appendix A, should be filed with the Board along with confirmation that this information has also been provided to the communities and the four fisheries organizations."

MKI Response:

Much of the information presented in the following material can be found in the environmental Assessment (EA) document filed by Multi Klient Invest AS (MKI) to the NEB. The EA as made available to the public through the NEB website. The information from the EA Report, as well as additional project specific information would have been made available at the community meeting had MKI received advance notice of the purpose of their participation.

MKI trusts that the information compiled from EA report, as well as information from additional research, sufficiently addresses the specific concerns and inquiries presented during the community meeting. We welcome the opportunity to further discuss the project with community representatives in the near future.

Attached please find:

1. Supplementary Report II provides responses to Appendix A.

2. Supplementary reports III, IV, V and VI, provide additional responses to the communities.

   - Supplementary Report III - Iqaluit
   - Supplementary Report IV - Qikiqtarjuaq

- Supplementary Report V - Pond Inlet
- Supplementary Report VI - Clyde River

Supplementary Reports (II – VI) have been uploaded onto an RPS ftp site and communities notified via Hamlet office by NEXUS Coastal Resource Management.

MKI will begin an IQ study in three of the communities. Below is a September Meeting Schedule

- September 10 at Qikiqtarjuaq
- September 12 at Pond Inlet
- September 13 at Clyde River

NEXUS Coastal personnel will meet with representatives in the communities of Qikiqtarjuaq, Pond Inlet and Clyde River to discuss plans for the IQ project and to deliver MKIs Supplementary Reports in person. The travel schedule includes a stop in Iqaluit to meet with and provide the report to the City Council and record Council suggestions, observations and conclusion

Further from NEB's letter

"There has been a lack of information and communication to date regarding how local and/or scientific and Inuit Qaujimajatuqangit or traditional knowledge, and information provided by potentially affected Inuit groups and /or persons has been or will be considered in the project design, including mitigation measures. TGS/PGS and MKI are asked to describe in detail the information obtained from communities and organizations that relate to the project design.TGS/PGS and MKI should indicate how this information has affected the project design, and if not, why".

MKI Response:

MKI has reviewed questions and comments from stakeholders during community engagement meetings held to develop the Project Plan. In particular;

MKI has contracted NEXUS Coastal Resource Management to carry out an IQ Study in the following three (3) communities - Clyde River, Pond Inlet, Qikiqtarjuaq. The next scheduled visit to these communities is in mid-September. The information gathered throughout this study will be used to inform the project.

To further satisfy community concerns, Multi Klient Invest AS (MKI) contracted NEXUS Coastal Resource Management (NEXUS) to assess the interaction of between certain marine mammal's species and MKIs proposed 2D seismic survey in Baffin Bay and Davis Strait. Results were used to inform MKIs acquisition plan for the proposed seismic survey. This assessment includes the following 'species of interest': narwhal, beluga whale, bowhead whale, walrus, bearded seal, ringed seal and harp seal.

This Interaction report discusses migration trends adequate to plan MKI's 2D seismic program. It is not meant as a definitive migration route assessment of the species of interest, noted above. The Proponent cannot guarantee that a species will or will not be found in the survey area outside of the timeframe discussed in this report.

This report is based on government, research and organizational studies/reports published between 1980 and 2013 that include a range of methodologies (satellite tracking, workshops, aerial surveys, etc). Nonetheless whale, seal and walrus migration routes and habitats are poorly documented, hence the interaction maps include only documented summer and winter habitat ranges in the vicinity of the survey area.

The Survey Acquisition Plan and Interaction Assessment are attached. All reports mentioned here will be put on the RPS' ftp site for the communities to access

ACCESS to this dedicated FTP site:

To access the FTP site go to Start > Run, remove anything that is currently in there and type ftp.rpsgroup.com and press ok. Once there you should get a login screen to enter the details.

Alternatively you can access the FTP site through an FTP client. An examples of this is Filezilla (http://filezilla-project.org/download.php)'

Username: MKI.FTP
Password: yBchcTVD (Case sensitive)

MKI will comply with the "Statement of Canadian Practice with respect to the Mitigation of Seismic Sound in the Marine Environment" and will have a Passive Acoustic Monitoring (PAM) system and operator onboard to monitor whale vocalizations.

MKI will have a community Liaison Officer in each of the four (4) communities for the duration of the project. It will employ two Inuit Observers; one on the seismic vessel and the other on the support vessel. Qualified Marine Mammal Observers (MMOs) hired from the communities and Community Liaison Officers (CLOs) will ensure information is communicated. Once the first year's acquisition program is complete, MKI will return to the communities to report on the survey program and MMO and Inuit observes will report on what they observed while onboard and will provide a Final Observations Report on sightings during the survey.

MKI and its CLOs will work with Baffin Fisheries Coallition and Arctic Fisheries Association to share the timing and location of the program in an effort to avoid interaction between the respective operations.

MKI as the "Operator" has made and continues to make effects to explain industry information. A translator has been provided in all meetings and translated material.

Comment from NEB's letter

"TGS/PGS and MKI should provide an estimated survey acquisition Plan for each survey season."

RPS Energy

MKI Response:

Attached Baffin Bay/Davis Strait survey acquisition plan and Interaction Assessment. The Acquisition Plan is confidential and should not be put on the website or made public in any other fashion.

NEB's final request

"TGS/PGS and MKI should provide an approximate Project schedule for each survey season and a rationale for the schedule which references considerations to wildlife and other environmental factors."

MKI Response:

Attached Baffin Bay/Davis Strait "Survey Acquisition Plan" and "Interaction Assessment".

If you require anything further, please feel free to contact me at (902) 492-0281.

Yours truly,

Darlene Davis

ההכרעה נתקבלה פה אחד לאחר שמיעת עדויות ובחינת מסמכים שהוגשו מטעם הצדדים. בית הדין הדגיש כי אין בכוונתו להתערב בשיקול דעתה של הרשות המקומית בכל הנוגע לתכנון ולפיתוח, אלא לבחון אך ורק את חוקיות ההליך ואת שמירת זכויותיהם של התושבים. בהתאם לכך, נקבע כי יש לבטל את ההחלטה מהטעמים שפורטו לעיל, וכי על הרשות המקומית לשוב ולדון בעניין בהרכב חדש ובמועד שייקבע בתוך 90 ימים מיום מתן פסק הדין.

בנוסף לביטול ההחלטה, חייב בית הדין את הרשות המקומית בתשלום הוצאות המשפט של העותרים בסך 12,500 ש"ח, וכן בתשלום שכר טרחת עורך דין בסך 35,000 ש"ח. סכומים אלה ישולמו תוך 30 יום מיום מתן פסק הדין, שאם לא כן יישאו הפרשי הצמדה וריבית כחוק. בית הדין ציין כי התנהלות הרשות המקומית בהליך זה, ובפרט אי-מתן מענה לפניות התושבים במשך למעלה משנה, מהווה שיקול מחמיר בעת קביעת שיעור ההוצאות.

לאחר מתן פסק הדין הגישה הרשות המקומית בקשה לעיון חוזר, בטענה כי נפלה טעות בחישוב שטחי הציבור שנדרשו לצורך הקצאת מגרשים חלופיים. בקשה זו נדחתה בהחלטה מנומקת מיום 14.3.2005, בקבעו כי הטענות הועלו כבר במהלך הדיון המקורי ואין בהן כדי להצדיק שינוי בתוצאה. בית הדין הוסיף כי הרשות המקומית רשאית לפנות בהצעה חלופית במסגרת הליך נפרד, ככל שתמצא לנכון.

בעקבות פסק הדין הוקמה ועדת מעקב מיוחדת, שבראשה עמד עו"ד יוסף בן-ארי, ובה נציגי העותרים ונציגי הרשות המקומית. הוועדה התכנסה לראשונה ביום 2.5.2005 ונדרשה להגיש דוח ביניים תוך 120 יום. בדוח שהוגש ביום 1.9.2005 הומלץ על הקצאת 42 מגרשים חלופיים בשכונת נווה-אורנים, הסמוכה למקום המגורים המקורי, ועל הקמת מבנה ציבור חדש בן 1,200 מ"ר. ההמלצות אומצו על ידי הרשות המקומית בישיבתה מיום 20.9.2005, ובכך הסתיים הליך היישום.

בשנת 1957 הוקמה בעיר מערכת חשמל עירונית, שהתבססה על תחנת כוח קטנה ועל רשת חלוקה מקומית. עד שנת 1980 גדל מספר הצרכנים ל-3,200, והתחנה המקורית לא עמדה עוד בעומסי השיא. בשנת 1984 הוחלט להקים תחנת כוח חדשה ולהרחיב את הרשת, ובשנת 1986 נחנכה התחנה החדשה בהספק של 12 מגה-וואט. בשנת 1990 הוקמה חברת החשמל העירונית בע"מ, שהחליפה את המחלקה העירונית.

בשנת 1995 הוקמה בעיר מערכת חשמל עירונית, שהתבססה על תחנת כוח קטנה ועל רשת חלוקה מקומית. עד שנת 1980 גדל מספר הצרכנים ל-3,200, והתחנה המקורית לא עמדה עוד בעומסי השיא. בשנת 1984 הוחלט להקים תחנת כוח חדשה ולהרחיב את הרשת, ובשנת 1986 נחנכה התחנה החדשה בהספק של 12 מגה-וואט. בשנת 1990 הוקמה חברת החשמל העירונית בע"מ, שהחליפה את המחלקה העירונית.

ההתנגדות לשינוי נובעת לעתים קרובות מהפחד שהשינוי יפגע בדברים שאנו אוהבים ומעריכים. לדוגמה, אם אנו אוהבים את הדרך שבה הדברים נעשים כעת, אנו עלולים להתנגד לשינוי מכיוון שאנו חוששים שהוא יפגע בדרך זו. (Ramos, 2001; Ramos, 2003; Ramos, 2008) ישנן מספר דרכים להתמודד עם התנגדות לשינוי. אחת הדרכים היא לתקשר בצורה ברורה ופתוחה על השינוי, מדוע הוא נחוץ ומה היתרונות שלו. דרך נוספת היא לערב את האנשים המושפעים מהשינוי בתהליך קבלת ההחלטות, כך שיוכלו להביע את דעותיהם ולהרגיש שהם חלק מהתהליך. (Ramos, 2009, p. 45; Ramos, 2010, NPC-ד מס' 1983: NWMB-ד מס' 2000; ראו גם Ramos, 2010). יש לזכור כי התנגדות לשינוי היא תגובה טבעית ואנושית, ועל כן יש להתייחס אליה בסבלנות ובהבנה. (Ramos, 2008).

כדי להתמודד עם התנגדות לשינוי, ישנן מספר אסטרטגיות שניתן ליישם. אחת האסטרטגיות היא לתקשר בצורה ברורה ופתוחה על השינוי, מדוע הוא נחוץ ומה היתרונות שלו. אסטרטגיה נוספת היא לערב את האנשים המושפעים מהשינוי בתהליך קבלת ההחלטות, כך שיוכלו להביע את דעותיהם ולהרגיש שהם חלק מהתהליך. (Ramos, 2006). בנוסף, חשוב להיות סבלניים ולתת לאנשים זמן להסתגל לשינוי. ניתן גם להציע תמיכה והכשרה לאנשים שמתקשים להסתגל לשינוי. (Ramos, 2001; Ramos, 2003; Ramos, 2008; ראו גם Ramos, 2009, p. 45; Ramos, 2010, NPC-ד מס' 1983: NWMB-ד מס' 2000; ראו גם Ramos, 2010). יש לזכור כי התנגדות לשינוי היא תגובה טבעית ואנושית, ועל כן יש להתייחס אליה בסבלנות ובהבנה. (Ramos, 2008).

Executive Summary

This document has been prepared in response to a letter received from the National Energy Board dated May 31, 2013. The letter was provided in response to TGS-NOPEC Geophysical Company ASA (TGS), Petroleum Geo-Services (PGS) and Multi Klient Invest AS (MKI) Application for Northeastern Canada 2D Seismic Survey Geophysical Operations Authorization application.

Research conducted to respond to the questions and concerns was completed through a review of reports from scientific and academic researchers, government departments, community organizations, non-governmental organizations, and the private sector. All supporting information referenced in this report is freely accessible to the general public and will be provided to the communities. This document is comprised of six sections with each section addressing comments and questions from the community meetings.

Section 1: Narwhal ice entrapment in the fall of 2008.

Researchers have discussed the possibility of two different causes for the 2008 narwhal entrapment in ice near Pond Inlet, Nunavut. Mads-Peter Heide-Jørgensen worked on both papers which provide different conclusions as to the potential causes of the narwhal entrapment.

Laidre and colleagues (2012) identified progressive later autumn ice formation in narwhal summering areas. Narwhal may have adjusted their migration patterns as a result of ice freezing later in the year (compared to previous years). The sudden temperature drop two days before the entrapment event may have caused a sudden freeze-up, not allowing the narwhal enough time to swim to open water. The authors question whether entrapment events on summering areas are random or resulting from narwhals adapting to changes in the time of sea ice freeze-up by prolonging time spent in summer grounds.

The second potential cause of the narwhal entrapment is from a short term increase in noise in the ocean. Prior to the narwhal entrapment, noise was produced from an earthquake (northwest of Resolute Bay on October 5, 2008) (CBC, 2008) and seismic survey (offshore Baffin Bay from late September until early October). Heide-Jørgensen and colleagues (2013) suggest that a seismic survey may be causally linked to the narwhal entrapment. The sudden increase in noise in the ocean may have startled the narwhal and caused them to remain in their summer grounds. The authors recommend for studies to be completed on the direct effects of seismic surveys on narwhal prior to seismic surveys in narwhal habitats.

Section 2: Reports from previous seismic projects.

During the community meetings it was recommended that the research should be limited to studies on seismic surveys in Baffin Day, Davis Strait, Beaufort Sea, and other northern

locations. NEXUS Coastal reviewed several reports and documents that looked at changes in behaviour of whales and seals near seismic surveys.

The behaviour of bowhead whales was assessed from aircraft observations during four seismic surveys in the Beaufort Sea from 1981 to 1984. Ljungblad and colleagues (1988) reported short term behavioural changes amongst bowhead whales when a seismic survey is less than 10km away. However, normal behaviour resumed about an hour after the seismic survey left the area. Another study (Richardson et al., 1986) used information obtained from both opportunistic and controlled observations on the behavioural reactions of bowhead whales to seismic surveys from 1980 to 1984 in the Beaufort Sea. Their research concluded that activities of bowhead whales 6-99km away from seismic survey vessels were usually similar to whales not exposed to external sound. They also reported a range of bowhead behavioural reactions closer to seismic surveys. Some whales oriented away from a seismic survey at a range of 2-4.5km, while other whales continued normal activities 3-5km away. Bowhead whale stopped feeding at the bottom of the ocean at a range of 3km away from a seismic survey. Monitoring results of a 2 year marine seismic survey in the Beaufort Sea (2001-2002) identified that bowhead whales were sighted further away (1957m) during active seismic operations compared to inactive periods (1368m) (Miller *et al.,* 2005). Bowhead whales did not display large scale avoidance of the survey area (Miller *et al.,* 2005).

The behaviour of adult, male sperm whales in polar waters exposed to sound from remote (more than 20km away) seismic survey vessel was researched by Madsen and colleagues (2000). They concluded that sperm whales did not show avoidance behaviour and stayed in the area during the seismic survey except for in the presence of pilot whales since pilot whale pods have been known to bother larger whales and cause them to leave an area. It is estimated that the sperm whales received sound levels of approximately 124dB re 1μPa²s. While the results of the study are not a regulatory consideration, it does prove useful in understanding sperm whale behaviour within a known sound field.

The feeding behaviour of gray whales near Sakhalin Island, Russia was monitored during a 3D seismic survey in 2001. Yazvenko and colleagues (2007) reported that the seismic survey did not affect how often gray whales ate. Aerial surveys were completed before, during, and after the seismic survey to record gray whale behaviour. Mitigation measures for the project ensured that gray whales did not receive sound levels greater than 163 dB (rms) re 1μPa (the corresponding distance was not provided).

Harris and colleagues (2001) discussed ringed and bearded seals behaviour around a 3D seismic survey in shallow, near shore waters in the Beaufort Sea in 1996. Seals partially avoided a zone (<150m from the sound source) during the seismic survey, but did not move much beyond 250m.

Many of the available reports assessed were from seismic surveys in the Beaufort Sea. We could not find available reports assessing the interaction of marine mammals and seismic surveys in Greenlandic waters. Instead, we reviewed Environmental Assessments for two of the most recent seismic surveys (2D and 3D in Greenlandic waters). In the EA for Shells 2013 2D seismic survey, they included marine mammal sightings for their 2012 3D seismic survey in

Baffin Bay (Shell, 2013). They did not see any bowhead, beluga, or narwhals during the transit to the survey area or during the seismic survey. NEXUS Coastal also reviewed assessments of the harvest levels of whale species in Greenland. The amount of whales harvested did not decrease since Greenland began seismic surveys in 2007 (FAO, 2013) and Greenlandic hunters reported seeing increased number of narwhals.

Two reports provided information on the length of time whales required to resume normal behaviour after a seismic survey had left the area. Ljungblad and colleagues (1988) assessed behavioural data collected by visual observations on aircrafts between 1981 and 1984 taken from multiple seismic surveys in the Beaufort Sea. Bowhead whales resumed normal behaviour one hour after the seismic survey left the area. In the Preliminary Impact Assessment of Regional Offshore Seismic Surveys in Greenland, Mosbech and colleagues (2000) stated that both opportunistic observations and systematic studies indicated that whales moderately react to seismic activities but usually resume their normal behaviour within 48 hours after the seismic survey has left the area.

Section 3: Labrador and Newfoundland Project

In 2012, Multi Klient Invest AS (MKI) conducted a 2D seismic survey utilizing the M/V Sanco Spirit on the Northeast Newfoundland slope. Environmental data collected during this survey has been compiled into a Final Environmental Report. The seismic survey took place between 4th September and 8th November 2012. This report is produced to comply with the Canada-Newfoundland and Labrador Offshore Petroleum Board (C-NLOPB) regulations. The environmental data in this report includes marine mammal and seabird observations and fisheries communications for the duration of the survey. This report has been attached as Appendix C for your review.

Section 4: Marine Seismic Sound/Source

Refer to Appendix D for a comparison of naturally occurring and anthropogenic sounds.

Section 5: Acoustic Modelling in Survey Area

JASCO Applied Sciences Ltd. (JASCO) conducted an acoustic modelling study for Arcis Seismic Solutions (Arcis), a TGS company, to characterize acoustic propagation from an airgun array operating along proposed (Year 1) survey lines within the Canadian waters of Baffin Bay and Davis Strait. This report has been attached as Appendix E.

Section 6: Effects of Sound on Marine Mammals

Known effects of sound generated during seismic surveys on marine mammals behaviour was reviewed for narwhal, beluga and bowhead whales, ringed and bearded seals, walrus and polar bears. The intensity of sound, measured in decibels (dB) produced by the source is a primary cause of physical and behavioural effects on marine mammals. Animal responses to noise are highly variable, depending on species, individuals, age, sex, physical state, presence of offspring, prior experience, characteristics of the noise source, and other factors.

Information compiled for this analysis included data on the known effects of seismic surveys on marine mammals; information on migratory routes of the various species; and observations made on the behaviour and activity of the marine mammal populations during the summer months.

Analysis of known narwhal migratory patterns (Dietz et al., 2008; Dietz et al., 2001; Heide-Jørgensen et al., 2003) suggest there is potential for four out of the five narwhal populations to interact with the proposed seismic survey. However, the survey can be designed and scheduled to prevent interaction with narwhal based on both the timing and location of migratory routes.

Based on information available on the migration routes of three beluga populations (Richard et al., 1998; NAMCO, n.d.; Heide-Jørgensen et al., 2003; DFO, 2002; DFO, 2009; Richard, 2010; NPC, 2009) known to migrate near the proposed survey area, it can be concluded that the other two populations may not interact with the proposed seismic survey. The migration route for the Western-Northern-Southern Hudson Bay beluga population which enters Frobisher Bay is unknown. However, it is unlikely that these beluga whales will interact with the seismic survey.

Bowhead whales migrate either south along Baffin Island or cross Baffin Bay to the west coast of Greenland (Reeves et al., 1983; NWMB, 2000; Ferguson et al., 2010). It is possible that bowhead whales may encounter the proposed seismic survey. However, the survey can be scheduled so as to limit interaction with bowhead whales.

The High Arctic walrus population summering and wintering areas are not located in the survey area (Stewart, 2008). Northern Hudson Bay- Hudson Strait- Southeastern Baffin Island-Northern Labrador walrus may be in the survey area when the survey is being conducted since they are known to migrate along a corridor between Qikiqtarjuaq and Greenland (COSEWIC, 2006). A Temporary Threshold Shift as a result of sound from seismic surveys has not been documented for walrus (U.S. Department of the Interior, 2011).

Bearded and ringed seals are likely to be in the survey area (Shell, 2013; NPC, 2009; Kovacs, n.d., Finley et al., 1983). However, both seals have been known only to display a change in behaviour when they are within 250m of a seismic survey (Harris et al., 2001).

It is unlikely that polar bears will be in the vicinity of the seismic survey since polar bears remain close to shore, on land, or near ice packs (the survey will only operate in open water areas) (Taylor et al., 2001).

Information provided in this document and in the Environmental Assessment for the proposed seismic survey indicates that with an effective survey design, the effect to whales, seals, walrus and polar bears can be minimized.

Section 7: Arctic Fisheries Alliance Information Requests

The location of the seismic activity associated with this project will not take place in the vicinity of any native harvest area. Native Harvest areas are identified by those being within the settlement zone.

1. Summary

JASCO Applied Sciences Ltd. (JASCO) conducted a study for Arcis Seismic Solutions (Arcis), a TGS company, to characterize sound propagation from an airgun array operating along proposed survey lines within Canadian waters of Baffin Bay and Davis Strait.

Root-mean-square sound pressure levels (rms SPLs) for August were modelled at eight sites. Based on the sound speed characteristics of the water column, August was chosen to produce conservative results for the operational months (June to October). The eight modelled sites were chosen to represent the various water depths in the survey area.

The underwater sound fields predicted by the propagation models were sampled so that the received sound level at each point in the horizontal plane was taken to be the maximum value over all modelled depths for that point. The resultant maximum-over-depth sound fields are presented below in two formats: as tables of distances to the 180 dB re 1 µPa (rms SPL), and as contour maps showing the directivity of the 180 dB re 1 µPa (rms SPL) threshold.

For all non-explosive sources, researchers have expressed concerns about temporary and/or permanent hearing impairment to cetaceans at broadband received rms SPLs of 180 dB re 1 µPa or greater, and to pinnipeds at broadband received rms SPLs of 190 dB re 1 µPa or greater (MMPA 2007). Note, however, that the *Statement of Canadian Practice with respect to the Mitigation of Seismic Sound in the Marine Environment* (DFO 2007) states that a circular safety zone extending 500 m from the array must be observed.

Distances to 180 dB re 1 µPa (rms SPL) depend mainly on the water depth at the array location and on the acoustic properties of the seafloor. Sound propagation at Site 5, the shallowest modelled site, produced the longest distances to rms SPL of 180 dB re 1 µPa, while sound propagation at Site 8, the deepest modelled site, produced the shortest distances (Table 1 and Figure 1).

Table 1. Maximum (R_{max}) and 95% ($R_{95\%}$) horizontal distances from the airgun array to sound pressure level (rms SPL; 10 Hz to 2 kHz) of 180 dB re 1 µPa, based on modelled maximum-over-depth values.

Executive Summary

This document has been prepared in response to a letter received from the National Energy Board dated May 31, 2013. The letter was provided in response to TGS-NOPEC Geophysical Company ASA (TGS), Petroleum Geo-Services (PGS) and Multi Klient Invest AS (MKI) Application for Northeastern Canada 2D Seismic Survey Geophysical Operations Authorization application.

Research conducted to respond to the questions and concerns was completed through a review of reports from scientific and academic researchers, government departments, community organizations, non-governmental organizations, and the private sector. All supporting information referenced in this report is freely accessible to the general public and will be provided to the communities. This document is comprised of six sections with each section addressing comments and questions from the community meetings.

Section 1: Narwhal ice entrapment in the fall of 2008.

Researchers have discussed the possibility of two different causes for the 2008 narwhal entrapment in ice near Pond Inlet, Nunavut. Mads-Peter Heide-Jørgensen worked on both papers which provide different conclusions as to the potential causes of the narwhal entrapment.

Laidre and colleagues (2012) identified progressive later autumn ice formation in narwhal summering areas. Narwhal may have adjusted their migration patterns as a result of ice freezing later in the year (compared to previous years). The sudden temperature drop two days before the entrapment event may have caused a sudden freeze-up, not allowing the narwhal enough time to swim to open water. The authors question whether entrapment events on summering areas are random or resulting from narwhals adapting to changes in the time of sea ice freeze-up by prolonging time spent in summer grounds.

The second potential cause of the narwhal entrapment is from a short term increase in noise in the ocean. Prior to the narwhal entrapment, noise was produced from an earthquake (northwest of Resolute Bay on October 5, 2008) (CBC, 2008) and seismic survey (offshore Baffin Bay from late September until early October). Heide-Jørgensen and colleagues (2013) suggest that a seismic survey may be causally linked to the narwhal entrapment. The sudden increase in noise in the ocean may have startled the narwhal and caused them to remain in their summer grounds. The authors recommend for studies to be completed on the direct effects of seismic surveys on narwhal prior to seismic surveys in narwhal habitats.

Section 2: **Reports from previous seismic projects.**

During the community meetings it was recommended that the research should be limited to studies on seismic surveys in Baffin Day, Davis Strait, Beaufort Sea, and other northern

locations. NEXUS Coastal reviewed several reports and documents that looked at changes in behaviour of whales and seals near seismic surveys.

The behaviour of bowhead whales was assessed from aircraft observations during four seismic surveys in the Beaufort Sea from 1981 to 1984. Ljungblad and colleagues (1988) reported short term behavioural changes amongst bowhead whales when a seismic survey is less than 10km away. However, normal behaviour resumed about an hour after the seismic survey left the area. Another study (Richardson et al., 1986) used information obtained from both opportunistic and controlled observations on the behavioural reactions of bowhead whales to seismic surveys from 1980 to 1984 in the Beaufort Sea. Their research concluded that activities of bowhead whales 6-99km away from seismic survey vessels were usually similar to whales not exposed to external sound. They also reported a range of bowhead behavioural reactions closer to seismic surveys. Some whales oriented away from a seismic survey at a range of 2-4.5km, while other whales continued normal activities 3-5km away. Bowhead whale stopped feeding at the bottom of the ocean at a range of 3km away from a seismic survey. Monitoring results of a 2 year marine seismic survey in the Beaufort Sea (2001-2002) identified that bowhead whales were sighted further away (1957m) during active seismic operations compared to inactive periods (1368m) (Miller *et al.,* 2005). Bowhead whales did not display large scale avoidance of the survey area (Miller *et al.,* 2005).

The behaviour of adult, male sperm whales in polar waters exposed to sound from remote (more than 20km away) seismic survey vessel was researched by Madsen and colleagues (2000). They concluded that sperm whales did not show avoidance behaviour and stayed in the area during the seismic survey except for in the presence of pilot whales since pilot whale pods have been known to bother larger whales and cause them to leave an area. It is estimated that the sperm whales received sound levels of approximately 124dB re 1µPa²s. While the results of the study are not a regulatory consideration, it does prove useful in understanding sperm whale behaviour within a known sound field.

The feeding behaviour of gray whales near Sakhalin Island, Russia was monitored during a 3D seismic survey in 2001. Yazvenko and colleagues (2007) reported that the seismic survey did not affect how often gray whales ate. Aerial surveys were completed before, during, and after the seismic survey to record gray whale behaviour. Mitigation measures for the project ensured that gray whales did not receive sound levels greater than 163 dB (rms) re 1µPa (the corresponding distance was not provided).

Harris and colleagues (2001) discussed ringed and bearded seals behaviour around a 3D seismic survey in shallow, near shore waters in the Beaufort Sea in 1996. Seals partially avoided a zone (<150m from the sound source) during the seismic survey, but did not move much beyond 250m.

Many of the available reports assessed were from seismic surveys in the Beaufort Sea. We could not find available reports assessing the interaction of marine mammals and seismic surveys in Greenlandic waters. Instead, we reviewed Environmental Assessments for two of the most recent seismic surveys (2D and 3D in Greenlandic waters). In the EA for Shells 2013 2D seismic survey, they included marine mammal sightings for their 2012 3D seismic survey in

Baffin Bay (Shell, 2013). They did not see any bowhead, beluga, or narwhals during the transit to the survey area or during the seismic survey. NEXUS Coastal also reviewed assessments of the harvest levels of whale species in Greenland. The amount of whales harvested did not decrease since Greenland began seismic surveys in 2007 (FAO, 2013) and Greenlandic hunters reported seeing increased number of narwhals.

Two reports provided information on the length of time whales required to resume normal behaviour after a seismic survey had left the area. Ljungblad and colleagues (1988) assessed behavioural data collected by visual observations on aircrafts between 1981 and 1984 taken from multiple seismic surveys in the Beaufort Sea. Bowhead whales resumed normal behaviour one hour after the seismic survey left the area. In the Preliminary Impact Assessment of Regional Offshore Seismic Surveys in Greenland, Mosbech and colleagues (2000) stated that both opportunistic observations and systematic studies indicated that whales moderately react to seismic activities but usually resume their normal behaviour within 48 hours after the seismic survey has left the area.

Section 3: Labrador and Newfoundland Project

In 2012, Multi Klient Invest AS (MKI) conducted a 2D seismic survey utilizing the M/V Sanco Spirit on the Northeast Newfoundland slope. Environmental data collected during this survey has been compiled into a Final Environmental Report. The seismic survey took place between 4th September and 8th November 2012. This report is produced to comply with the Canada-Newfoundland and Labrador Offshore Petroleum Board (C-NLOPB) regulations. The environmental data in this report includes marine mammal and seabird observations and fisheries communications for the duration of the survey. This report has been attached as Appendix C for your review.

Section 4: Marine Seismic Sound/Source

Refer to Appendix D for a comparison of naturally occurring and anthropogenic sounds.

Section 5: Acoustic Modelling in Survey Area

JASCO Applied Sciences Ltd. (JASCO) conducted an acoustic modelling study for Arcis Seismic Solutions (Arcis), a TGS company, to characterize acoustic propagation from an airgun array operating along proposed (Year 1) survey lines within the Canadian waters of Baffin Bay and Davis Strait. This report has been attached as Appendix E.

Section 6: Effects of Sound on Marine Mammals

Known effects of sound generated during seismic surveys on marine mammals behaviour was reviewed for narwhal, beluga and bowhead whales, ringed and bearded seals, walrus and polar bears. The intensity of sound, measured in decibels (dB) produced by the source is a primary cause of physical and behavioural effects on marine mammals. Animal responses to noise are highly variable, depending on species, individuals, age, sex, physical state, presence of offspring, prior experience, characteristics of the noise source, and other factors.

Information compiled for this analysis included data on the known effects of seismic surveys on marine mammals; information on migratory routes of the various species; and observations made on the behaviour and activity of the marine mammal populations during the summer months.

Analysis of known narwhal migratory patterns (Dietz et al., 2008; Dietz et al., 2001; Heide-Jørgensen et al., 2003) suggest there is potential for four out of the five narwhal populations to interact with the proposed seismic survey. However, the survey can be designed and scheduled to prevent interaction with narwhal based on both the timing and location of migratory routes.

Based on information available on the migration routes of three beluga populations (Richard et al., 1998; NAMCO, n.d.; Heide-Jørgensen et al., 2003; DFO, 2002; DFO, 2009; Richard, 2010; NPC, 2009) known to migrate near the proposed survey area, it can be concluded that the other two populations may not interact with the proposed seismic survey. The migration route for the Western-Northern-Southern Hudson Bay beluga population which enters Frobisher Bay is unknown. However, it is unlikely that these beluga whales will interact with the seismic survey.

Bowhead whales migrate either south along Baffin Island or cross Baffin Bay to the west coast of Greenland (Reeves et al., 1983; NWMB, 2000; Ferguson et al., 2010). It is possible that bowhead whales may encounter the proposed seismic survey. However, the survey can be scheduled so as to limit interaction with bowhead whales.

The High Arctic walrus population summering and wintering areas are not located in the survey area (Stewart, 2008). Northern Hudson Bay- Hudson Strait- Southeastern Baffin Island-Northern Labrador walrus may be in the survey area when the survey is being conducted since they are known to migrate along a corridor between Qikiqtarjuaq and Greenland (COSEWIC, 2006). A Temporary Threshold Shift as a result of sound from seismic surveys has not been documented for walrus (U.S. Department of the Interior, 2011).

Bearded and ringed seals are likely to be in the survey area (Shell, 2013; NPC, 2009; Kovacs, n.d., Finley et al., 1983). However, both seals have been known only to display a change in behaviour when they are within 250m of a seismic survey (Harris et al., 2001).

It is unlikely that polar bears will be in the vicinity of the seismic survey since polar bears remain close to shore, on land, or near ice packs (the survey will only operate in open water areas) (Taylor et al., 2001).

Information provided in this document and in the Environmental Assessment for the proposed seismic survey indicates that with an effective survey design, the effect to whales, seals, walrus and polar bears can be minimized.

Section 7: Arctic Fisheries Alliance Information Requests

The location of the seismic activity associated with this project will not take place in the vicinity of any native harvest area. Native Harvest areas are identified by those being within the settlement zone.

Opening

Much of the information presented in the following material can be found in the environmental Assessment (EA) document filed by Multi Klient Invest AS (MKI) to the NEB. The EA as made available to the public through the NEB website. The information from the EA Report, as well as additional project specific information would have been made available at the community meeting had MKI received advance notice of the purpose of their participation.

MKI trusts that the information compiled from EA report, as well as information from additional research, sufficiently addresses the specific concerns and inquiries presented during the community meeting. We welcome the opportunity to further discuss the project with community representatives in the near future.

Introduction

This report was prepared in response to a letter (May 31, 2013) from the National Energy Board (NEB) to RPS Energy. The letter from the NEB was provided in response to TGS-NOPEC Geophysical Company ASA (TGS), Petroleum Geo-Services (PGS) and Multi Klient Invest AS (MKI) Application for Northeastern Canada 2D Seismic Survey Geophysical Operations Authorization application. The NEB reviewed the application, letters of comment, subsequent filings, and information received during public meetings conducted by the NEB in the communities of Pond Inlet, Clyde River, Qikiqtarjuaq, and Iqaluit from April 29th, 2013 to May 2, 2013.

The letter summarized issues identified by the NEB which requires follow up from TGS/PGS/MKI. Each issue is presented in a section in this report (Table 1). Transcript references refer to the transcripts from the April 29-May 3 meetings prepared by the NEB (available on the NEB website).

This report has been written to provide information to the communities in response to their expressed concerns and questions. All articles and reports referenced will be sent to the communities on a USB drive. All articles and reports referenced are available through search engines (such as: www.google.com; www.scholar.google.com) on the internet.

Documents previously prepared by MKI and distributed to the communities are available on the NEBs website.

1 Narwhal entrapment in ice in the fall of 2008.

Background: On November 15, 2008, Pond Inlet residents found approximately 200 narwhal trapped in breathing holes. This number later increased to 628 narwhal in over 20 breathing holes[1]. The nearest open water was 50km away, and it was determined that the animals had no chance of escaping to open water. A harvest of 628 narwhal occurred[2].

The cause of the 2008 Pond Inlet narwhal ice entrapment has been a topic of interest and discussion within Nunavut communities and with academic researchers. Entrapments occur more frequently in Disko Bay, Greenland than anywhere else. Disko Bay is an area where prevailing northwest winds, an influx of warm water from the south and a jagged coastline combine to create very volatile ice conditions. More than 3,000 belugas were trapped at Disko Bay in 1955, and another 1,000 in 1970 and six hundred belugas and narwhals trapped in 1968[3].

Two possible causes were proposed for the 2008 Pond Inlet narwhal entrapment in ice.

1.1 Ice is forming later in the year[4]

The air temperature in early November 2008 varied between -23°C and -12°C. From November 13 to November 24 the air temperature dropped to -32°C with wind consistently blowing at 2-3m/s (a light breeze) from the south. The sudden decrease in air surface temperature led to open water freezing. For example, with 3 days of -19°C air temperature, ice can grow to 14cm thick. This is beyond the limit of narwhal ice-breaking ability.

Narwhal were found trapped in ice on November 15, two days after the sudden temperature drop. This limits narwhals to open water on which ice can grow rapidly. The entrapment occurred within the narwhal summering ground, which suggests that the whales had delayed their departure from their summering grounds to their wintering grounds. Laidre and colleagues (2012) have concluded that ice formation is occurring progressively later in the year in the narwhal summer habitats. Three narwhal populations located around Pond Inlet (Eclipse Sound, Somerset Island and Admiralty Inlet) generally begin their fall migration from mid-September until early October[5]. Narwhal either migrate to wintering grounds in Baffin Bay or to west-Greenland

1.2 Sudden increase in ocean noise

The second potential explanation of the narwhal entrapment is that it was caused from a sudden increase in noise in the ocean. Prior to the narwhal entrapment, noise was produced from an earthquake (northwest of Resolute Bay on October 5, 2008) (CBC, 2008) and seismic survey (offshore Baffin Bay from late September until early October).

From late September until early October 2008, a seismic survey took place in Baffin Bay[6]. The authors hypothesized that there may be a causal connection with the seismic survey interrupting

the narwhals outward migration to their wintering grounds. (However, as noted above, there is also evidence that the migration has generally been shifting to later in the season due to other climatic factors.)

On October 7, 2008, there was 5.7 magnitude earthquake 755 km northwest of Resolute Bay[7]. A 5.0 magnitude earthquake produces a sound roughly 235 dB[8], which is louder than a seismic survey. The noise may have startled the narwhal and as a result interrupted their outward migration from their summering grounds to their wintering grounds.

1.3 Summary

We don't know the exact cause of the 2008 Pond Inlet narwhal entrapment in ice. Researchers have identified two possible explanations: narwhal were trapped in ice due to a rapid drop in temperature or the sudden increase in noise in the ocean. In this situation, we are trying to explain how the narwhals became trapped by looking back at the event to identify potential causes. In the 2-3 weeks before the entrapment, the sound produced from the earthquake and seismic program would have dissipated, while the air temperature dropped significantly a few days before entrapment. We may never know the real reason why or how narwhals became trapped in ice.

Inuit and scientific researchers have discussed the importance of conducting research to document narwhal behaviour around sound produced by humans. As development proceeds in Nunavut, ocean noise is increased from these activities. Airplanes, cargo ships, transport boats, fishing boats, military submarines, and seismic surveys all produce sound. It is important to understand how whales behave around anthropogenic (man-made) sound. Activities can be planned (scheduling and operational) to limit interaction with marine mammals.

2 Reports from previous seismic projects

NEXUS Coastal reviewed available published reports and documents that included observations of marine mammals near active seismic surveys. The reports were published by government organizations, private sector companies, and academic researchers. Published research involving studies on marine mammals in captivity were excluded due to the potential differences in behaviour in the different environments (experimental versus natural).

The focus of the literature review was on animals present in northern waters such as Baffin Bay, Davis Strait, and the Beaufort Sea. Attendees at the community meetings had requested reports that focused on whales and seals in the Arctic since they were under the impression that the EA had only used information on southern whale populations. Communities reported that northern whales and seals respond differently to noise than southern whales[9].

Information compiled in the review indicate that whale and seal responses to noise are highly variable, depending on age, sex, physical state, presence of offspring, prior experience, characteristics of the noise source, and other factors[10].

The “Review of Scientific Information on Impacts of Seismic Sound on Fish, Invertebrates, Marine Turtles and Marine Mammals” provides case studies and analysis on seismic surveys throughout the world[11]. This document forms the basis for Canadian standards on mitigating the effects of seismic surveys on marine wildlife[12].

Hamlet Councils, HTOs, and community members also requested to see reports on the effects on marine mammals of seismic surveys conducted in Greenland. Many of the Marine Mammal Observer reports are the possession of the company that conducted the seismic survey. This information is not available to the public.

Reports from and studies[13] which are available include analysis of seismic survey effects on marine mammals in northern waters are summarized below.

2.1 Reports which include observations on whales

Source: Miller, G.W., V.D. Moulton, R.A. Davis, M. Holst, P. Millman, A. MacGillivray, and D. Hannay (2005). Monitoring seismic effects on marine mammals—southeastern Beaufort Sea, 2001-2002.p. 511-542. *In* Armsworthy, S.L., Cranford, P.J. and K. Lee. (2005). Offshore Oil and Gas Environmental Effects Monitoring: Approaches and Technologies. Battelle Press, Columbus Ohio. 629p.
Study/Project: Devon Canada Corporation conducted a two-year marine seismic program offshore of the Mackenzie Delta in the southeastern Beaufort Sea during 2001 and 2002. Data was collected from aerial surveys, Marine Mammal Observers, and Passive Acoustic Monitoring. The seismic survey occurred in relatively shallow water (minimum water depth of 10m).
Observation: Beluga whale sighting rates at distances of 10-20km from the seismic survey were significantly lower than those in areas 20-30 km from the seismic source, where sightings were unexpectedly high. Belugas closest to the seismic survey (1540-2500m) would have received sound levels of approximately 165dB re 1 µPa.
Bowhead whales were sighted further away (1957m) during active seismic operations compared to inactive periods (1368m). Bowheads tended to be closer to the vessel during inactive periods. The aerial surveys did not document bowhead avoidance of the seismic operations area.
Discussion: Beluga whales tended to move away from an operating seismic vessel to a distance of 20-30km. At a minimum, the distance by which bowhead whales avoided seismic operations was about 600m greater than the average distance by which they avoided general vessel operations. The seismic survey did not include post-survey monitoring.
Implication: Beluga whales may display avoidance behaviour to a seismic survey up to 20km away. During an active seismic survey, bowhead whales were sighted approximately 2km away from the seismic survey. Bowhead whales did not display large scale avoidance of the survey area.

Source: Patterson, H., Blackwell, S.B., Haley, B., Hunter, A., Jankowski, M., Rodriques, R., Ireland, D. and W. Funk. (2007). Marine mammal monitoring and mitigation during open water seismic exploration by Shell Offshore Inc. in the Chukchi and Beaufort Seas, July-September 2006: 90-day report. LGL Draft Report P891-1. Report from LGL Alaska Research Associates Inc., Achorage, AK, King Cite, Ont, and Greenridge Sciences Inc., Goleta, CA, for Shell Offshore Inc, Houston, TX, and National Marine Fisheries Service, Silver Spring, MD. 199p.
Study/Project: seismic surveys in the Chukchi and Beaufort Seas during the summer of 2006
Observation:
Chukchi Sea Survey Results: The seismic surveys were active for 1092 hours. Visual observations were recorded for 2788 hours, of which 1366 hours was useable due to visibility conditions. Spotted and ringed seals were the most abundant marine mammals identified in the Chukchi Sea surveys. The only large whale seen during seismic periods was a minke whale. However, gray whales were seen most often in non-seismic periods. Gray whales sightings tended to be clustered and their distribution is more likely an indication of distribution of food resources than a response to seismic activity. Fifteen of 17 walrus observed during non-seismic period swam away from the boat. Whale behaviour was recorded for 41 sightings. One sighting occurred during an active seismic period. Most of the whales (45%) swam parallel to the seismic vessel.
A total of 10 power downs and 38 shut downs of the air source was required due to sighting of seals and walrus within or approaching the marine mammal safety zone. Whales did not approach the sound source and therefore did not require the seismic survey to shut down.

Beaufort Sea Survey Results: The seismic survey was active for 10 hours. This included four hours of useable results. No sightings were noted during the limited periods of seismic surveying.
Discussion: No marine mammal was observed during the Beaufort Sea seismic survey.
Implication: No marine mammal was observed during the seismic survey

Source: Madsen, P.T., Mohl, B., Nielsen, B.K and M. Wahlberg. (2002) Male sperm whale behaviour during exposures to distant seismic survey pulses. *Aquatic Mammals, 28(3):* 231-240.
Study/Project: Seismic survey off Andenes, northern Norway in 2000.
Observation: Andenes (northern Norway) is a location in which adult male sperm whales inhabit all year round (presumably for feeding). The active seismic survey vessel would have been between 20 and 140km SW of this location while operating. Adult male sperm whales were observed for 12 of a 13 day seismic survey. On July 17, no sperm whales were observed, however, the following day, a large pod of long-finned pilot whales were observed in the area (pilot whales are known to harass sperm whales). Adult male sperm whales were observed remaining in the area into September after the seismic survey finished.
Discussion: Adult male sperm whales did not move away from the operating seismic survey. The one day when no sperm whales were observed may be explained by the presence of long-finned pilot whales the following day.
Implication: Adult male sperm whales did not change their behaviour in the presence of a seismic survey.

Source: Yazvenko, S.B., McDonald, T.L., Blokhin, S.A., Johnson, S.R., Melton, H.R., Newcomer, M.W., Nielson, R. and P.W. Wainwright. (2007). Feeding of western gray whales during a seismic survey near Sakhalin Island, Russia. *Environmental Monitoring Assessment, 134:* 93-106
Study/Project: 3D seismic survey in shallow, near-shore waters of Sakhalin Island, Russia from July 19- November 19, 2001.
Observation: The 3D seismic survey took place when a population of gray whales were feeding off the coast of Sakhalin Island, Russia. Aerial surveys were carried out throughout the seismic survey, in partto record feeding activity (indicated by mud plumes) of grey whales before, during and after the seismic survey. Statistical analysis indicated that a seismic survey did not change the frequency of mud plumes created by western grey whales. Mitigation measures for the project ensured that gray whales did not receive sound levels greater than 163dB (rms) re 1µPa (the corresponding distance was not provided).
Discussion: After analysis of grey whale feeding behaviour prior, during and after a seismic survey, it was concluded that seismic surveys do not affect grey whales while they are feeding.
Result: The 3D seismic survey did not affect gray whale feeding behaviour.
Implication: No implications. Gray whales are not located in the survey area.

Source: Ljungblad, D.K., Wursig, B., Swartz, S.L., Keene, J.M. (1988). Observations on the behavioural responses of bowhead whales (*Balaena mysticetes)* to active geophysical vessels in the Alaskan Beaufort Sea. *Arctic, 41(3):* 183-194.
Study/Project: From 1981-1984, behavioural data (through visual observations on aircrafts) was collected on bowhead whales at varying distances from operating seismic survey vessels.
Observation: The following bowhead whale behaviours were assessed: surfacing, respiration and dive characteristics at varying distances from an active seismic survey vessel. Four

instances of seismic survey vessels approaching different bowhead whale pods over three years were recorded:

- Seismic survey vessel 3.5 to 8.2 km away: subtle behavioural response
- Seismic survey vessel 3.5 to 7.6 km away: partial avoidance (some whales left, while other whales remained in the observation area)
- Seismic survey vessel 1.3 to 7.2 km away: total avoidance (all whales leave the observation area).

Discussion: Similarities among experiments suggest that short-term behavioural changes, such as bowheads leaving the observation area, occur when bowhead whales are exposed to seismic surveys less than 10km away. However, these behavioural changes diminish within one hour after disturbance.
Implication: Bowhead whales may change their behaviour when they are within 10km of a seismic survey. Normal bowhead whale behaviour resumed one hour after the seismic survey left the area.

Source: Richardson, W.J., Wursig, B., and C.R. Greene, Jr. (1986). Reactions of bowhead whales, *Balaena mysticetes,* to seismic explorations in the Canadian Beaufort Sea.
Study/Project: Opportunistic and controlled observations on the behavioural reactions of bowhead whales to seismic surveys from 1980 to 1984. Observations were made from an aircraft[14].
Observation: Activities of bowhead whales 6-99km away from seismic survey vessels were usually similar to those of whales not exposed to man-made noise (including seismic surveys). Bowheads usually continued normal activities when an airgun was operational 3-5km away (received levels 118-133dB re: 1µPa). Bowheads oriented away from seismic surveys at ranges of 2-4.5km (received levels 134-124dB re: 1µPa). Surfacing and respiration behaviour did not change dramatically when an airgun was operational 2-5km away. Bowhead whale near bottom feeding stopped at a range of 3km. There were no observations of bowhead whale behaviour post seismic survey.
Discussion: Bowhead whales did not change their behaviour to operating seismic survey vessels from up to six km away. Once the distance between vessel and whale was closer, some behavioural changes were observed, such as the bowheads stopped feeding.
Implication: Bowhead whales may change their behaviour within 6km of a seismic survey vessel.

Source: Moulton, V.D. and M. Holst (2010). Effects of seismic survey sound on cetaceans in the Northwest Atlantic. *Environmental Studies Research Funds Report No. 182.* St. John's 28p.
Study/Project: Monitoring data on marine mammals from eight 3D seismic surveys (three areas offshore Newfoundland and one area offshore Nova Scotia) from 2003-2008 was collected and analysed. Seismic surveys were carried out in both deep (greater than 2000m) and shallow (less than 200m) water. Sighting data was grouped separately for baleen whales, large toothed whales and small dolphins[15].
Observation: Baleen whales were seen further away, less often and moving away from the seismic vessel during operations. Different dolphin species were consistently seen within several kilometres of the seismic vessel during seismic and non-seismic periods. Dolphins were often detected 200-300m further away from the seismic vessel during seismic vs. non-seismic periods. However, there was no significant difference between the numbers of dolphin sightings during seismic vs. non-seismic periods. Long-finned pilot whales often approached the operating vessel within 150m. In most cases, dolphins avoid seismic activity at a distance of 1km or less.

Discussion: This study reported that baleen whales appear to be sensitive to sound from seismic surveys. This was indicated by baleen whales moving away from the seismic vessel and being observed less often during seismic periods compared to non-seismic periods. Behavioural and anatomical evidence suggests that baleen whales hear well at frequencies below 1kHz where most of the energy from the sound source is focused.
Large toothed whales and delphinids often moved away from an operating seismic vessel (200-300m), but there was no significant difference in sighting rates. These results suggest that large toothed whales and delphinids may display localized displacement (200-300m). However, these species remain in the area as indicated by there being no significant difference in sighting rates in times active and inactive seismic periods.
Implication: Baleen whales, such as the bowhead whale, move further away and are seen less often during an active seismic survey. Toothed whales and delphinids move further away (200m-3000m) from an active seismic survey but their diving patterns (indicated by how frequent the whales are observed) do not change.

Source: Shell. (2013). Shell Greenland A/S 2013 Site Survey in Baffin Bay Blocks 5 (Anu) and 8 (Napu). Preliminary Environmental Impact Assessment
Study/Project: The EIA is for a two-dimensional high resolution seismic survey in Blocks 5 and 8. The EIA includes results of Shell's 2012 seismic survey in Baffin Bay.
Observation: Sightings from Shell's 2012 seismic survey in Baffin Bay included numerous seals, primarily harp, ringed and hooded seals, but also bearded and harbour seals. Most whales were observed during transit to and from the survey area, with sightings of sperm whale, minke whale and sei whale within the license blocks. One polar bear was also seen within the two license blocks (Figure 1). It was not indicated if the seismic survey was stopped due to the proximity of a whale or seal to the operating seismic survey.
Discussion: The location or name of the 2012 seismic survey project was not provided in the EIA. Additional research identified that Shell completed a 3D seismic survey and coring in lease blocks 5 and 8 in 2012 (Figure 2)[16]. The EIA for the 3D seismic survey indicated that the project would operate from July until October, 2012 in water depths of 150m to 700m[17].
The report did not say if the seismic survey was stopped due to marine mammals entering the safety zone (800m for whales and 500m for other marine mammals).
During the seismic survey no bowhead, narwhal or beluga whales were seen during transit to the survey area or during surveying. In the category of 'large whales' it is not known if any of the 'large whales' observed were bowhead whales (Figure 1).
Implication: The proposed Baffin Bay and Davis Strait seismic survey would occur in the general vicinity of the Shell 2012 3D seismic survey in Greenland waters (both occur in the deep waters of Baffin Bay). The 2012 Shell survey did not report sightings of narwhal, bowhead and beluga whales in the survey area or in transit to the survey area. This observation may be from the whales avoiding the survey area, or that the whales have yet to begin their fall migration to their wintering grounds.

2.2 Reports which include observations on seals

Source: Harris, R.E., Miller, G.W., and W.J. Richardson. (2001). Seal responses to airgun sounds during summer seismic surveys in the Alaskan Beaufort Sea. *Marine Mammal Science, 17(4):* 795-812.
Study/Project: 3D seismic survey in shallow, near-shore waters of the Beaufort Sea near Prudhoe Bay from July 24 to September 18, 1996.
Observation: Ringed seals, bearded seals and spotted seals are common in the area. The seismic survey occurred on 49 of 57 days. Seals were observed through binoculars and flood lights (at night). Seals partially avoided a zone (<150m from the sound source) during the seismic survey, but did not move much beyond 250m. Seals were more likely to 'swim away' during an active seismic survey than when no sound was being produced. No seals were observed to leave the general area of operation during the active seismic survey.
Discussion: Observations from this study indicate that ringed, bearded and spotted seals may not be significantly affected by an operating seismic survey. The most common behaviour was that seals were swimming away from the sound source to a distance of 250m. This distance is well within the marine mammal exclusion zone (500m) for this project.
Implication: Ringed, bearded, and spotted seals were not affected at a distance of 250m from an active seismic survey. Phocid seals, which include ringed and bearded seals have low hearing sensitivity below 1kHz, though they can hear underwater sounds at frequencies up to 60kHz and make calls between 90Hz and 16kHz[18].

Source: Frost, K.J and L.F. Lowry. (1988). Effects of industrial activities on ringed seals in Alaska, as indicated by aerial surveys. *In:* Sackinger, W.M., Jeffries, M.O. (1988). Port and ocean engineering under arctic conditions (Vol II). Symposium of noise and marine mammals. Fairbanks, Alaska.
Study/Project: In the spring of 1982, a simulated seismic survey was generated on ice to observe the rates at which seals abandoned breathing holes.
Observation: Seals were three times as likely to abandon breathing holes and lairs within 150 metres of a seismic survey.
Discussion: This study supports ringed seals reactions to seismic sources (Harris et al., 2001); however, there are a number of differences in the study design. The simulated seismic source was simulated by using trucks and instruments on ice to simulate seismic sound. As well, marine seismic surveys generally occur in ice free waters away from haul out locations of seals.
Implication: Ringed seals change their behaviour within 150m of a seismic source.

Source: Shell. (2013). Shell Greenland A/S 2013 Site Survey in Baffin Bay Blocks 5 (Anu) and 8 (Napu). Preliminary Environmental Impact Assessment
Study/Project: The EIA is for a two-dimensional high resolution seismic survey in Blocks 5 and 8. The EIA includes results of Shell's 2012 seismic survey in Baffin Bay.
Observation: Sightings from Shell's 2012 seismic survey in Baffin Bay included numerous seals, primarily harp, ringed and hooded seals, but also bearded and harbour seals (Figure 1). It was not indicated if the seismic survey was stopped due to the proximity of a whale or seal to the operating seismic survey.
Discussion: The location or name of the 2012 seismic survey project was not provided in the EIA. Additional research identified that Shell completed a 3D seismic survey and coring in lease blocks 5 and 8 in 2012 (Figure 2)[19]. The EIA for the 3D seismic survey indicated that the project would operate from July until October, 2012 in water depths of 150m to 700m[20].
The report did not say if the seismic survey was stopped due to marine mammals entering the safety zone (800m for whales and 500m for other marine mammals). The seismic survey was intended to operate from July until October. Bearded seals and ringed seals were identified in the National Energy Board meetings as seals which individuals would like more information on. In the 2012 Shell Baffin Bay seismic survey, 109 ringed seals and 13 bearded seals were seen in the survey area. There were 1399 animals sighted in the survey area.
Implication: The proposed Baffin Bay and Davis Strait seismic survey would occur in the general vicinity of the Shell 2012 3D seismic survey in Greenland waters (both occur in the deep waters of Baffin Bay). The 2012 Shell seismic survey identified both ringed and bearded seals. It is likely that the proposed seismic survey will also encounter ringed and bearded seals.

Source: Miller, G.W., V.D. Moulton, R.A. Davis, M. Holst, P. Millman, A. MacGillivray, and D. Hannay (2005). Monitoring seismic effects on marine mammals—southeastern Beaufort Sea, 2001-2002.p. 511-542. *In* Armsworthy, S.L., Cranford, P.J. and K. Lee. (2005). Offshore Oil and Gas Environmental Effects Monitoring: Approaches and Technologies. Battelle Press, Columbus Ohio. 629p.
Study/Project: Devon Canada Corporation conducted a two-year marine seismic program offshore of the Mackenzie Delta in the southeastern Beaufort Sea during 2001 and 2002. Data was collected from aerial surveys, Marine Mammal Observers, and Passive Acoustic Monitoring. The seismic survey occurred in relatively shallow water (minimum water depth of 10m).
Observation: Both ringed seals and bearded seals were observed by aerial surveys, Marine Mammal Observers, and Passive Acoustic Monitoring. Ringed seals were observed most often during the seismic program.

In 2001, seals were observed slightly closer to the vessel during non-seismic periods compared to seismic periods, indicating that seals may have been exhibiting some avoidance of the sound produced from the seismic survey. However, the observed difference between distances at which seals were initially observed during non-seismic and seismic periods (average distance from the sound source of 150 vs. 210 m, respectively) were minor and the avoidance behaviour was localised to a few individuals. It was estimated that seals at a distance of 210 m would have been exposed to sound levels of 190 dB re 1 µPa.
Contrary to the 2001 findings, in 2002 results showed that seals were observed closer to the seismic vessel during seismic periods than during non-seismic periods (average distance from the sound source of 153 vs. 236 m respectively).
Discussion: Combined data from 2001 and 2002 suggest that there were minor and variable effects on seals within a few hundred metres (150m-236m) of the seismic vessel as a result of seismic operations. The marine mammal safety zone for the proposed project is 500m from the sound source. Therefore the seismic survey would stop if a seal were to be observed in this area.
Implication: Observations from this study indicate that seals are not displaced by seismic operations, which agrees with findings from other similar studies in the Beaufort Sea.

2.3 Reports from Greenland

A common theme throughout the NEB organized community meetings was the concern that seismic surveys may affect Inuit's ability to successfully harvest marine mammals (whales, seals, walrus and polar bears). Like in Nunavut, marine mammals are a large part of Inuit food and culture in Greenland. Many people at community meetings requested information from Greenland as they are actively completing seismic surveys in Baffin Bay.

NEXUS Coastal searched for sources of government reports and scientific research reports as well as reports from the seismic survey companies to provide insight into possible effects from seismic surveys in Baffin Bay on Inuit harvesting activities in Greenland. Unfortunately, such reports or documents are not publically available. NEXUS Coastal undertook an examination of the harvest levels of whales and seals by Inuit in Greenland. Seismic surveying is a relatively recent development in Baffin Bay[21] and only began in Greenland waters in Baffin Bay in 2007. Therefore, the review focused only on Inuit whale and seal harvest levels before and after the commencement of these seismic surveys.

Comparing the number of marine mammals harvested before and during seismic surveys can provide insight as to whether seismic surveys are affecting the number of marine mammals available. This analysis assumes that there has been little or no change in Inuit hunting efforts.

The information for this analysis came from the United Nations Food and Agriculture Organization (FAO)[22], academic literature, and other public documents.

Hunting whales in Greenland is a long-standing traditional and commercial activity. FAO provides information on catches of whales kill in Greenland (Table 2)[23]. Quota systems are in place for blue whales, fin whales, sperm whales and pilot whales[24]. Seismic surveys began in

2007 and no changes were detected in the harvest of these whales following the implementation of seismic surveys.

Table 2: Capture production by species for Greenland (FAO, 2010)

Species[25]	2001	2002	2003	2004	2005	2006	2007	2008	2009	2010

Greenland Inuit concentrate their hunting efforts on narwhal and beluga whales and harp and ringed seals as indicated by the increased animal capture (Table 2). Whales are included in Table 2 to show potential effects of seismic surveys on whales. If certain whales change their behaviour around seismic surveys, then the ability of Inuit to harvest the animal may decrease[26].

The Greenland Home Rule Government introduced a quota system for narwhal and beluga harvesting in West Greenland in 2004. The International Whaling Commission, the North Atlantic Marine Mammal Commission (NAMMCO), the Canada/Greenland Joint Commission on Narwhal and Belugas (JCNB), and other non-government organizations collectively determine

the number of narwhal and beluga that can be harvested. Quota-setting organizations must consider the fact that narwhal and beluga populations are highly migratory and are harvested in several regions (DFO, 2008)[27].

The Greenland quota system was set in place in 2004 to protect belugas and narwhals after increasing catches were being reported despite declining populations and no increase in hunting efforts (Figure 3). A licence is now required under the quota to hunt narwhals in West Greenland (Nielsen and Mielby, 2013)[28]. The increase in narwhal catches before the quota system was introduced is suggested to be a result of climate change and easier access to whales by hunters (Nielsen, 2009) [29]. The quota in West Greenland is set at 300 narwhals and 165 belugas, which is higher than the level recommended by biologists from the Greenlandic Institute of Natural Resources and the NAMMCO (Ecoadvise & Communication, 2013)[30].

The narwhal population in West Greenland is separated into at least two populations. The stock separation is not clear, but there are distinct populations in Baffin Bay and in Smith Sound (between Greenland and Ellesmere Island). According to traditional knowledge, the Smith Sound stock either migrates to Canada (past Ellesmere Island) or stays in Smith Sound. There are no reliable estimates for the Melville Bay narwhal stock, which is the stock that is known to overwinter in central Baffin Bay; therefore accurate quotas cannot be set for specific stocks in West Greenland (Nielsen, 2009) [31].

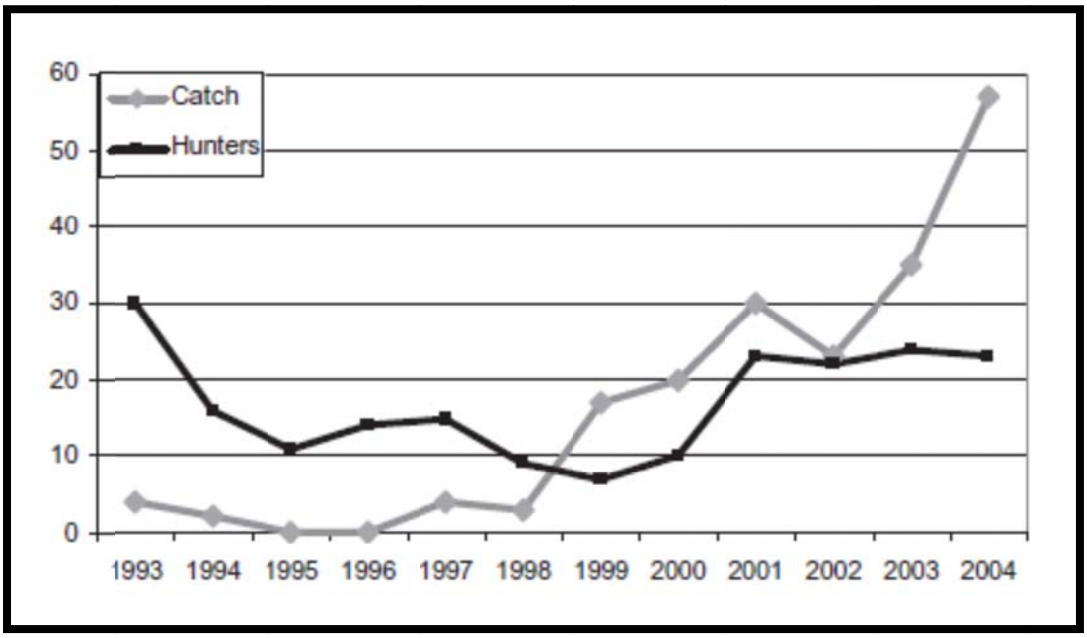

Figure 3: Narwhal catch by hunters from Siorapaluk and total number of hunters from 1993-2004 (from Nielsen, 2009).

Seismic activity began after the implementation of a quota system for narwhal and beluga hunting in West Greenland. Therefore, catches are kept at a set rate and it is impossible to tell if catches have increased or decreased since seismic activity began. In 2004, narwhal and beluga stocks were declining (Alvarex-Flores & Heide-Jorgensen, 2004)[32]. However, both stocks have reportedly stabilized or been increasing since stock surveys began in 2007, after both

introduction of quotas and after seismic surveys began (Greenland Institute of Natural Resources, 2012)[33].

DISCUSSION

It appears that harvest of minke whales, fin whales, humpback whales, long-finned pilot whales, beluga whales, narwhal, walrus, harp seal, ringed seal, bearded seal and hooded has not changed since seismic survey activity began in 2007[34]. For the more traditionally harvested species of narwhal and beluga, overharvesting and declining populations led to the introduction of a quota system in 2004. Since the introduction of this quota, stocks have apparently been increasing in size. It appears that harvest rates since 2007 have not been negatively affected by seismic surveying.

4 Marine Seismic Source

Vol. 1, para 237, 255, 263, 277 and 673; Vol. 3, para 1326, 1341, 1694

“Acoustic properties or modeling of marine seismic including information indicating how far travels sound and specifically how the sound would compare to the sound of a .22 rifle firing or a whale”, “MKI committed to providing a video that demonstrates the comparison of air guns and sound sources that are familiar to communities.”

MKI believes that audio representation would be more effective than a video to best represent “seismic sound”. We propose to present a “representation” recording of the seismic source sound in future meetings while supplementing it with the other deliverables such acoustic modelling, sound comparison tables, etc.

See Appendix D

5 Acoustic Modelling in Survey Area

See Appendix E

6 Effects of Sound on Marine Mammals

MKI prepared and distributed a ‘Supplementary Report’ to communities (Kimmirut, Iqaluit, Pangnirtung, Qikiqtarjuaq, Clyde River, and Pond Inlet) in November 2012. Communities were provided paper and electronic copies of the report in Inuktitut and English.

The Supplementary Report provided information on how seismic surveys are conducted, the known effects of seismic sound on fish, whales, and seals, and the proposed project’s mitigation measures. This report was prepared in response to comments brought forward during community information sessions held in June and October, 2012.

During the National Energy Board meetings with the communities of Iqaluit, Qikiqtarjuaq, Clyde River and Pond Inlet, additional questions were asked about the effects of the project on specific marine mammals. Marine mammals identified by community members at the meetings include narwhal, beluga, bowhead, walrus, bearded seals, ringed seals and polar bears. Overall, community representatives wanted to know if the proposed project would affect the migration of whales, seals, walrus, and polar bears or on the physical wellbeing of animals themselves.

This section includes observations from past seismic surveys, information on the marine mammal’s migration paths and their behaviours during summer months. Information was obtained from Inuit Knowledge studies, scientific journals, government reports and seismic operator’s reports. The information was analysed to determine what effects, if any, the proposed seismic survey may have on marine mammals.

As requested in meetings (community, Hamlet, and HTO), this section will only include observations and reports focused on seismic surveys in northern waters. These reports include 2D, 3D, and 4D seismic surveys acquired from the 1980s until present. Many of the reports do not provide details on the level of sound the whales and seals receive from the seismic survey.

If there are no reports discussing the behaviour of a marine mammal to sound from seismic surveys then DFOs most recent review of the effects of seismic sound on marine mammals is referenced.

6.1 Seismic Surveys, Whales and Seals

SEISMIC SURVEYS

Marine seismic surveys are conducted to map geologic formations below the seafloor. A seismic survey includes the following (Figure 4):

1. The sound source uses a piston to force compressed air into the water column generating a sound wave. The sound source is towed by the research vessel 6-10 metres (18-30 feet) below the surface of the water.
2. Sound waves travel downward through the water and into the underlying rock formations below the seafloor. The sound waves bounce back off the different layers of sedimentary rocks, return to the surface of the water.
3. The returning sound waves are detected by hydrophones (underwater microphones) spaced less than 2m apart and embedded in a cable or streamer 6-12 kilometres (18,000- 36,000 feet) long. The cable and hydrophones are referred to as a 'streamer'.
4. The information collected during the survey is then analyzed using computer programs that produce images of the different types of rock layers lying beneath the seafloor.

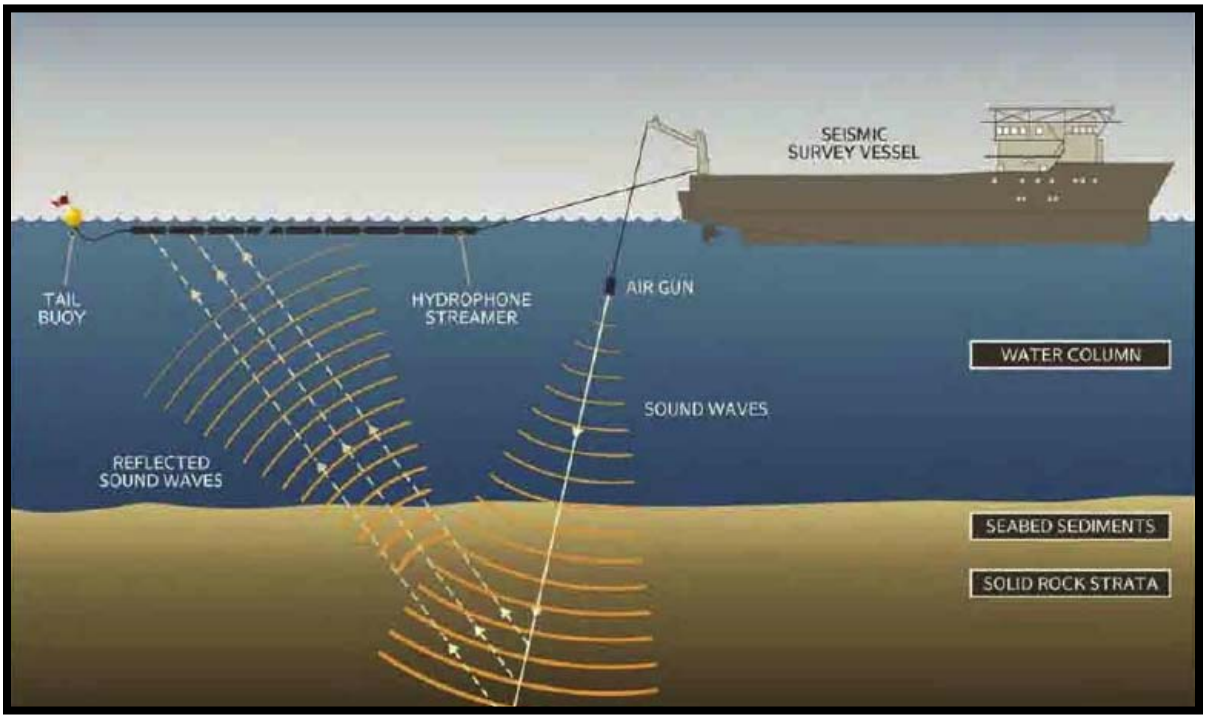

Figure 4: Seismic survey diagram (Sikumuit. 2008. Sikumuit Environmental Management Ltd. 175 Hamlyn Road. St. John's, Newfoundland and Labrador, A1E 5Z5)

WHALES AND SEALS

Information sources used by officials to regulate seismic surveys to minimize impacts on marine mammals include the following:

- Captive Studies: These studies use animals being held in captivity to measure auditory sensitivity, auditory function and the effects of noise exposure. It is important to note, however, that general behavioural changes in animals due to their unnatural surroundings may affect their natural responses to sound.
- Field Studies: These studies are based on opportunistic observations made from vessels on the behaviour of whales in the observable vicinity of a seismic survey vessel.
- Modelling: These research studies involve computer-based mathematical models and are used to predict the effect of sound on the hearing of marine mammals.
- Tracking devices: Transponders or radio beacons attached to marine mammals to track and document individual underwater behaviour, physiological responses and obtain information on the environment.

Governments, communities, researchers, and non-governmental organizations are generally concerned with the effect of the sound intensity on whales, seals and walrus. Whale responses to noise are highly variable, depending on species, individuals, age, sex, physical state, presence of offspring, prior experience, characteristics of the noise source, and other factors[35]. Suspected effects on marine mammals from seismic surveys:

- Mortality and physical effects: stranding/mortality, hearing impairment and non-auditory effects (for example, ship strikes).
- Direct behavioural effects: displacement, migratory diversion, changes in dives and respiratory patterns, and changes in social behaviour and vocalization patterns.

There are two categories characterizing the effect of sound on marine mammals hearing:

- Permanent Threshold Shift (PTS): permanent reduction in hearing sensitivity.
- Temporary Threshold Shift (TTS): temporary hearing loss (completely recoverable within minutes to hours).

PTS and TTS are qualitative indicators used in preparing guidelines to mitigate the effects of sound on whales and seals. Mitigation measures for this project include ensuring that marine mammals do not receive sound levels that could result in a permanent reduction in hearing sensitivity (PTS).

Existing reports and studies on whales and seals related to the sound intensity received from sound sources have led to researchers recommending guidelines for seismic surveys. For exposure to multiple sound pulses (like seismic surveys), permanent threshold shift (loss of hearing, not recoverable) is assumed to occur if the following sound exposure level is exceeded:

- Whales: approximately 198 dB re 1µPa²s
- Seals : approximately 186 dB re 1µPa²s

DFO used this and other information in preparing the *Statement of Canadian Practice with Respect to the Mitigation of Seismic Sound in the Marine Environment*[36]. As stated in the Environmental Assessment for the project, the received sound level at 500m from the sound source is 180dB re 1µPa?. Therefore, based on available information, whales and seals should not be permanently affected from the proposed seismic survey. Changes in behaviour may be observed. Based on previous reports and studies, these changes are temporary.

Physical Effect of Acoustic Sounds on Marine Mammals

There have been no documented cases of marine mammal (whales, seals and walruses) mortality or permanent loss of hearing upon exposure to oil and gas exploration seismic surveys[37].

Behavioural Effect of Acoustic Sounds on Marine Mammals

In field studies, behavioural responses to sounds (seismic surveys, drilling platforms and rigs, airplanes, sonar, commercial shipping, recreational boating) have been recorded for a few whale species in a limited range of conditions[38]. Responses include startle and fright, avoidance, and changes in behaviour and vocalization patterns. However, behavioural observations are variable and some findings are contradictory. The biological significance of behavioural changes (for example, reproducing, feeding, or having offspring) has not been measured.

The primary cause of behavioural effects on marine mammals from seismic surveys is thought to be from the intensity of sound received by marine mammals. There are many sources of naturally occurring and anthropogenic (man-made) sound in the oceans. Whales communicating, rain, earthquakes, sea ice fracturing and pieces of ice breaking off icebergs are examples of naturally occurring sound in the oceans. Boats (recreational and commercial), fishing, harbour dredging, seismic surveys, and military boats are a few of the sources from humans that contribute to the amount of sound in the ocean. Seismic sources generate sound and the sound waves are directed downwards towards the ocean floor. As the sound wave moves through the ocean, the sound intensity decreases.

The sound eventually reaches fish, whales, and other marine life. The loudness of the sound (sound intensity) when it reaches marine life is the focus of discussion and research by scientific and academic researchers, government, and industry. The animal's response to the received sound is highly variable, depending on species, individuals, age, sex, physical state, presence of offspring, prior experience, characteristics of the noise source, and other factors[39].

Section 6.2 provides available reports on the reaction of whales and seals to sound. Reports indicate that behavioural reactions of whales and seals to seismic surveys were variable. Whale's normal behavioural patterns often resumed 48 hours after the seismic survey left the

area[40]. A whale's normal behaviour is different between and within species. Behaviour can be normal for an individual when it is consistent with the most common behaviour for that individual. Normal is also used to describe when an individual's behaviour conforms to the most common behaviour in the group (known as conforming to the norm). For some whale species, research has been conducted to determine how much time whales spend on different activities in an attempt to determine 'normal behaviour'. For example, sperm whales spend 80% of their time foraging and 20% of their time resting[41]. While for other species, normal behaviour is defined as the behaviour observed prior to an event (for example, predator attacking) occurring[42].

6.2 Narwhal (*Monodon monoceros*), *Qilalugaq qernartaq*

The narwhal is a toothed whale that inhabits ice covered arctic seas, feeding on benthic flatfish, shrimp and squid. Natural predators include polar bears and killer whales. In Canadian waters two populations of Narwhal are recognized, based on their summer distribution. The Baffin Island population is estimated between 60, 000 and 80, 000 animals, while the Hudson Bay population is approximately 5000 animals (Richard, 2007)[43]. Narwhal are harvested by Inuit and co-managed by Department of Fisheries and Oceans (DFO), the Nunavut Wildlife Management Board (NWMB), and local Hunters and Trappers Organizations (HTOs) through the 2013 Narwhal Integrated Fishery Management Plan. Narwhal in the eastern Canadian Arctic have been identified as a species of special concern by the Committee on the Status of Endangered Wildlife in Canada (COSEWIC). International management efforts are currently coordinated by the *Canada/Greenland Joint Commission* on Conservation and *Management* of *Narwhal* and Beluga.

In Canada, six management units have been identified based on summering aggregations or stocks of the two populations (Baffin Island and Hudson Bay) (Figure 5). Narwhal management units are as follows:

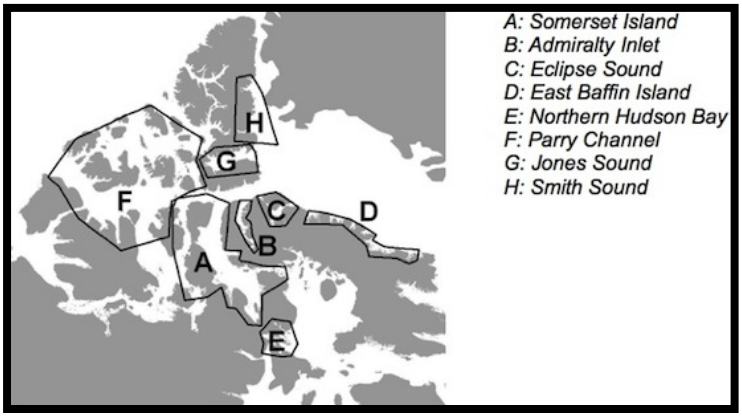

Figure 5: Proposed DFO narwhal management units for the 2013 narwhal integrated fishery management plan

- Somerset Island
- Admiralty Inlet
- Eclipse Sound
- East Baffin Island
- Jones Sound, Smith Sound and Parry Channel
- Northern Hudson Bay

NARWHAL MIGRATION

There are three papers published by academic and scientific researchers which discuss the Canadian narwhal migration and provide information on where and when narwhal are located.

Heide-Jørgensen, M.P., Dietz, R., Laidre, K.L., Richard, P., Orr, J. and H.C. Schmidt. (2003). The migratory behaviour of narwhals (*Monodon monoceros*). *Canadian Journal of Zoology, 81:* 1298-1305.

Narwhals were captured and tagged at Creswell Bay, Somerset Island, Nunavut over a two year period (9 narwhals were tagged in August, 2000 and 7 narwhals were tagged in August, 2001). By mid-September, most narwhal were within 200km of Somerset Island. By early October, narwhal began to migrate east out of Lancaster Sound with most whales remaining close to

shore near Devon Island. By early November, narwhal reached their overwintering area in Baffin Bay. Somerset Island narwhal generally maintained an offshore migration to their overwintering grounds.

Dietz, R., Heide-Jørgensen, M.P., Richard, P.R. and M. Acquarone. (2001). Summer and fall movements of narwhals (*Monodon monoceros)* from Northeastern Baffin Island towards Northern Davis Strait. *Arctic, 54(3):* 244-261.

Ten narwhal were captured and tagged over a two year period (between August 8 and 24, 1997 and August 14 and 25, 1998) in Tremblay Sound, Nunavut (Figure 6). During the summer, tagged narwhals stayed within by the Bylot Island area, including Tremblay Sound, Milne Inlet, Eclipse Sound, Navy Board Inlet, Oliver Sound and Pond Inlet. Four whales were monitored on their southward migration, along the east coast of Baffin Island to their wintering grounds. In both years, the whales left the Bylot Island area between September 20 and 29[44]. Generally, the Eclipse Sound narwhal travelled south along Baffin Island remaining close to fjords until they reached Broughton Island and moved into the deep part of Baffin Bay (narwhal overwintering ground). This trip generally ended between October 13 and November 7.

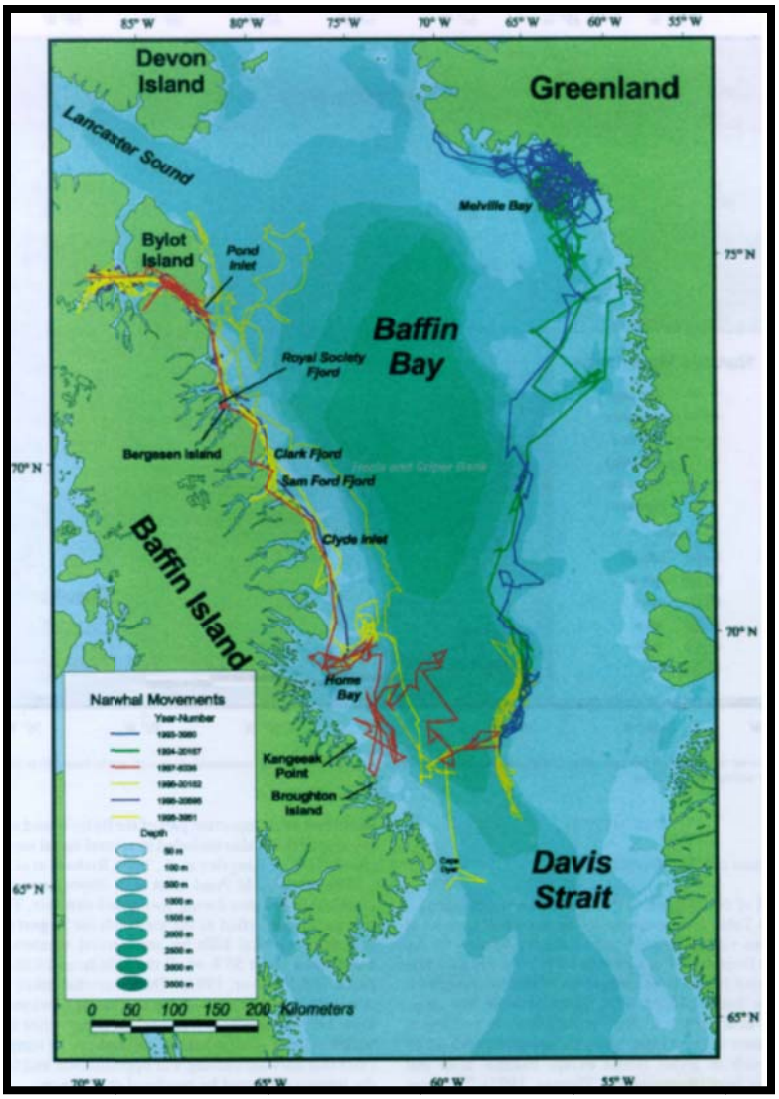

Figure 6: Fall migration of four narwhal tagged over a two year period (1997-1998**)** (from Dietz et al., 2001)

Dietz, R., Heide-Jørgensen, M.P., Richard, P., Orr, J., Laidre, K., and H.C. Schmidt. (2008). Movements of narwhals (*Monodon monoceros)* from Admiralty Inlet monitored by satellite telemetry. *Polar Biology, 31:* 1295-1306.

Thirteen Narwhals were captured and tagged at Kakiak Point in Admiralty Inlet, Nunavut over a two year period (between August 10 and 23, 2003 and 8 narwhals were tagged between August 10 and 23, 2004) (Figure 7). On average, the whales left their summering range (Admiralty Inlet) between September 14 and October 11, and completed their southern migrations between October 17 and November 15. Admiralty Inlet narwhal generally migrated 100km or further offshore from the coastline in 500m or deeper waters.

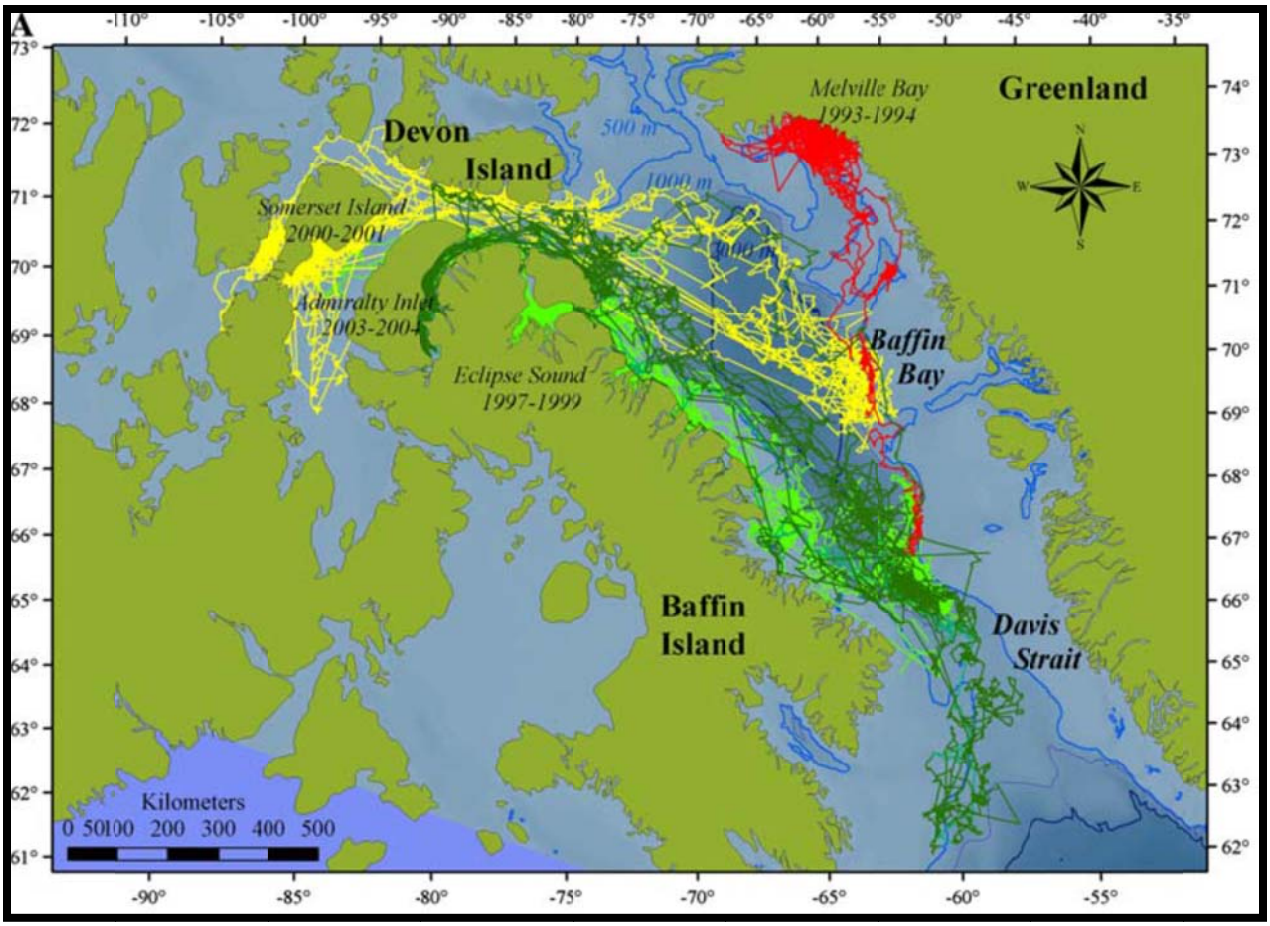

Figure 7: Comparative analysis of narwhal migration
From Admiralty Inlet (dark green), Somerset Island (yellow) and Eclipse Sound (light green). Red lines represent narwhal from Melville Bay, Greenland (Dietz et al., 2008).

Nunavut Planning Commission (2009). State of Knowledge in Maps. Nunavut Planning Commission. 28p.

Narwhal range extends throughout the entire Baffin Bay and Davis Strait region as well as the High Arctic. Narwhal summering and winter ranges were not identified on the map (Figure 8).

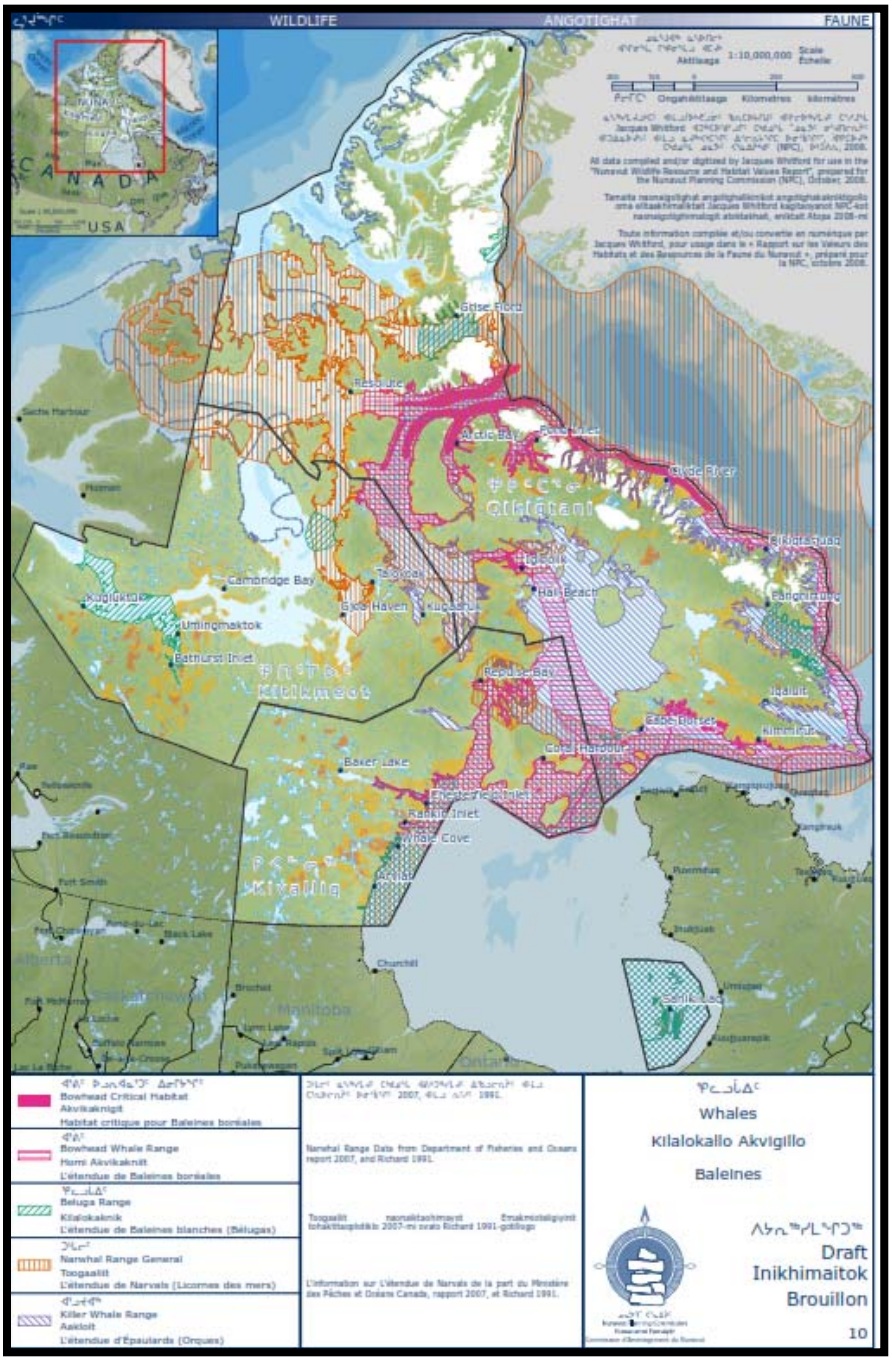

Figure 8: Narwhal range (orange) (from NPC, 2009).

SUMMARY

Information from three tagging studies on the Eclipse Sound, Somerset Island and Admiralty Inlet narwhal management units provide insight into the migration paths of narwhal (Table 3). Eclipse Sound and Admiralty Inlet narwhal generally remain close to shore while travelling south along eastern Baffin Island and move offshore once they reach Broughton Island, heading towards their overwintering grounds. These narwhal begin their migration earlier (around mid-September) compared to Somerset Island narwhal. Somerset Island narwhal begin their fall migration in early October and travel offshore to their overwintering grounds in Baffin Bay. All three management units (Eclipse Sound, Somerset Island, and Admiralty Inlet) reach their overwintering grounds around the same time (mid-November).

Table 3: Summary of narwhal fall migration

Narwhal Management Unit	Fall Migration Begin	Arrival at Wintering Grounds	Migratory patterns	Source
Eclipse Sound	September 20 to 29	October 13 to November 7	Generally close to Baffin Island travelling in fjords. Move out into Baffin Bay at Broughton Island.	Dietz et al., 2001
Somerset Island	Early October	Early November	Direct offshore to Baffin Bay	Heide-Jørgensen et al., 2003
Admiralty Inlet	September 14 to October 11	October 15 to November 15	Generally within 100km offshore, or along the 500m contour line.	Dietz et al., 2006

NARWHAL BEHAVIOUR DURING SUMMER MONTHS

During the summer months, narwhal migrate to various fjords and inlets around Baffin Island. This migration appears to be related to calving needs, and not feeding opportunities[45]. However, during the summer, narwhal do feed on Arctic cod (*Boreogadus saida),* Greenland halibut (*Reinhardtius hippoglossoides),* squid (*Gonatus fabricii)*, redfish (*Sebastes marinus),* and polar cod (*Arctogadus glacialis)*[45]*.*

A study by Finley and Gibb (1982) analyzed the summer diet of narwhal in Pond Inlet[46]. It was noted that narwhal feed at the ice edge in spring, when the ice begins to break up in July, narwhals move through the cracks and use seal holes to move toward traditional summering areas. Finally, when the ice is gone, narwhal remain in their traditional summering grounds, engaged in local movements. Narwhals calve in their traditional summering grounds in July and August.

NARWHAL AND SEISMIC SURVEYS

There are no available reports on the effects of seismic surveys on narwhals from past seismic surveys.

There is no available information from DFO on the known effect of sound from seismic survey equipment on narwhal. DFO provides regulations on how to limit potential effects from seismic sound on baleen whales, toothed whales, and seals.

The Canadian Science Advisory Secretariat completed a review of recent scientific information on the effects of sound from airguns on marine mammals[47]. Narwhal were not discussed in the report. This may be a result of an absence of information on the interaction between narwhal and seismic sound. In this paper the authors discussed potential behavioural and physiological effects on toothed whales (odontocetes), baleen whales (mysticetes), seals and walrus (pinnipeds), and polar bears (fissipeds).

Whales' (toothed and baleen) hearing can be impaired if the received sound level from multiple sound exposures is 230 dB re 1µPa. Very little information addresses the potential for functional consequences of physical and behavioural effects, chronic effects, and indirect effects of seismic survey sound on marine mammals.

DISCUSSION

The level of sound at a distance of 500m from the source (the extent of the marine mammal safety zone) is 180dB re 1µPa. It is understood that if a narwhal were to enter the safety zone, the surveying activity would stop until the animals pass through the zone. At this distance, research indicates that narwhal should not be negatively affected by sound. An individual whale's hearing can be impaired if the received sound level from multiple sound exposures is 198 dB re 1µPa^{2}s or greater.

There is an absence of available information of how narwhal behave around seismic surveys. This may be an indication that due to their natural migratory patterns, narwhal have not come into contact with seismic surveys or that they avoid surveying activities when migrating. Currently, the behavioural effects on narwhal from seismic surveys are unknown.

It is unlikely that narwhal will be in the survey area during July and August. Available research indicates that narwhal remain in their summering grounds, located along the coast of Baffin Island and in the fjords and bays of Baffin Island and Ellesmere Island, to calve in July and August. These narwhal are known to eat a variety of marine animals in their summering grounds.

It appears that narwhal begin their migration to their overwintering grounds in September. Narwhal that undergo a longer migration (travelling south down Baffin Island) begin their migration earlier compared to narwhal that travel directly offshore to their overwintering grounds.

Based on available information, it is understood that Eclipse Sound, Admiralty Inlet, and Somerset Island narwhal will enter the survey area beginning in October. However, this is gradually changing, as narwhal remain longer in the fjords and bays since the ice is forming later around Baffin Island. The seismic survey can be scheduled to limit potential interaction with narwhal using up-to-date information on the timing and location of migratory routes.

6.3 Beluga (*Delphinapterus leucas*), *Qilalugaq*

The beluga whale inhabits arctic and subarctic waters, feeding opportunistically on benthic species including octopus, crab, squid, snails, and a variety of fish species. Natural predators include polar bears, killer whales, and Greenland sharks. Belugas have a circumpolar distribution, migrating between shallow bays and estuaries to more southern ice packs and polynas. The International Whaling Commission (IWC) recognizes 29 subpopulations of Beluga[48]. There are seven populations[49] of beluga which inhabit Canadian waters, representing approximately 72, 000 - 144, 000 animals[50]. Beluga whales are harvested by Inuit hunters for subsistence, and are managed by DFO through Resource Management Boards composed of Inuit and Government representatives. COSEWIC identified the Cumberland Sound beluga population as “Threatened” while the Eastern Hudson Bay and Baffin Bay-Eastern High Arctic populations are listed as “Special Concern”[51].

BELUGA MIGRATION

There are three beluga whale populations whose summer or winter range are within proximity to the proposed MKI seismic survey: Eastern High Arctic- Baffin Bay; Western-Northern-Southern Hudson Bay; Cumberland Sound.

Richard, P.R., Heide-Jørgensen, M.P. and D. St. Aubin. (1998). Fall movements of Belugas (*Delphinapterus leucas)* with Satellite-linked Transmitters in Lancaster Sound, Jones Sound, and Northern Baffin Bay. *Arctic, 51(1):*5-16.

Six adult beluga whales were tagged with satellite-linked transmitters in the Canadian High Arctic in mid-September 1995. All but one beluga moved to the eastern side of Devon Island, staying close to shore while migrating. Arctic cod, an important prey of belugas occur in large schools near the shores in the Canadian High Arctic. The six tagged belugas spent between two and five weeks moving around eastern Jones Sound, Lady Ann Strait, and over the deep gully southeast of Coburg Island where they dove to depths of 400-800m, presumably to feed on Greenland halibut, squid, and octopus. All six belugas left Jones Sound around October 15-21 to go to the North Water.

Due to the small sample size, the results of this study were not sufficient to determine the extent of movement of belugas between the Canadian High Arctic and Greenland. It does provide a glimpse into the migratory nature of High Arctic belugas.

North Atlantic Marine Mammal Commission. (n.d.) Status of Marine Mammals in the North Atlantic: The Beluga Whale. North Atlantic Marine Mammal Commission. Tromsø, Norway. 12p.

Beluga whale seasonal movements depend on both oceanographic conditions (primarily the dynamics of ice cover) and the distribution of their prey species Belugas in the Canadian Eastern High Arctic- Baffin Bay population migrate to western Greenland or winter in the North

Water in Baffin Bay. Other beluga whales overwinter in the mouth of Cumberland Sound, Hudson Strait, and Hudson Bay.

Heide-Jørgensen, M.P., Richard, P., Dietz, R., Laidre, K.L., Orr, J. and H.C. Schmidt. (2003). An estimate of the fraction of belugas (*Delphinapterus leucas)* in the Canadian high Arctic that winter in Greenland. *Polar Biology, 26:* 318-326.

Based on the total number of belugas satellite-tracked in Canada between 1995 and 2001 with tags that lasted beyond October 1, approximately 15% of belugas in the Canadian high Arctic moved to west Greenland for the winter. The belugas that moved to west Greenland from Canada did so before or near October 1. Their migration path followed the North Water of Baffin Bay then along the coast of west Greenland.

DFO. (2002). Cumberland Sound Beluga. Stock Status Report. E5-32(2002).

Cumberland Sound belugas remain in Cumberland Sound year round (Figure 9). Their overwintering grounds are at the mouth of Cumberland Sound.

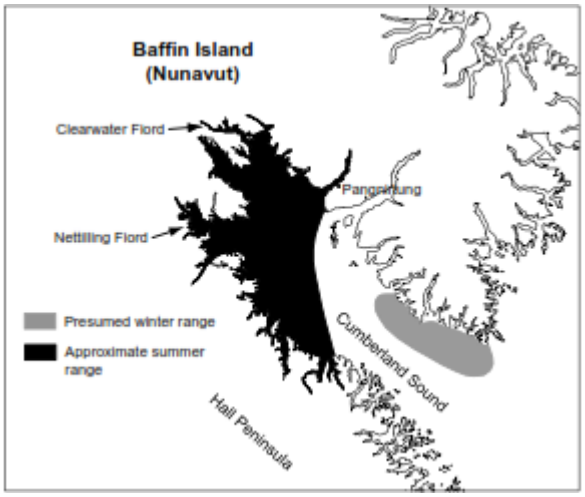

Figure 9: Cumberland Sound beluga whale range

DFO. (2009). Stock definition of Belugas and Narwhals in Nunavut. DFO Canadian Science Advisory Secretariat. Science Advisory Report 2009/079.

Belugas harvested near Iqaluit are thought to be from the Western-Northern-Southern Hudson Bay beluga stock. Most belugas caught around Kimmirut are harvested in autumn when the Western-Northern-Southern Hudson Bay beluga stock has moved into the Hudson Strait.

Richard, P.R. (2010). Stock definition of belugas and narwhals in Nunavut. *Canadian Science Advisory Secretariat. 2010/22.*18p.

All beluga's tagged in the Western-Northern-Southern Hudson Bay stock wintered in Hudson Strait.

Eastern High Arctic-Baffin Bay beluga stock were tagged at Cunningham Inlet and Elwin and Creswell bays, and then tracked into Peel Sound in late July- early August. They migrated east along Devon Island coast in September and October. Many entered Jones Sound, but wintered in the North Water polyna of northern Baffin Bay. A few moved to west Greenland for the winter.

Individual whales from the Cumberland Sound beluga stock were tagged near Clearwater Fiord and followed similar patterns of seasonal movements in Cumberland Sound. No whales left the Sound during autumn. They wintered in a polyna at the northeast corner of the mouth of Cumberland Sound.

Nunavut Planning Commission (2009). State of Knowledge in Maps. Nunavut Planning Commission. 28p.

The beluga whales' habitat extends from eastern Hudson Bay to Cumberland Sound to Jones Sound (Figure 10).

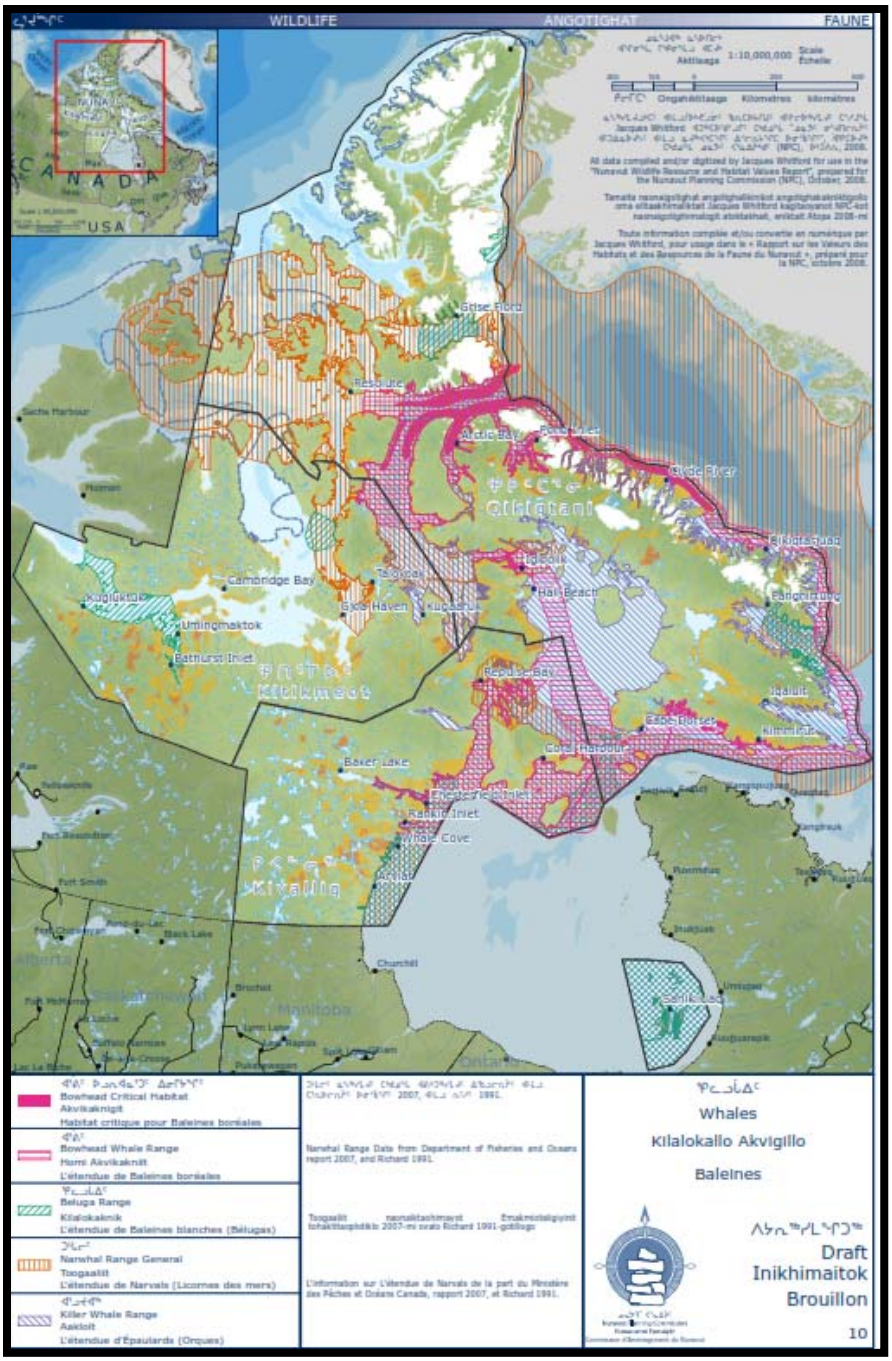

Figure 10: Beluga whale range (green) (from NPC, 2009).

COSEWIC. (2004). COSEWIC assessment and update status report on the beluga whale *Delphinapterus leucas* in Canada. Committee on the Status of Endangered Wildlife in Canada. Ottawa. Ix + 70p.

Beginning in mid-August, belugas begin to move away from the estuarine areas. Some populations, such as the High Arctic-Baffin Bay appear to make long journeys to deep-water areas away from land where they spend several weeks diving to the sea floor and engage in what appears to be intensive feeding activity. In mid to late September, belugas begin to actively move towards their winter areas (Figure 11).

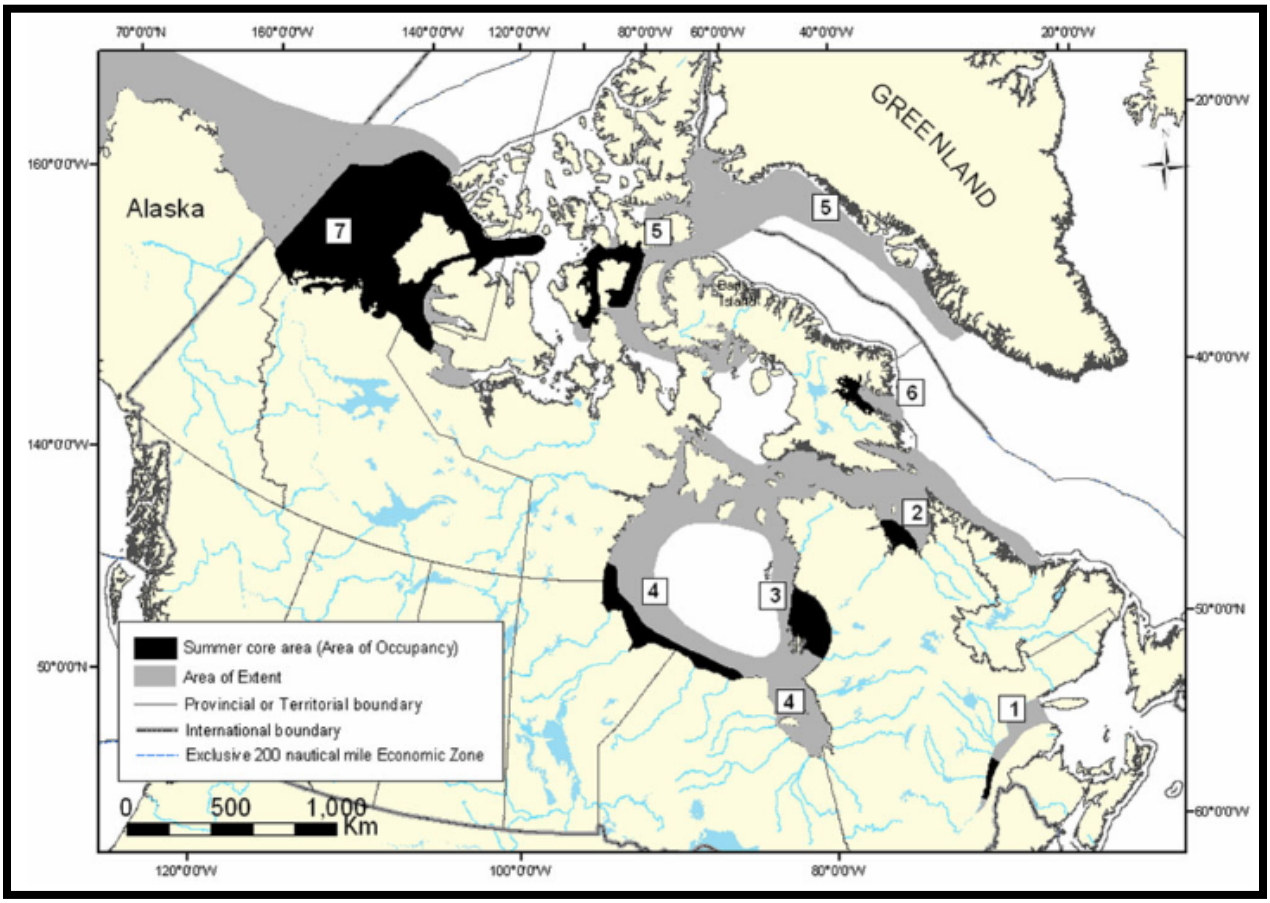

Figure 11: Location of the Canadian Beluga populations
1. St. Lawrence Estuary; 2. Ungava Bay; Eastern Hudson Bay; 4. Western Hudson Bay; 5. Eastern High Arctic-Baffin Bay; 6. Cumberland Sound; 7. Eastern Beaufort Sea

BELUGA BEHAVIOUR DURING SUMMER MONTHS

COSEWIC. (2004). COSEWIC assessment and update status report on the beluga whale *Delphinapterus leucas* in Canada. Committee on the Status of Endangered Wildlife in Canada. Ottawa. lx + 70p.

During the summer when the fast ice has broken up or completely disappeared, belugas are found along the coastlines and in relatively shallow waters. At this time, belugas spend time in river estuaries where they moult.

Researchers think that beluga whales moult, feed, and calve during the summer. These activities may vary from one location to another.

In late summer they appear to feed intensively, often in deep areas somewhat distant from centres of their summer distribution. There is no direct evidence of prey species involved in summer feeding. Arctic cod have a deep water distribution in these areas, suggesting they may be a food source. Inuit in Arctic Bay and Pangnirtung report that belugas feed extensively on Greenland halibut at the floe edge. Belugas also eat capelin, saffron cod, and marine invertebrates.

BELUGA AND SEISMIC SURVEYS

Miller, G.W., V.D. Moulton, R.A. Davis, M. Holst, P. Millman, A. MacGillivray, and D. Hannay (2005). Monitoring seismic effects on marine mammals—southeastern Beaufort Sea, 2001-2002.p. 511-542. *In* Armsworthy, S.L., Cranford, P.J. and K. Lee. (2005). Offshore Oil and Gas Environmental Effects Monitoring: Approaches and Technologies. Battelle Press, Columbus Ohio. 629p.

The results are from a two year marine seismic program offshore of the Mackenzie Delta in the southeastern Beaufort Sea during 2001 and 2002. The marine mammal safety zone was 1000m. At this distance, the expected received sound levels was estimated to be 180dB re 1 µPa. Data was collected through aerial surveys, Marine Mammal Observers, and Passive Acoustic Modelling. Beluga whale sighting rates at distances of 10-20km from the seismic survey were significantly lower than those in areas 20-30 km from the seismic source, where sightings were unexpectedly high. Belugas closest to the seismic survey (1540-2500m) would have received sound levels of approximately 165dB re 1 µPa.

The 180dB radius for the proposed project is 500m (marine mammal safety zone).

DISCUSSION

Beluga whales appear to be sensitive to sound. Researchers reported that beluga whales changed their behaviour within 20km of an active seismic survey. The general behavioural change was to leave the area of the seismic survey.

The Eastern High Arctic- Baffin Bay beluga whale population primarily overwinter in the North Water while approximately 15% of the population continues the migration eastward towards western Greenland. Belugas generally reside in Cumberland Sound year round. Belugas from

the Western-Northern-Southern Hudson Bay population appear to migrate north along Baffin Island and are hunted in Iqaluit and Kimmirut. The exact migration pattern for the Western-Northern-Southern Hudson Bay population is not known; however, it is likely that the belugas remain close to Baffin Island while migrating.

During the summer, beluga whales remain close to shore and can be located in estuarine areas and shallow water. Belugas can eat capelin, saffron cod, and marine invertebrate in the summer. Belugas may travel to deeper waters to feed on Arctic cod or Greenland halibut.

Despite beluga whale's sensitivity to seismic surveys it is unlikely that the proposed seismic survey will interact with the whales. Since beluga whales spend the majority of the summer in coastal areas, and their wintering areas are not located in the proposed seismic survey area, it is unlikely that the seismic survey will interact with beluga whales.

6.4 Bowhead, (*Balaena mysticetus*), *Arviq*

Bowhead whales frequent the edge of pack ice and move closer to shore during the summer months, feeding on crustacean zooplankton. Bowheads have few natural predators; killer whales represent their greatest threat. The whales have a circumpolar distribution, migrating great distances through the Canadian Arctic. There are approximately 7000 and 10 000 animals remaining in the wild in five populations, three of which occur in Canada[52]. The Western Canada-Eastern Greenland bowhead population occurs in Baffin Bay. Bowhead whales are hunted by Inuit for subsistence and are co-managed by DFO, the Nunavut Wildlife Management Board, and the Nunavik Marine Region Wildlife Board. COSEWIC lists bowhead whales as 'Threatened'[53].

BOWHEAD MIGRATION

Reeves, R., Mitchell, E., Mansfield, A. and M. McLaughlin. (1983). Distribution and Migration of the Bowhead Whale, *Balaena mysticetes,* in the Eastern North American Arctic. *Arctic, 36(1):* 5-64.

Historic (as early as 1719) whaling records and present-day trends were used to analyse the distribution of Bowheads in the Eastern Arctic. Opportunistic observations of whale harvests were used in the report. This may restrict the bowhead observations to those being close to shore, and not in the middle of Baffin Bay and Davis Strait. Nonetheless, the authors suggest that there has been little indication of bowhead whales deviating from historic migration routes.

In the winter, bowheads are mainly distributed from the northeast coast of Labrador to the Greenland coast between Sukkertoppen and Godhaven. In spring, bowheads follow the ice edge northward in Davis Strait. Some bowheads enter Hudson Strait and move westwards into Hudson Bay. During May and June, Bowheads move into Cumberland Sound and by June or July, bowheads reach the floe edge off Pond Inlet and Lancaster Sound. During summer months, bowheads enter the sounds, fjords, and inlets in the High Arctic. Bowheads are also found in northwestern Hudson Bay and western Foxe Basin[54] (Roes Welcome Sun and Repulse Bay) in the summer.

The fall migration begins in September and continues through October. Some whales that summered in the High Arctic move south along the coast of Baffin Island, reaching Cumberland Sound where a large concentration occurs in late autumn. Others cross to the West Greenland coast and begin to reappear at Upernavik in late September and October. Bowhead whales that entered Prince Regent Inlet may proceed southward through Fury and Hecla Strait into Foxe Basin. These whales may move eastward through Hudson Strait in the fall.

Nunavut Wildlife Management Board. (2000).Final report of the Inuit Bowhead Knowledge Study. *Nunavut Wildlife Management Board*, Iqaluit, NU. 101p.

This report includes the results of several workshops with Inuit communities throughout Nunavut. The report includes discussion on a number of topics which include population ecology of bowheads, distribution and migration, ecology and behaviour, and cultural and traditional importance of bowheads to Inuit and management of bowheads. This summary will include information on bowhead whale movement during summer and fall[55].

*Aujaq (*Summer): Bowheads have many different summering areas, with whales being widely but patchily distributed in inshore waters around Baffin Island. Some whales are still migrating to their summering areas during summer. In Foxe Basin, northern Hudson Bay and northeast Baffin Island, some whales are beginning their southward/offshore migrations.

Ukiassaaq (Early Fall): In early fall, bowhead whales are distributed in near-shore waters, but the southward and offshore migrations have begun. There is a migration of bowheads south along the east coast of Baffin Island. In the High Arctic (around Grise Fiord), bowheads are moving to the outer parts of their inshore summering habitat and beginning their southward and offshore migration. Bowheads also leave Cumberland Sound at this time. Bowheads are reported in the near shore waters of Repulse Bay and Igloolik/Hall Beach in the early fall. It was indicated that the whales were heading south from these areas towards northeastern Hudson Bay and Hudson Strait.

Ukiaq (Fall): During fall, as the southward and offshore migration continues, bowhead whales appear only in a few scattered locations. Only southern communities (Qikiqtarjuaq, Igloolik, and Kimmirut) have bowhead whales in their vicinity at this time.

Calendar months associated with Inuit seasons for the High Arctic

- *Aujaq*: mid-July to early September
- *Ukiassaaq*: early September to late October
- *Ukiaq:* late October to early January

Wheeler, B., Gilbert, M. and S. Rowe. (2012). Definition of critical summer and fall habitat for bowhead whales in the eastern Canadian Arctic. *Endangered Species Research, 17:* 1-16.

Bowhead critical habitat was identified from an analysis of information from published and grey literature, and bowhead specialists. Information on bowhead whale location was obtained from DFO (figure 1 in Wheeler et al., 2012), the private sector (figure 2 in Wheeler et al., 2012), and historic whaling records (figure 3 in Wheeler et al., 2012). The authors identified 'highly suitable habitat'[56] for bowhead (Figure 12). This information is supported by bowhead concentration areas identified by Inuit in late spring, summer and early fall (Figure 13) (see summary NWMB report).

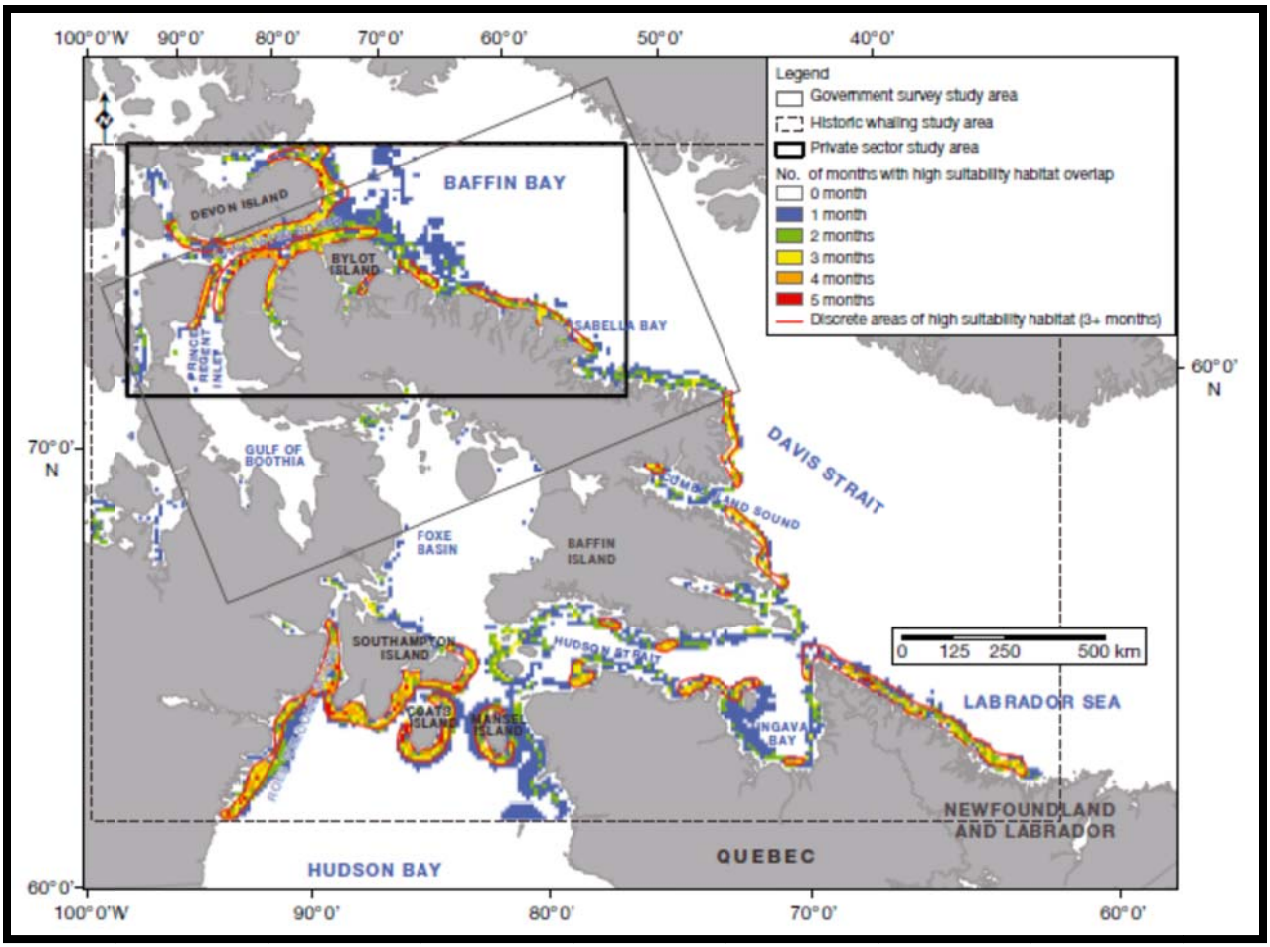

Figure 12: Highly suitable habitat map from June to October (figure 4 in Wheeler et al., 2012)

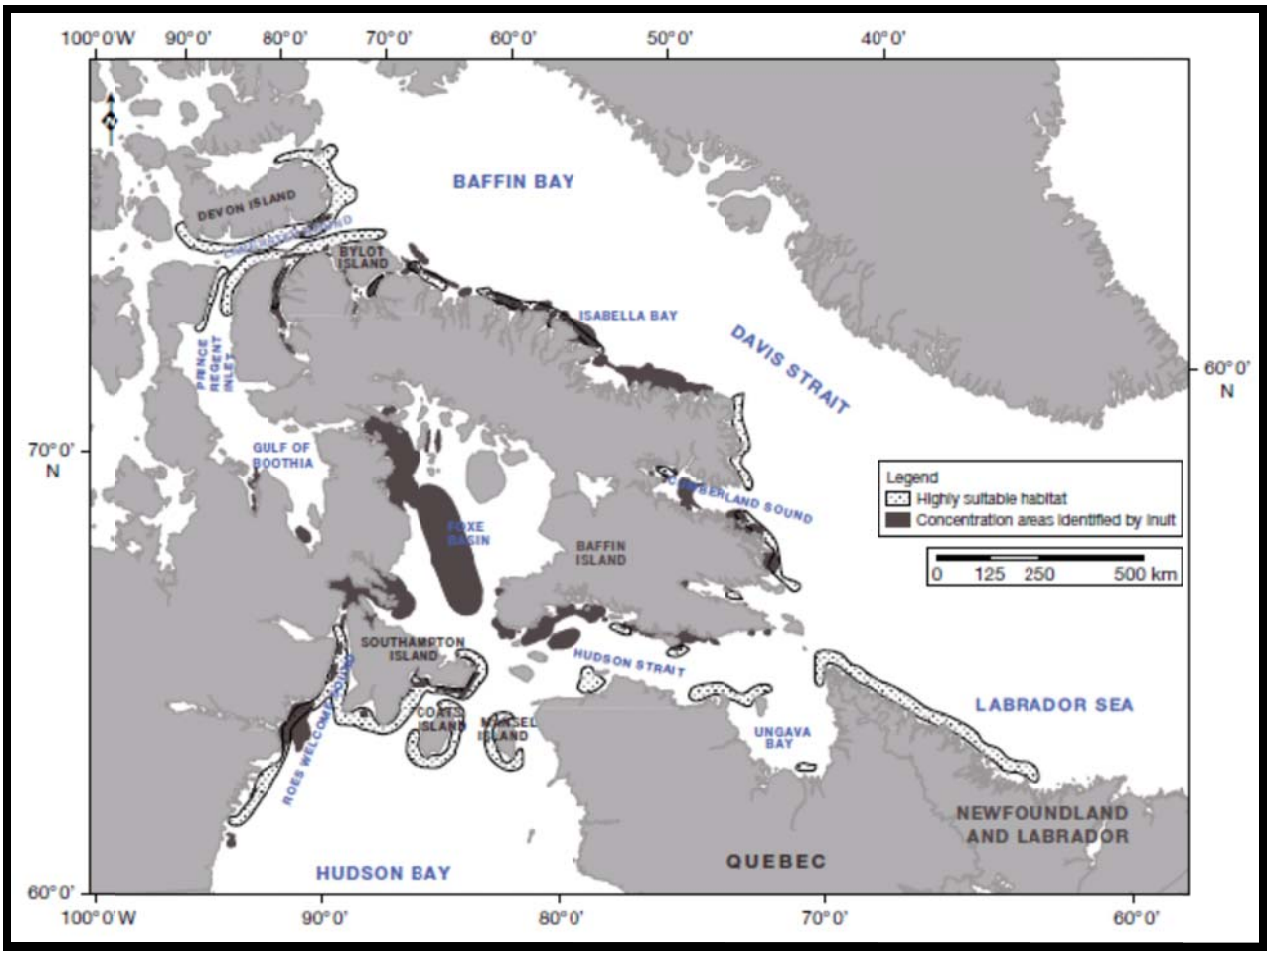

Figure 13: Comparison of highly suitable habitat with bowhead concentration areas identified by Inuit (figure 6 in Wheeler et al., 2012)

Ferguson, S.H., Dueck, L., Loseto, L.L. and S.P. Luque. (2010). Bowhead whale *Balaena mysticetes* seasonal selection of sea ice. *Marine Ecology Progress Series, 411:* 285-297.

Twenty-seven bowhead whales from the Western Canada-Eastern Greenland population were tagged with satellite transmitters in July from 2002 to 2003 in Foxe Basin and then in 2004 to 2006 in Cumberland Sound. There was an indication of two migrations during the summer-autumn period indicated by peaks in movement rates. These occurred around July 22 when the whales moved from the spring to summer range and around October 29 when whales were returning from the summer to the winter range. Movement rate is a good indicator that migrations have begun as bowhead whales travel long distances between their summer and wintering grounds. This is in comparison to the relatively low movement rates when bowheads are in their summering grounds, indicating that bowheads generally remain in the same area throughout the summer[57]. Figure 14 illustrates the movement of the tagged bowhead whales from July until early winter[58]. Bowhead whale movement patterns include a behavioural preference for ice-edge habitat[59] and the avoidance of competition from other baleen whales.

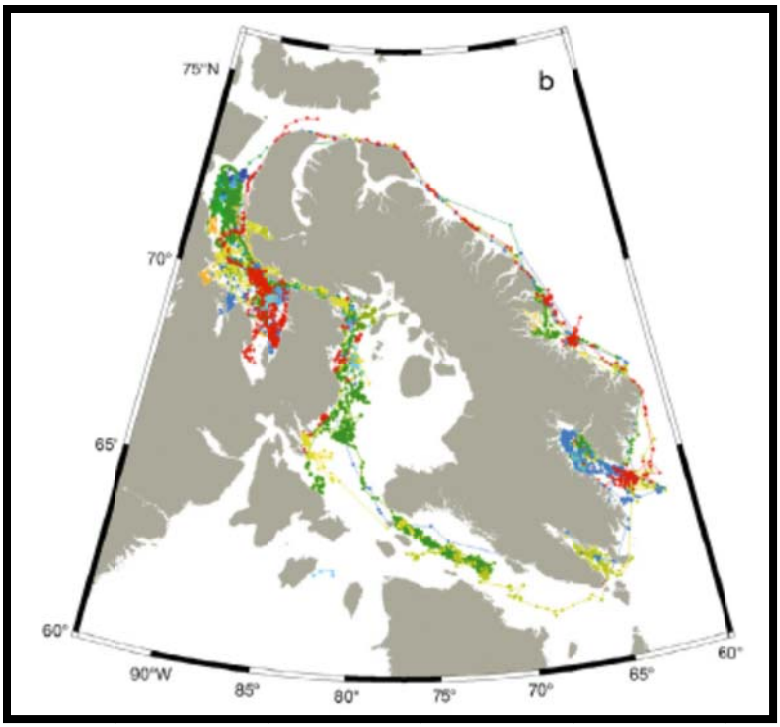

Figure 14: Movement of 27 tagged bowhead whales (fig.1 in Ferguson et al., 2010)

Nunavut Planning Commission (2009). State of Knowledge in Maps. Nunavut Planning Commission. 28p.

Bowhead whale critical habitat is along the western coast of Baffin Bay south of Clyde River into Lancaster Sound in the coastal region (Figure 15). Critical habitat is also located in Hudson Strait. Bowhead range is generally located in the coastal region of eastern Baffin Island, north through Lancaster Sound and south through Hudson Strait into Hudson Bay and Foxe Basin.

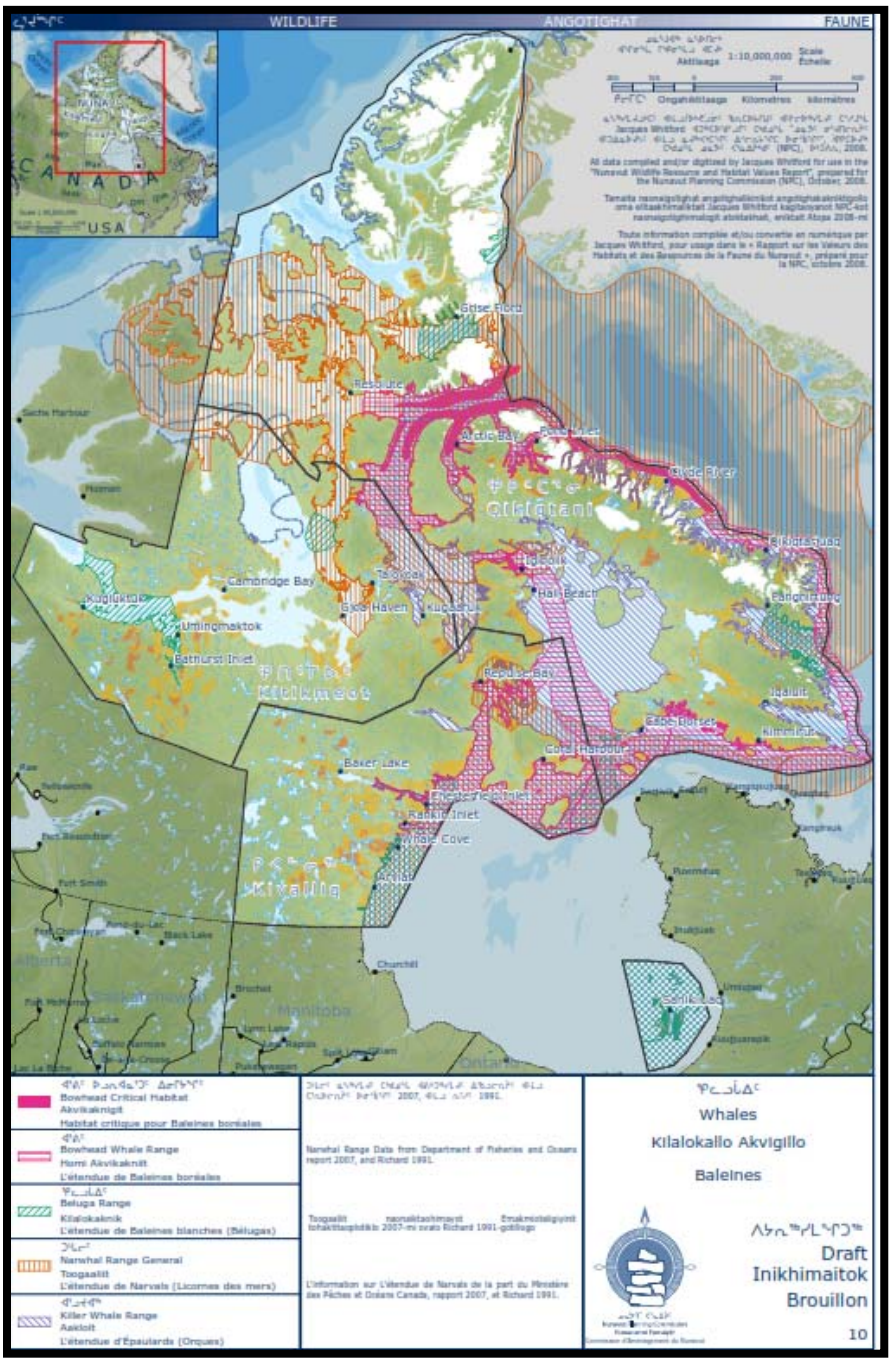

Figure 15: Bowhead whale critical habitat and habitat range (pink) (from NPC, 2009).

SUMMARY

Available reports provide information on general movements of the Western Canadian-Eastern Greenland bowhead whale population (Table 4). Based on this information the seasonal migration of the Western Canadian-Eastern Greenland bowhead whale population can be inferred (Figure 14). This migration pattern has been discussed in research reports which have involved tagging bowhead whales and reports from Inuit knowledge studies. Reports indicate that bowhead whales can begin their migration in early September.

Table 4: Summary of bowhead whale fall migration for Western Canada-Eastern Greenland population

Source	Data collection method	Bowhead Migration Begin	Migration path[60]
Reeves et al., 1983	Historic and contemporary data from records and archives	Begins in September, continues into October	1) Cross Baffin Bay from Lancaster Sound to Greenland 2) Travel south down Baffin Island toward Cumberland Sound
NWMB, 2000	Workshops with Inuit communities	*Ukiassaaq* (Early September to late October)	1) Whales from the High Arctic move south along the coast of Baffin Island or offshore 2) Whales in Cumberland Sound move south to Hudson Strait
Wheeler et al., 2012	Government, private sector and historical whaling records	No information	Report identified bowhead whale highly suitable habitat. The habitat (in and around Baffin Island) identified agrees with information obtained on bowhead whale migration
Ferguson et al., 2010	Satellite telemetry from 27 tagged bowhead whales	Bowhead whales began their fall migration on October 29.	Bowhead whales remained close to Baffin Island throughout the study.
NPC, 2009	Workshops with Inuit	No information	Bowhead highly suitable habitat and range (close to shore along Baffin Island, in Lancaster Sound, Hudson Strait and Foxe Basin) is similar to information obtained in other studies

Figure 16: Western Canada-Eastern Greenland Bowhead Whale population migratory pattern (green=spring; black=summer; orange=fall; purple=winter) (map courtesy of Google Earth). These lines are to show trends in bowhead whale migration.

During the spring migration, bowhead whales remain close to the floe edge which is generally located across Davis Strait towards Newfoundland and out to Sukkertoppen, Greenland. As the floe edge recedes, bowheads migrate north, remaining close to the east coast of Baffin Island. Some whales will go through Hudson Strait and remain in Foxe Basin and Hudson Bay, while the other whales migrate towards Lancaster Sound and spend time in the Gulf of Boothia and Prince Regent Inlet. During the summer time, bowhead whales remain in the many inlets, bays, and fjords in the High Arctic.

During the fall migration, bowhead whales in the High Arctic take one of two migration paths. Some bowhead whales begin their migration south along the east coast of Baffin Island, while other whales cross northern Baffin Bay and arrive near Upernavik, Greenland. It is at this time that large congregations of bowhead whales may occur in Cumberland Sound. As fall approaches, bowhead whales continue their southward migration. Bowhead whales from Foxe

Basin and Hudson Bay head eastward across Hudson strait. The whales then congregate at the floe edge outside of Davis Strait in the winter (Figure 16)

A report by Heide-Jørgensen and colleagues (2003)[61] assessed the movements of two tagged bowhead whales[62] as they began their spring migration from Disko Bay, Greenland through Baffin Bay to Lancaster Sound. Disko Bay is approximately 425km south of Upernavik, Greenland. Over an average of 9 to 10 days, in May and June, the bowhead whales traversed the ice pack filled Baffin Bay. It is suggested that Bowhead whales occur in seasonal aggregations along the coasts of Eastern Baffin Island and Western Greenland and traverse offshore areas only when moving and/or migrating to other concentration areas.

BOWHEAD BEHAVIOUR DURING SUMMER MONTHS

Bowhead whales primarily feed in late summer, early fall on pelagic and epibenthic zooplankton. Feeding can occur in late winter and early spring[63]. The Eastern Canada-Western Greenland bowhead whales are predominately located in Lancaster Sound, Isabella Bay, Prince Regent Inlet, Admiralty Inlet, Cumberland Sound, and the Gulf of Boothia in the summer months[64].

BOWHEAD AND SEISMIC SURVEYS

Behavioural and anatomical evidence suggests that baleen whales hear well at frequencies below 1kHz where most of the energy from the sound source is focused[65]. Therefore, bowheads, which are baleen whales, may be more sensitive to sound from seismic surveys than toothed whales. Observations on bowhead whale behaviour in response to seismic surveys corroborate that bowhead whales may be affected by seismic surveys; however, these observations suggest a threshold in which bowhead may react to seismic surveys. Table 5 provides a summary on the available information of the reaction between seismic surveys and bowhead whales:

Table 5: Summary on bowhead behavioural reactions to seismic surveys

Distance between bowhead whale and seismic vessel	Change in bowhead whale behaviour	Source
1.957km	Bowhead whales were sighted further away (1957m) during active seismic operations compared to inactive periods (1368m).	Miller et al., 2005
1.3-7.2km	Yes. Whales leave observation area	Ljungblad et al.,1988
2-4.5km	Yes. Bowheads oriented away from seismic survey. Remained in area.	Richardson et al., 1986
3km	Yes. Bowhead stopped bottom feeding	Richardson et al., 1986
3.5-8.2km	Yes. Subtle behaviour response	Ljungblad et al.,1988
3.5-7.6km	Yes. Partial avoidance (some whales left, while other whales remained in the observation area)	Ljungblad et al.,1988

Distance between bowhead whale and seismic vessel	Change in bowhead whale behaviour	Source
Instances of seismic surveys effecting and not effecting whales (no references provided)		Mosbech et al., 2000
3-5km	No. Bowheads maintained normal activities	Richardson et al., 1986
6-99km	No. Activities of bowheads in this area were the same compared to bowheads not near an active seismic survey	Richardson et al., 1986

According to available report, bowhead whales which changed their behaviour in the presence of a seismic survey normally resumed to their pre-seismic survey behaviour within one[66] or 48 hours[67] after interacting with a seismic survey.

DISCUSSION

Based on observations recorded on the interaction between seismic surveys and bowhead whales, it appears that bowhead whales may change their behaviour in the presence of seismic surveying. Bowhead whales have been observed to exhibit a variety of behavioural responses to sound from seismic surveys. It was reported that bowhead whales left the survey area within a range of 1.3km-7.2km from the sound source. However, some bowhead whales did not change their behaviour when an operating seismic survey was within 3km. Ljungblad and colleagues (1988) reported that bowhead whales resumed pre-seismic survey behaviour within one hour after the survey left the area. When seismic survey vessels stopped operating and remained in the area to observe bowhead whales, the whales resumed normal behaviour within one hour.

The Western Canada-Eastern Greenland bowhead population spend most of their summer in the fjords and sounds of Baffin Bay. It is unlikely that the MKI seismic survey will interact with bowhead whales at this time. Bowhead whales begin their fall migration in September and follow one of two migration routes; they either travel south along eastern Baffin Island or east across Baffin Bay to western Greenland. It is possible that migrating bowhead whales may encounter the proposed survey activity; however, the survey can be scheduled so as to limit this interaction.

6.5 Walrus (*Odobenus rosmarus*), *Aiviq*

The Atlantic Walrus inhabits arctic coastal regions, preferring shallow water with high bivalve productivity, where they feed primarily on clams and urchins. Natural predators include killer whales and sharks. Walrus require ice or low rocky shores with steep sub- tidal zones to 'haul out'. Atlantic Walrus can range from the high arctic to the more southerly latitudes of Nova Scotia and the Saint Lawrence River. Five populations are recognized for management purposes, with an approximate total population of 15 000[68]. Walrus are hunted by Inuit for subsistence, and is managed by DFO subject to the terms of the Nunavut Land Claims Agreement and the *Fisheries Act*. Atlantic Walrus are listed as "Special Concern" by COSEWIC.

WALRUS MIGRATION

Stewart, R. (2008). Redefining Walrus Stocks in Canada. *Arctic, 61(3):* 292-308.

Eighteen walrus were tagged with satellite transmitters between 1993 and 2004 in the fjords on south-west Devon Island, Grinnel Peninsula (Devon Island), Bathurst Island, Norfolk Inlet and Goose Fiord (adjacent to western Jones Sound). The tagged walrus wintering areas occurred in Cardigan Strait- Fram Sound area at the west end of Jones Sound, the floe edges of Jones and Lancaster Sound and in the North Water polyna.

The walrus tagged in this study are thought to belong to the North Water stock (stock 5 in Figure 17)

Born, E.W., Gjertz, I and R.R. Reeves. (1995). Population assessment of Atlantic walrus (*Obdenus rosmarus rosmarus*). Meddelelser Nr. 138. Oslo: Norsk Polar Institute. 100p.

The Northern Hudson Bay-Hudson Strait- Southeastern Baffin Island- Northern Labrador (stock 3 in Figure 17) may have some connection with southern and eastern Hudson Bay and with Central West Greenland. Walruses occur year round along portions of the coast of eastern Baffin Island south of Clyde Inlet and in the Hudson Strait. Although areas of summer concentrations have been identified (e.g. outer parts of Cumberland and Hall peninsulas, Lady Franklin Island group, Loks Land), some of these groups may undertake fairly long migrations while others are thought to move relatively short distances according to ice conditions and availability of food.

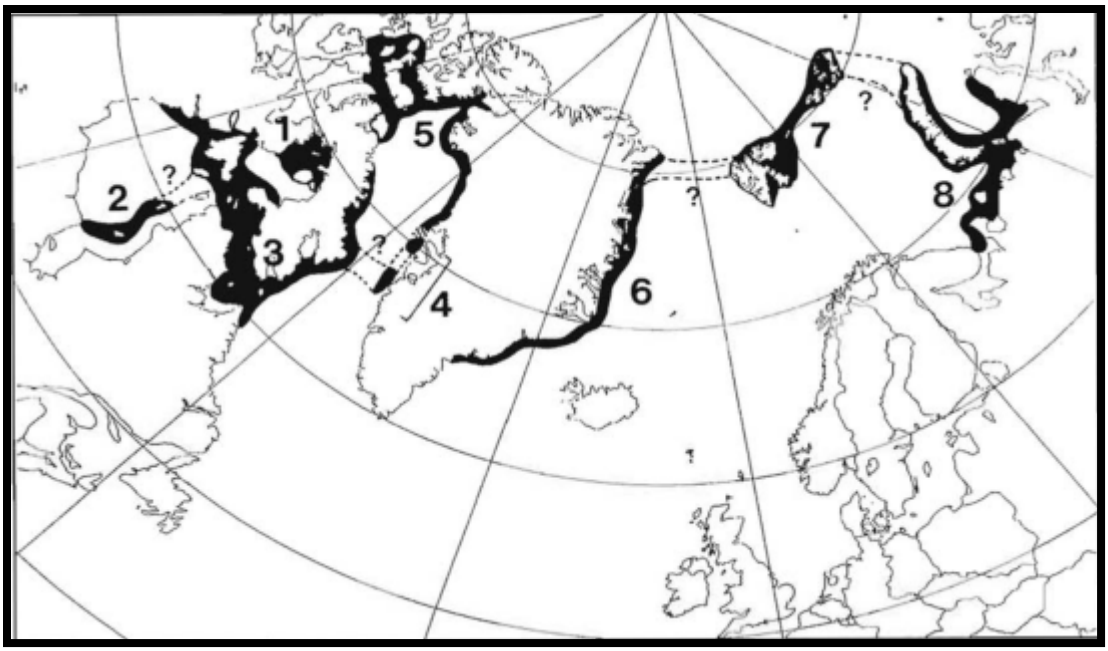

Figure 17: Delineation of walrus stocks
(1. Foxe Basin; 2. Southern and Eastern Hudson Bay; 3. Northern Hudson Bay; 4. Western Greenland; 5. North Water; 6. Eastern Greenland; 7. Svalbard; 8. Kara Sea (Figure 3 in Born et al., 1995).

COSEWIC. (2006). COSEWIC assessment and update status report on the Atlantic walrus *Odobenus roasmarus rosmarus* in Canada. Committee on the Status of Endangered Wildlife in Canada. Ottawa. Ix+65p. (www.sararegistry.gc.ca/status/status_e.cfm)

For the most part, the Northern Hudson Bay-Hudson Strait- Southeastern Baffin Island-Northern Labrador (stock 3 in Figure 17) walrus stock remains close to land during the summer months. However, there have been observations of walruses offshore over deep waters between southeastern Baffin Island and western Greenland. This migration path has not been documented as indicated in Figure 17.

The High Arctic population (stock 5, also known as North Water, in Figure 17) is separated geographically from other Canadian walrus populations to the south. This population is shared with Greenland and extends southwards to Disko Island, Greenland.

Walrus live in Foxe Basin (stock 1 in Figure 17) year round in relatively shallow waters. Walruses can also be found in the Gulf of Boothia (accessible from Fox Basin and Lancaster Sound); however these animals are believed to come from the Baffin Bay population to the north.

Nunavut Planning Commission (2009). State of Knowledge in Maps. Nunavut Planning Commission. 28p.

Walrus summering ranges occur off Qikiqtarjuaq, south of Cumberland Sound, southeastern Frobisher Bay, the mouth of Hudson Strait, in Hudson Bay, and Foxe Basin. Walrus wintering range includes the eastern Ellesmere Island in the High Arctic (Figure 18). Walrus are found year round in northern Foxe Basin and western Jones Sound.

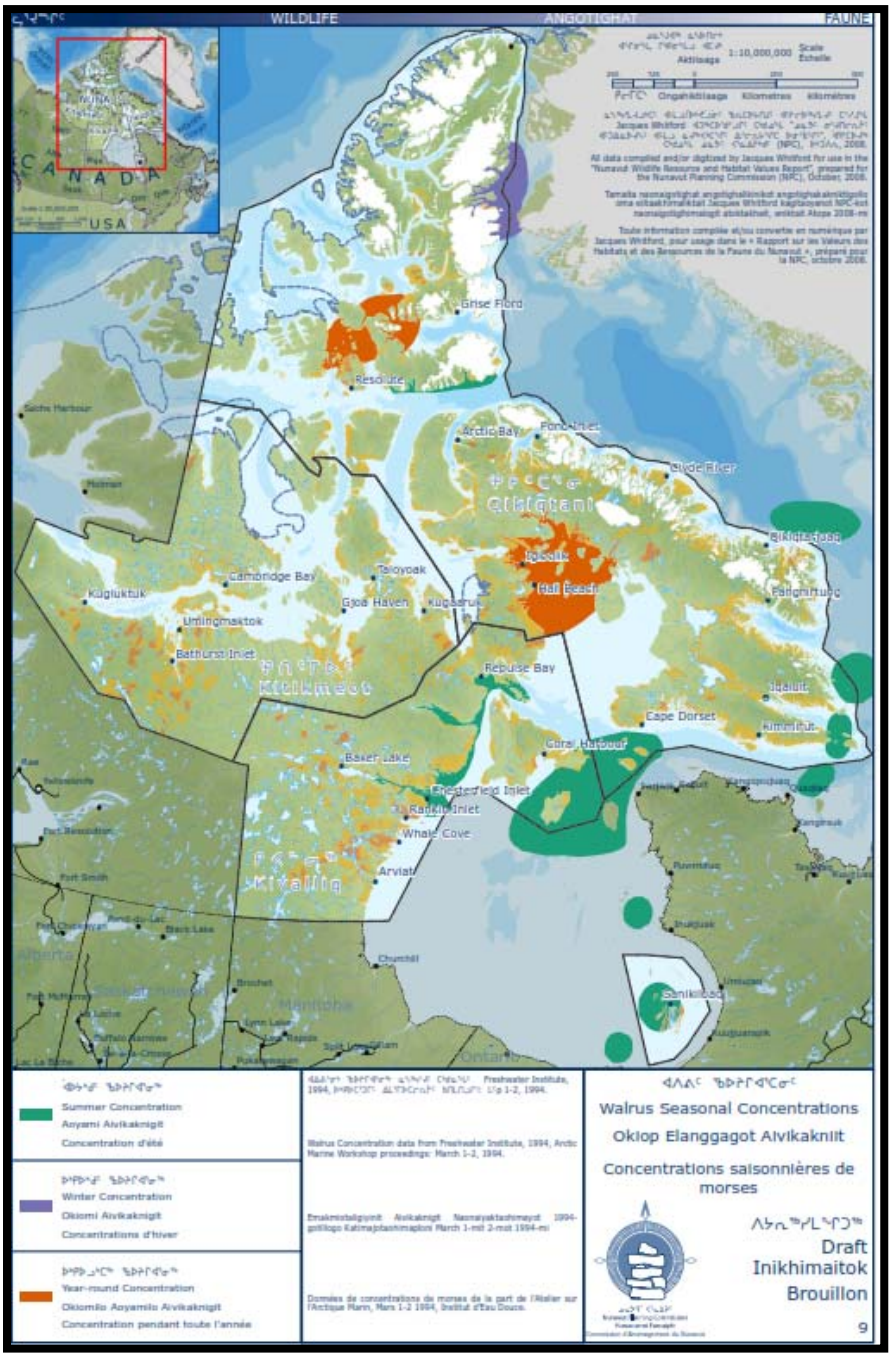

Figure 18: Walrus seasonal habitat range (from NPC, 2008)

WALRUS BEHAVIOUR DURING SUMMER MONTHS

During the summer the walrus population is segregated by age and sex, with mature males forming separate groups[69]. In many areas, walrus haul out on land, but they may also rest on floating ice.

Born, E.W., Gjertz, I and R.R. Reeves. (1995). Population assessment of Atlantic walrus (*Obdenus rosmarus rosmarus*). Meddelelser Nr. 138. Oslo: Norsk Polar Institute. 100p.

Haul out platforms are usually ice pans although terrestrial haul out sites are used in the ice-free summer and autumn period.

Fisher, K.I., and R.E.A. Stewart. (1997). Summer foods of Atlantic walrus, *Obdenus rosmarus rosmarus,* in northern Foxe Basin, Northwest Territories. *Canadian Journal of Zoology, 75:* 1166-1175.

Walrus in Foxe Basin eat more prey in September to November compared to July. If the feeding behaviour of walrus in Foxe Basin is similar to walrus in Baffin Bay, then it can be expected that walrus remain close to shore in September until November to feed on bivalves and mollusks in waters less than 100m.

Fay, F.H. and J.J. Burns. (1988). Maximal Feeding Depths of Walruses. Arctic, 41(3), 239-240.

Walruses feed mainly on benthic invertebrates in waters less than 80m deep.

WALRUS AND SEISMIC SURVEYS

There are no available reports analyzing the potential effects of seismic surveys on walrus.

DFO describes the hearing ability of walrus and does not provide information on the effects of seismic surveys to walrus[70]. A Temporary Threshold Shift as result of sound from seismic surveys has not been documented for walrus[71].

DISCUSSION

Reports indicate that the Foxe Basin and High Arctic walrus populations do not interact with the Northern Hudson Bay-Hudson Strait- Southeastern Baffin Island- Northern Labrador population.

Behavioural characteristics suggest that walrus preferentially spend the summer months close to land where they can haul out (as available ice is limited) and eat bivalves located on the ocean floor. This routinely occurs in coastal areas within 80 metres of water.

Walrus have been reported travelling between Canada (off Qikiqtarjuaq) and Greenland during the summer months; however, it is not known how many walrus make this journey and what time of year this journey takes place. We suggest that the walrus congregation area off Qikiqtarjuaq identified by Inuit may be the starting point for the route walrus take between Canada and Greenland.

Therefore, except for the few offshore areas where walrus congregate in the summer, and a suspected migration route between Canada and Greenland, it is unlikely that walrus would come within close proximity to the proposed seismic survey.

The apparent absence of reports assessing the interaction between seismic surveys and walrus may be an indication that walrus are generally not located in areas where seismic surveys have been completed. Available reports indicate that walrus generally remain close to land with a few offshore areas in southern Baffin Bay (near Qikiqtarjuaq, Iqaluit, and Kimmirut) where walrus congregate in the summer.

6.6 Bearded Seal (*Erignathus barbatus*), *Udjuk*

The Bearded seal inhabits ice flows and shallow waters, feeding on crabs, clams, squid, and fish in the Arctic. Natural predators include polar bears, sharks, and walrus. Bearded seals have a circumpolar distribution, found throughout southern latitudes of the Arctic, along the coasts of Labrador and the northern coasts of Newfoundland. They require ice flows to haul out, although occasionally haul out on land. The population of Bearded Seals is not known (DFO, 2011)[72]. The seals are hunted by Inuit for subsistence and are managed by the DFO (2011) through the *2011-2015 Integrated Fisheries Management Plan for Atlantic Seals*. The SARA and COSEWIC status for bearded seals is 'Data Deficient'.

BEARDED SEAL MIGRATION

Finley, K.J. and W.E. Renaud. (1980). Marine Mammals Inhabiting the Baffin Bay North Water in Winter. *Arctic, 30(4):* 724-738.

Aerial surveys over the North Water were completed in 1978 and 1979. Bearded seals were seen in deep water (200-500m) near SE Ellesmere Island in 1979. Bearded seals are mostly restricted to areas where ice cover is thin or broken. Since they are normally bottom feeders, they must have access to relatively shallow areas where benthic prey is available.

Finley, K.J. and C.R. Evans. (1983). Summer Diet of the Bearded Seal (*Erignathus barbatus)* in the Canadian High Arctic. *Arctic, 36(1):* 82-89

During the summer, bearded seal are found widely distributed in small numbers throughout much of the archipelago. In the eastern Canadian High Arctic, bearded seals are hunted in fjords, primarily from July to October.

Shell. (2013). Shell Greenland A/S 2013 Site Survey in Baffin Bay Blocks 5 (Anu) and 8 (Napu). Preliminary Environmental Impact Assessment

Fourteen bearded seals were observed by Marine Mammal and Seabird Observers throughout a 2012 3D seismic survey in Baffin Bay blocks 5 and 8 (includes transit time to survey area). Thirteen bearded seals were observed in the survey area. The report did not indicate if the bearded seals appeared in the 500m safety zone for seals.

Nunavut Planning Commission (2009). State of Knowledge in Maps. Nunavut Planning Commission. 28p.

The Nunavut Planning Commission prepared a report which used IQ to prepare maps depicting wildlife and Inuit use of the land and resources. Figure 19 shows areas of high bearded seal density. These areas include the western side of Hudson Bay, northern Fox Basin, and Lancaster Sound.

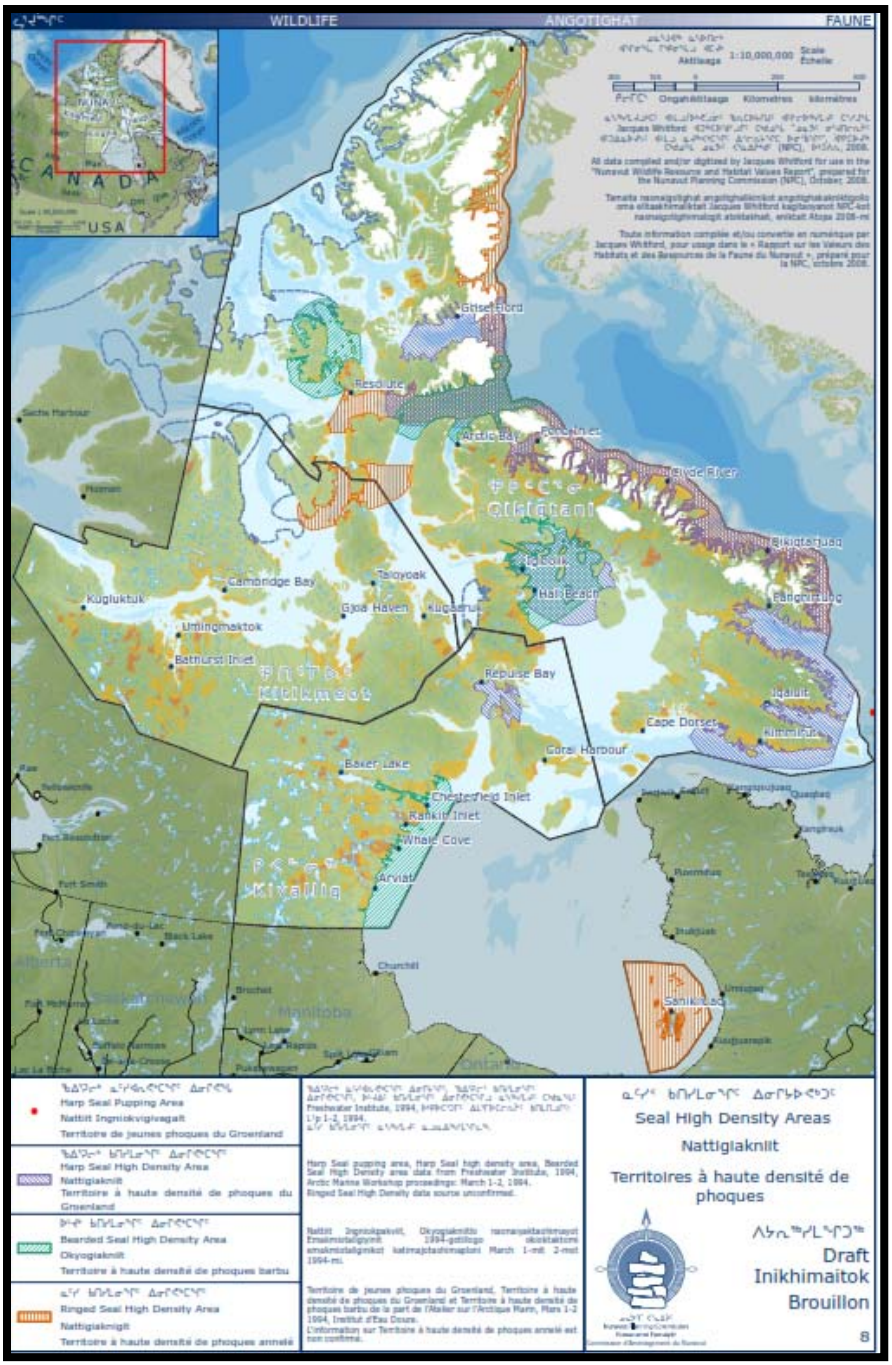

Figure 19: Seal High Density Areas (Nunavut Planning Commission, 2008)

BEARDED SEAL BEHAVIOUR DURING SUMMER MONTHS

Finley, K.J. and C.R. Evans. (1983). Summer Diet of the Bearded Seal (*Erignathus barbatus)* in the Canadian High Arctic. *Arctic, 36(1):* 82-89

Stomach contents of 34 bearded seals harvested in three High Arctic communities (Grise Fiord, Pond Inlet and Clyde River) during the summers of 1978 and 1980 were examined. At least 12

species of fish were present in the stomach contents, but sculpin and arctic cod comprised the bulk of the diet.

BEARDED SEAL AND SEISMIC SURVEYS

Bearded seals were observed to swim away from an active seismic survey to a distance of 250m (Harris et al., 2001) in the Beaufort Sea. During this seismic survey (3D seismic survey in 1996 in the Beaufort Sea), no seals were observed to leave the survey area during an active seismic survey (Harris et al., 2001). In Shell's 2012 3D seismic survey off Greenland in lease blocks 5 and 8, 13 bearded seals were observed by Marine Mammal and Seabird Observers in the survey area. It was not specified if the bearded seals entered the 500m safety zone.

DISCUSSION

Bearded seals spend a large portion of the summer in coastal areas and in the many fjords and bays within and around Baffin Island and Ellesmere Island. Being benthic feeders, bearded seals must remain near relatively shallow waters (approximately 80m) to eat. Both Inuit and scientific observations indicate areas where bearded seals are most likely to be observed as close to land.

Bearded seals have been known to venture into deeper water, particularly off Ellesmere Island in the High Arctic. There is no known summer migration of bearded seals in the deep waters of Baffin Bay or Davis Strait. Bearded seals were observed in the deep waters of Baffin Bay and Davis Strait during the 2012 3D seismic survey by Shell.

The documented effects of seismic surveys on bearded seals appear to be negligible beyond 250m. This was demonstrated in a 3D seismic survey in the Beaufort Sea in 1996. In this survey, bearded seals did not move beyond 250m away from an active seismic survey vessel.

Therefore, with the mitigation measures proposed for this seismic survey, it is unlikely that bearded seals will be negatively affected. Specifically, the seismic survey will stop if a seal (or any other marine mammal) is within 500m of an active sound source.

6.7 Ringed Seal (*Pusa hispida*), *Natsik*

The Ringed Seal inhabit ice flows and pack ice, feeding on shrimp, cod, herring, smelt, whitefish, sculpin, and various other small fish and crustaceans. Ringed seals have a circumpolar distribution. Ringed seals haul out on ice year round, although they occasionally use land as well. The total population of Ringed seals is estimated at over one million (DFO, 2011)[73]. The seals are hunted by Inuit for subsistence and are managed by the DFO (2011) through the *2011-2015 Integrated Fisheries Management Plan for Atlantic Seals.* Ringed Seals are listed as "Not at Risk" by COSEWIC.

RINGED SEAL MIGRATION

Born, E.W., Teilmann, J., Acquarone, M. and F.F. Riget. (2004). Habitat use of Ringed Seals (*Phoca hispida)* in the North Water Area (North Baffin Bay). *Arctic, 57(2):* 129-142.

Twenty-three ringed seals were tracked for an average of 108 days from August 12, 1996 until June 30, 1999 in the North Water area. Four seals left the North Water area. During all seasons, the seals that remained in the North Water area, spent about 90% of their time in coastal (less than 100m deep) waters in the eastern parts of the North Water area. Individual movements were significantly greater during the open-water season than during winter and spring. Maximum dive depths were 500 m outside of the North Water area and 376m inside. It was suggested that prey availability determined the depths of dives for ringed seals.

Kovacs, K.M. (n.d.). Background document for development of a circumpolar ringed seal (*Phoca hispida)* monitoring plan. Retrieved June 19, 2013 from http://www.arlis.org/docs/vol1/D/778551575.pdf

In the summer and fall, when land-fast ice is not available, ringed seals show considerable diversity in their distribution patterns. Some animals remain in the general vicinity of their breeding sites (along packs of ice) while others disperse along coastlines where ice from glaciers is available. Ringed seals are generally found at highest densities over shallow to mid-depths (100-200m) of water. Ringed seals try to remain where there is some ice coverage throughout the year. When seals are offshore, sea ice concentration and the time of year influenced habitat selection by ringed seals.

Information regarding seasonal and inter-annual movement patterns of ringed seals is somewhat limited. Near Baffin Bay, ringed seals seem to leave coastal areas in the summer, while in other, generally more northern areas, large influxes of ringed seals occur during the open water period.

Finley, K.J., Miller, G.W., Davis, R.A. and W.R. Koski. (1983). A distinctive large breeding population of ringed seals (*Phoca hispida)* inhabiting the Baffin Bay pack ice. *Arctic, 36(2):* 162-173.

There may be two populations of ringed seals in Baffin Bay based on morphological and ecological differences. Small numbers of ringed seals were seen during aerial surveys in May, but the peak of haul-out in both offshore and coastal areas occurred during the latter half of June and into early July.

Group sizes were similar in offshore and coastal areas, although they tended to increase in size towards July. Ringed seals were distributed throughout the offshore pack ice and the coastal fast ice of NW Baffin Bay (north of Clyde River). Few seals were seen in peripheral areas of the pack-ice fields where the ice was more active and broken.

Nunavut Planning Commission (2009). State of Knowledge in Maps. Nunavut Planning Commission. 28p.

High density ring seal locations include south-eastern Hudson Bay and coastal areas of Lancaster Sound (Figure 19).

RINGED SEAL BEHAVIOUR DURING SUMMER MONTHS

Kovacs, K.M. (n.d.). Background document for development of a circumpolar ringed seal (*Phoca hispida)* monitoring plan. Retrieved June 19, 2013 from http://www.arlis.org/docs/vol1/D/778551575.pdf

Invertebrate prey seems to become more important to ringed seals in most areas during the open-water season. During the late summer, fall, and winter, ringed seals eat to gain weight for the fasting period during late March or early April until late summer. During the fasting period, females would have given birth and are lactating, while males defend their underwater territories and interact with adult females as they become available for copulation.

RINGED SEAL AND SEISMIC SURVEYS

Ringed seals were observed to swim away from an active seismic survey to a distance of 250m (Harris et al., 2001) in the Beaufort Sea. During this seismic survey (3D seismic survey in 1996 in the Beaufort Sea), no seals were observed to leave the survey area during an active seismic survey (Harris et al., 2001).

In Shell's 2012 3D seismic survey off Greenland in lease blocks 5 and 8, 109 ringed seals were observed by Marine Mammal and Seabird Observers in the survey area. It was not specified if the ringed seals entered the 500m safety zone.

DISCUSSION

During the summer months, ringed seals can either be found near the coast of Baffin Island or offshore in northern Baffin Bay and the North Water. There may be two populations of ringed seals with one group preferring coastal fast ice, while the other prefers offshore pack ice. Seals

use the ice to ‘haul out’ and to protect their pups. In the summer months, when the ice in Baffin Bay breaks up and melts, some ringed seals move towards the coast, while other seals remain in the remnants of ice in the North Water.

During the summer, ringed seals eat to restore their weight after an intense fasting period (females have pups, while males protect their territory). Ringed seals tend to prefer invertebrate species at this time of year.

Since the majority of ringed seals either remain close to pack ice in northern Baffin Bay and the North Water or near coastal areas, it is unlikely that the proposed seismic survey will interact with large numbers of ringed seals.

The documented effects of seismic surveys on bearded seals appear to be negligible beyond 250m. This was demonstrated in a 3D seismic survey in the Beaufort Sea in 1996. In this survey, bearded seals did not move beyond 250m away from an active seismic survey vessel.

With the mitigation measures proposed for this seismic survey, it is unlikely that bearded seals will be negatively affected. Specifically, the seismic survey will stop operating if a seal (or any other marine mammal) is found within the 500m marine mammal safety zone around the sound source.

6.8 Polar Bears (*Ursus maritimus*), *Nanuq*

Polar bears inhabit arctic ice sheets and coastal waters; they typically hunt seals, but also feed on a variety of opportunistic food sources. Polar bears have a circumpolar distribution and are present on land during the summer, but rely on ice flows during the remainder of the year to hunt seals. There are generally 19 recognized populations of Polar bears with a worldwide population of approximately 20 000 – 25 000[74]. Twelve[75] populations reside in Canadian waters with three populations near the seismic survey area: Baffin Bay, Lancaster Sound, and Davis Strait.

In Canada, polar bears are managed by provincial governments, territorial governments, and wildlife management boards (Stewart & Lockhart, 2005)[76]. The bears are hunted by Inuit and Cree for subsistence, as well as for commercial sport hunting. SARA and COSEWIC (2008) both list Polar Bears as a species of "Special Concern".

POLAR BEAR MIGRATION

Unlike other marine mammals, polar bears in different management units may have similar migratory patterns. Since polar bears spend time on land and are highly dependent on the ice floe, their migration from summering to wintering grounds are highly variable each year. One reason for this they are highly dependent on ice floe for travel and hunting.

There is some information on the migration of polar bears in Hudson Bay, with little information on polar bears in other management units. The focus on polar bears in Hudson Bay may be an indication of the increased attention to this management unit as the polar bears often venture into southern communities[77]. Trends in polar bears movements in the Baffin Bay, Parry Channel, and Davis Strait management units are discussed (please refer to Figure 20 for polar bear management units).

Read, C.J. and S.E. Stephansson. (1976). Distribution and Migration Routes of Marine Mammals in the Central Arctic Region. Fisheries and Marine Service. Technical Report No. 667. Environment Canada.

In the winter, hunters find polar bears in Prince Regent Strait, the waters to the northwest of Baffin Island. The polar bears aggregate here due to open water and lead-ice areas in this region. Areas containing open water and lead-ice are also present in Lancaster Sound and polar bears are hunted there in the winter.

Tayler, M. and J. Lee. (1995). Distribution and Abundance of Canadian Polar Bear Populations: A Management Perspective. *Arctic, 48(2):* 147-154.

This study identified polar bear movements by marking polar bears and noting areas where they were later seen again. This allowed for the delineation of polar bear populations by area, although no physical or genetic barriers to interaction between populations are identified. These delineations can be used for management purposes (Figure 20).

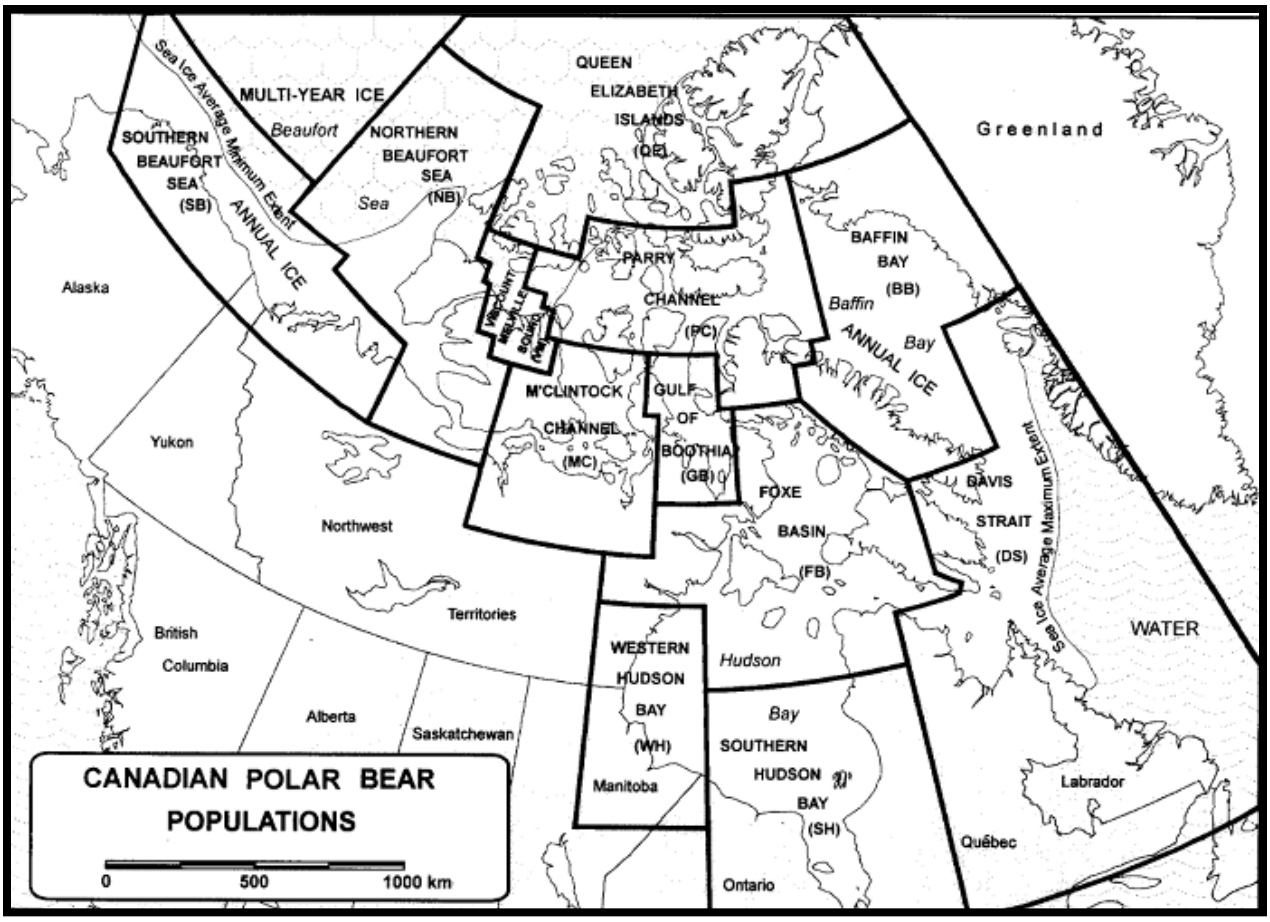

Figure 20: Polar bear management units in Canada

Taylor, M.K., Akeeagok, S., Andraishek, D., Barbour, W., Born, E.W., Calvert, W., Cluff, H.D., Ferguson, S. Laake, J., Rosing-Asvid, A., Stirling, I., and F. Messier. (2001). Delineating Canadian and Greenland polar bear (*Ursus maritimus*) populations by cluster analysis of movements. *Canadian Journal of Zoology, 79*: 690-709.

Baffin Bay and Davis Strait are covered with pack ice from December to July, which polar bears can use for hunting. In the late summer and fall (August-November) polar bears move on shore; however, in Baffin Bay the sea ice tends to come earlier and last longer than in Davis Strait, suggesting that the bears may be able to stay at sea for a longer period of time and spend less time on land. Polar bears in Baffin Bay and Davis Strait spend the open water seasons (August – November) on Baffin Island, Bylot Island, and the northern Labrador coast. The two populations (Baffin Bay and Davis Strait) could interact but tend to remain separate populations. This is likely due to the disappearance of consolidated pack ice from the central Baffin Bay during spring and summer, forcing bears to either eastern Baffin Island or the Melville Bay area.

In Lancaster Sound, polar bears are abundant during the ice-cover season in Lancaster Sound there is always ice along the coast and in inlets and bays that is heavily used by polar bears for movement and feeding. Prince Regent Inlet has a high density of polar bears during the spring.

Polar bears also use the pack ice in Lancaster Sound, on the side closer to Baffin Bay during the spring and early summer.

POLAR BEAR BEHAVIOUR DURING SUMMER MONTHS

Polar bears rely on the sea ice for movement and hunting, therefore, when sea ice is sparse or disappears in the late summer and early fall, polar bears move on shore.

Stirling, I., & Parkinson, C. L. (2006). Possible effects of climate warming on selected populations of polar bears (Ursus maritimus) in the Canadian Arctic. Arctic, 261-275.

Observed numbers of polar bears on land during the open water season are increasing. This is likely due to climate change and earlier break-up of sea ice, resulting in polar bears retreating to land earlier. Moving on shore earlier means that polar bears are starving from a shortage of food and may be entering into human communities in search of alternative food sources.

POLAR BEAR AND SEISMIC SURVEYS

There are no reports specifically addressing how polar bears respond to marine seismic activity. Environment Canada did not identify marine seismic surveys as a threat to polar bears[78]. This is likely due to the fact that polar bears are not solely marine animals and can escape the sound created by seismic activity if they wish.

Airgun effects on polar bears have not been studied; however, polar bears on ice floes would be less affected by sound from seismic surveys.

The received sound level produced by the seismic source will be less than other marine mammals, as polar bears generally remain at the surface or within a few metres of the surface[79]. The sound source will be within 6-10 metres of the surface with the sound being directed to the bottom of the ocean.

DISCUSSION

Polar bears move onto the land when sea ice melts in the late summer and fall. Therefore, it is unlikely[80] that seismic surveys conducted offshore during the late summer and fall will affect polar bears as they will be either on land or on the ice near the shore at this time.

6.9 Summary

Table 6: Summary of potential effects of the proposed seismic survey to narwhal, beluga, and bowhead whales, ringed and bearded seals, walrus and polar bears

Population	Summer Distribution	Winter Distribution	Migration	Potential interaction with seismic survey
Narwhal				
Somerset Island	Gulf of Boothia	Offshore Baffin Bay (north)	Leave summer grounds in early October, arriving in early November	Possible interaction. Migration route likely to overlap with survey area. Overwintering area is in the survey area.
Admiralty Inlet	Admiralty Inlet	Offshore Baffin Bay (south)	Travel south along Baffin Island in mid-September, then east to Baffin Bay near Broughton Island arriving mid-October	Possible interaction. Overwintering area is in the survey area.
Eclipse Sound	Bylot Island	Offshore Baffin Bay (south)	Travel south along Baffin Island in late September, then east to Baffin Bay at Broughton Island arriving around mid-October	Possible interaction. Overwintering area is in the survey area.
East Baffin Bay	Coastal region between Clyde River to Qikiqtarjuaq	Offshore Baffin Bay (south)	No information is available. It is assumed they follow Admiralty Inlet and Eclipse Sound narwhal migrations	Possible interaction. Overwintering area is in the survey area
Parry Channel, Jones Sound and Smith Sound	Parry Channel, Jones Sound and Smith Sound	North Water	*no tagging studies completed. Presumably direct migration to the North Water	No interaction. Summer and winter areas are not in survey area
Beluga				
Canadian High Arctic	Lancaster Sound, Gulf of Boothia, Beaufort Sea	North Water and/or West Greenland	Northern migration to the North Water, or continued on to the coast of west Greenland	No interaction. Summer and winter habitats are not in survey area. Based on satellite tagging, migration path is north of the survey area.
Cumberland Sound	Cumberland Sound	Cumberland Sound	No migration. Beluga whales remain in Cumberland Sound	No interaction. Summer and winter habitats are not in survey area. Beluga remain in

Population	Summer Distribution	Winter Distribution	Migration	Potential interaction with seismic survey
			all year round.	Cumberland Sound
Western-Northern-Southern Hudson Bay	Hudson Bay	Hudson Strait	Beluga whales have travelled as far north as Iqaluit. Since they overwinter in Hudson Strait, it is unlikely that belugas travel offshore into Baffin Bay into late fall.	Limited to no interaction. The migration route taken by the belugas from Hudson Bay to Frobisher Bay (Iqaluit) is unknown.
Bowhead				
Western Canada-Eastern Greenland	Widely distributed in the inshore waters around Baffin Island.	West Greenland; Cumberland Sound; Hudson Strait	Bowhead whales in the High Arctic either move south along Baffin Island toward Cumberland Sound or cross northern Baffin Bay to Upernavik, Greenland. As fall approaches, all other bowhead whales migrate south along Baffin Island and overwinter at the floe edge in Davis Strait	Possible interaction during fall migration which may begin in the mid-September. Generally, bowhead whales displayed mild behavioural changes within 8.2km of a seismic survey. There were also instances of no response within 3km of a seismic survey.
Walrus				
Northern Hudson Bay- Hudson Strait-Southeastern Baffin Island-Northern Labrador	Along the coast of Eastern Baffin Island, south of Clyde Inlet and in the Hudson Strait	Along the coast of Eastern Baffin Island, south of Clyde Inlet and in the Hudson Strait	Walrus have been recorded travelling between Canada and Greenland during the summer. This is a suspected migration corridor off Qikiqtarjuaq.	Possible interaction. Walrus have been recorded travelling between Canada and Greenland during the summer. This is a suspected migration corridor off Qikiqtarjuaq.
High Arctic	High Arctic	North Water and West Greenland, south to Disko Island.		No interaction. Summering and overwintering areas are not in study area.
Bearded Seal				
One population. Ranges from the High Arctic south along Baffin Island	High Arctic, south along Baffin Island in the fjords and bays	High Arctic, south along Baffin Island in the fjords and bays	Not known	It is likely that bearded seals may occur in the survey area. However, bearded seals do not exhibit behavioural changes beyond 250m from the sound source.

Population	Summer Distribution	Winter Distribution	Migration	Potential interaction with seismic survey
				Therefore, the mitigation measures should prohibit potential effects
Ringed Seal				
Circumpolar. Found in Baffin Bay, south to Labrador, Northern Newfoundland and the northeast Gulf of Saint Lawrence	North Water, along coastlines where ice is available, or offshore	North Water, coastal areas	In the summer months, when the ice in Baffin Bay breaks up and melts, some ringed seals move towards the coast, while other seals remain in the remnants of ice in the North Water	It is likely that ringed seals may occur in the survey area. However, bearded seals do not exhibit behavioural changes beyond 250m from the sound source. Therefore, the mitigation measures should prohibit potential effects
Polar Bear				
Circumpolar. Three populations are near the survey area: Parry Channel, Baffin Bay and Davis Strait	Primarily on land. May be present in the waters of Baffin Bay, Davis Strait and the North Water	Mainly on the ice in Baffin Bay, Parry Channel, and Davis Strait	No district migration route.	Limited interaction. Polar bears will be most likely close to shore or on land.

7 Arctic Fisheries Alliance Information Requests

Presentation Questions in response to mitigation measures in section 5.2:

- *The seismic activity will not take place near any harvest area*
- *The Community Liaison Officer will maintain communication with the company to provide updates to the Hamlet Council, HTAs and the community.*
- *A Fisheries Liaison Officer will maintain communication with all fishing vessels near the vicinity of the seismic survey*
- *The seismic vessel will avoid all active fixed gear fishing area*

Arctic Fisheries Alliance Questions

1. *The seismic activity will not take place near any native harvest area*

AFA requests that the phrase 'near any native harvest area' be clarified:

- *How will these native harvest areas be identified?*

Section 5.2 (7) the location of the seismic activity associated with this project will not take place in the vicinity of any native harvest area. Native Harvest areas are identified by those being within the Inuit Settlement Zone.

All proposed program activities will occur seaward of Canada's 12 nautical mile boundary, to the east of the land-fast ice limit. No Geophysical data will be recorded within the Land Fast Ice Zone. Information related to commercial fishing is provided in Section 5.2 of the Environmental Assessment.

- *What will the defined minimum safe distance be?*

MKI will define the minimum safe distance ~ 12 km buffer (for seismic vessel turning radius) from the land-fast ice and territorial sea boundaries, to the western end of the seismic lines.

- *A Fisheries Liaison Officer will maintain communication with all fishing vessels near the vicinity of the seismic survey*
- *The statement 'near the vicinity' lacks a specific definition. AFA suggests this be better defined*

Fishers have noted that good communications, exchange of plans and gear locations, understanding of fishing practices and co-operation at sea are the keys to addressing this issue. MKI will establish advance communications with representatives of any fisheries and DFO survey teams that may be present in the survey area. Open lines of communication between the commercial fishery and the proposed seismic survey program should prevent potential adverse effects. Prior to the commencement of the program a "Notice to Mariners" is issued by the Survey Vessel and the Fisheries Liaison Officer initiates and maintains radio communications between fishing vessels throughout the project. There is not specific distance.

- AFA insists that this measure be expanded to include wording to the effect: "*The Fisheries Liaison Officer will send a daily email to the four turbot quota holders of daily vessel location and planned tracks*"

MKI will send daily email to Arctic Fisheries Alliance contact and Baffin Fisheries Coalition. MKI will also have a community contact in each community that will be notified every 12 hours of vessel position. Acquisition Plan and scheduling of acquisition lines will be shared with AFA and BFC prior to commencement of the survey. The proponent, AFA and BFC can exchange each other's location and season's planning.

2. *The seismic vessel will avoid all active fixed gear fishing areas*

- *At what distance will the seismic vessel circumvent active fixed fishing gear?*

Potential impacts on fishing gear will be mitigated by avoiding active fixed gear fishing areas during the survey. If gear is deployed in a survey area, the diligence of the Fisheries Liaison Officer (FLO), good at-sea communications and mapping of current fishing locations have usually proven effective at preventing such conflicts. Thus for, Seismic vessels avoid fixed gear as to protect both the fishing and seismic equipment.

- AFA insists that the minimum safe distance (MSD) between the seismic vessel, its towed array and the fishing gear be established and noted in the mitigation measures.
- To ensure the MSD, the Fisheries Liaison Officer should communicate fixed fishing gear areas with the seismic vessel.
- If catch rates are determined to have reduced as a result of the testing, how will we (*AFA)* be compensated?

MKI will meet with AFA representatives to coordinate activities to mitigate potential concerns and so no lost fishing time occurs.

In case of accidental damage to fishing gear, the operator will have available a gear damage compensation contingency plan to provide appropriate and timely compensation to any affected fisheries participants. The Notices to Shipping filed by the vessel will also inform fishers that they may contact the SPOC, if they believe that they have sustained survey-related gear damage. The Operator is familiar with the C-NLOPB / CNSOPB Compensation Guidelines Respecting Damages Related to Offshore Petroleum Activity (C-NLOPB / CNSOPB, 2002), and with programs developed jointly by the fisheries industry and offshore petroleum operators (e.g. by the Canadian Association of Petroleum Producers and other Operators) as alternatives to claims through the courts, to address all aspects of compensation for attributable gear damage. These programs include provisions for paying compensation for lost or damaged gear, and any additional financial loss that is demonstrated to be associated with the incident. The programs include mechanisms for claim payments and dispute resolution. The operator will implement similar procedures to settle claims promptly for any gear damage that may be caused by survey operations, including the replacement costs for lost or damaged gear, and any additional financial loss that is demonstrated to be associated with the damage, as recommended under the C-NLOPB Guidelines. The operator will provide the NEB with the details of any compensation to be paid.

[9] It has been suggested that southern (non-Arctic) whales are used to noise in the ocean due to the increased use (commercial and non-commercial) of southern oceans. This may have increased southern whales abilities to tolerate man-made noise, such as seismic surveys and therefore respond differently.

[25] FAO has recorded Greenland hunting multiple dolphin species
[26] One concern is that the seismic survey would change whale's migration routes. If this were to occur, then fewer whales would be present at their summering or wintering grounds where they are either hunted or eat to restore fat lost in the previous season. If whales are prevented from eating, there is a chance that they may not survive. Therefore, Inuit would have less animals to harvest the following season.

[54] This may be part of the Foxe Basin and Hudson Bay bowhead whale population
[55] The report indicated that the bowhead whale sightings are to some extent due to observer effort. Most observations are within the marine-use zones of the communities.
[56] Highly suitable habitat is areas predicted to be used by bowheads more often than expected by chance, relative to habitat available in the environment.
[57] Only six tagged whales transmitted information into the winter months, therefore it was difficult to obtain accurate movement rates for bowhead whales in the winter
58 The authors do not state when the tags stopped transmitting information, however analysis on six whales was completed for the winter.
59 Commonly, zooplankton, copepods and eupausiids congregate at the ice edge. These species are an important part in the bowhead whale diet. Furthermore, ice packs provide bowhead whales protection from killer whales. Bowhead whales use sea ice to avoid killer whales and it is thought that killer whales avoid areas of heavy sea ice due to their large dorsal fin.
[60] Migration path assumes a general summering ground in the High Arctic around Lancaster Sound

Supplementary Report III

Follow-Up to the National Energy Board Letter dated
May 31, 2013

Information provided in response to

IQALUIT

TGS-NOPEC Geophysical Company ASA, Petroleum Geo-Services and Multi Klient Invest AS (TGS/PGS/MKI) Northeastern Canada 2D Seismic Exploration Survey.

August 22, 2013

Iqaluit Questions

The following questions were asked during the National Energy Board's (NEB) meeting in Iqaluit, Nunavut on May 2, 2013. Each question and response is referenced to the report provided by the NEB, 'Public Review of the TGS-NOPEC Geophysical ASA (TGS), Petroleum Geo-Services (PGS) and Multi Klient Invest AS (MKI) Northeastern Canada 2D Seismic Survey Application, Volume 4'. Some original responses have been edited to ensure clarity. Verbatim responses can be found on the NEB website (www.neb.com)

Line numbers are referenced in brackets (Line xxxx).

To understand the context of each question, please refer to the Transcript Report for Iqaluit on the National Energy Board website.

A list of acronyms used in this report can be found in Appendix A.

1. ***Q: I am curious to know how -- from my understanding is it's outside of the Nunavut settlement area that this is occurring, but how are you coordinating with the Nunavut Impact Review Board or how are they integrated into this process at all? (Line 2005)***

Response:

The National Energy Board has the responsibility to deal with issues offshore outside the 12 nautical mile zone. The Nunavut Impact Review Board has the responsibility within the 12 nautical mile zone. The Nunavut Impact Review Board referred this to the National Energy Board because it is within the jurisdiction of their responsibility.

2. ***Q: So in your presentation at one point you said that the NEB will be making a recommendation. So who is that recommendation going to? (Line 2007)***

Response:

It is delegated to me (D. Hamilton, NEB Member) as a board member to review the application and provide a recommendation to the full board. The full board then makes a decision based on my report, and the recommendations, whether to grant or deny the application. Therefore, it is the full board that makes the final decision.

3. ***Q: My question is how are those effects going to be monitored or is there going to be any other third-party responsible for ensuring that -- you know -- fish aren't disturbed***

or traditional harvesting areas aren't being altered by the seismic process? (Line 2009)

Response:

For commercial fishing, there is a Fisheries Liaison Officer on the vessel whose duty it is to report back the operations to the fishing industry. There will also be a Marine Mammal Observer on board who has the authority to cease the operation until the whales have passed. There is a passive acoustic monitoring system on board as well, which ensures that once the seismic activity has stopped they can hear if the whales are still in the area. All of this information will go back to the communities.

4. ***Q: I guess my question also was trying to address not only the marine mammals that are impacted but other fish and invertebrates species as well. (Line 2013)***

Response:

The Fisheries Liaison Officer is the one who report on that. It is standard in the industry to ensure constant communication with the fishing industry to ensure it is not negatively impacted.

5. ***Q: Has there been studies to show what the -- you know, the migration patterns are at the time and would there be studies after the surveys to determine if there's been any negative impact, you know, by these surveys? (Line 2021)***

Response:

A lot of studies have gone on at the fisheries biology levels that look at individuals. There has been research on pelagic, benthic, ground fish and crustaceans. The results of which show no net negative impact on the biota. Your question is more about impact on collective populations. The industry standard is to stop the survey when a pelagic spawning aggregate passes through the area, not because of a proven long-term effect, but because of the perception of one. The long-term effects are much more complex, requiring an understanding of multiple complex factors.

6. ***Q: Should there be negative impacts, how and when would that be measured because this survey is supposed to be a five-year survey I believe initially? Is there going to be any attempt to measure the impact of these seismic surveys after each year or is there going to be -- something that's going to be done after the -- you know, at the end of the five-year period? (Line 2222)***

Response:
It is very difficult to measure the impacts on any marine population. The effects of seismic surveys, climate change, nutrient balances or water quality are all complex factors, and are interrelated. Trying to separate the effects of one factor is not possible.

7. ***Q: What happens if there is damage, okay, if it's determined that there's been damage to the -- you know, to maybe the marine ecology or maybe fish are not spawning properly or the marine life has altered its migration patterns? What sort of, I guess, guarantees are there, would there be bonds, would there be insurance or something like that to ensure that those who have been negatively impacted because this is an entire, really, I would say an entire nation could be affected by this? (Line 2223)***

Response:

Compensating for these changes is highly unlikely because it cannot be understood why there has been a given change. What is important, and is the point here, is to ensure a positive relationship between stakeholders. It is about working together to avoid problems, identifying conflicting activities and behaviors and avoiding them. These kinds of things are more important than the issue of potential compensation.

8. ***Q: Will there be a (fisheries biomass) study done before and after? (Line 2047)***

Response:

No, one is not planned at this time.

9. ***Q: Marine mammals, what does that mean? That's a very large term. (Line 2055)***

Response:

The Project proponent committed to providing information after the meetings.

Additional Response Information

Marine mammals are a diverse group of 128 species that rely on the ocean for their existence. The following marine mammal species have been identified in the Environmental Assessment as having the potential to be in the survey area at any point in the year: ringed seal, bearded seal, harp seal, harbour seal, hooded seal, Atlantic walrus, killer whale, beluga whale, narwhal, bowhead whale, harbour porpoise and polar bear (LaPierre et al., 2011).

LaPierre, Tony., Arnott, Alexandra., Hawkins, Chris., Simpson, Kent., & Davis, Darlene.(2011). Environmental Impact Assessment For Marine 2d Seismic Reflection Survey Baffin Bay And Davis Strait Offshore Eastern Canada By Multi Klient Invest As. RPS Energy. Report No. HOPH417(B)

10. ***Q: Okay, do you have an agreement with the Nunavut Impact Review Board for in the future oil and gas development? (Question asked to the National Energy Board) (Line 2062)***

Response:

NEB Response: Yes, the National Energy Board has a Memorandum of Understanding with the Nunavut Impact Review Board.

11. ***Q: This is a very interesting -- the Nunavut Impact Review Board is required to take into account Inuit -- how you might need to guide as part of their process. What process does NEB have to incorporate that? (Line 2064)***

Response:

NEB Response: There is no established process to do that. It is not required as part of the Environmental Impact Review but companies submit it as part of the application.

12. ***Q: I want to know from the company if it will affect walrus migration routes. (Line 2070)***

Response:

The Project proponent committed to providing information after the meetings.

Additional Response Information:

Available reports indicate that walrus generally remain close to land with a few offshore areas in southern Baffin Bay (near Qikiqtarjuaq, Iqaluit and Kimmirut) where walrus congregate in the summer.

Behavioural evidence suggests that walrus preferentially spend the summer months close to land (as available ice is limited) where they can haul out and eat bivalves located on the ocean floor (Fisher and Stewart, 1997; Fay and Burns, 1988). This routinely occurs in coastal areas within 80 – 100 m of water (Fay and Burns, 1988).

Walrus have been recorded travelling between Canada (off Qikiqtarjuaq) and Greenland during the summer months (COSEWIC, 2006); however, it is not known if a few or many walrus make this journey nor at what time of year this journey takes place. It is suggested that the walrus congregation area off Qikiqtarjuaq identified by Inuit (NPC, 2009) may be the starting point for the walrus migration between Canada and Greenland.

Therefore, except for the few offshore areas where walrus congregate in the summer and a suspected migration route between Canada and Greenland, it is unlikely that walrus would come within close proximity to the proposed seismic survey.

For more information on walrus and the known effects of sound please refer to Section 6 in the 'Supplementary Report II'.

Nunavut Planning Commission (2009). State of Knowledge in Maps. Nunavut Planning Commission. 28p.

13. Q: Seals, bearded seal, ring seal, ugjuk, bearded seal are very important to Inuit. That is a fall migration time. What effect will this project have on them? (Line 2073)

Response:

The Project proponent committed to providing information after the meetings.

Additional Response Information:

Bearded seals are generally located in the fjords and bays around Baffin Island and Ellesmere Island, where shallow coastal waters offer a variety of food sources in the summer. Both scientific and Inuit observations indicate bearded seals are most likely to be located near the shore, but they sometimes venture into deeper water. There are no known summer migrations that occur in the deep waters of Baffin Bay or Davis Straight. In the Beaufort Sea, it was documented that a seismic survey did not affect bearded seals behaviour at a distance of 250 m or further (Harris *et al*., 2001).

In the summer, ringed seals can be located on the coasts of Baffin Island or offshore in northern Baffin Bay and the North Water. The majority of these seals remain close to pack ice in northern Baffin Bay, or along the coastline in more southern regions. It is unlikely that the proposed survey will interact with migrations of ringed seals. In the Beaufort Sea, a seismic survey did not affected ringed seals behaviour at a distance of 250 m or further (Harris *et al.,* 2001).

Marine Mammal Observers on board the seismic vessel and supply vessel will have the authority to shut down the source if a marine mammal (including seals) comes within the 500 m safety zone.

For more information on the known effects of sound on seals, whales, walrus and polar bears please refer to Sections 2 and 6 of the 'Supplementary Report II'

Sources

Harris, R.E., Miller, G.W., and W.J. Richardson. (2001). Seal responses to airgun sounds during summer seismic surveys in the Alaskan Beaufort Sea. *Marine Mammal Science, 17(4*): 795-812.

14. Q: Polar bears; there's a lot of information, both traditional knowledge, scientific. Traditional knowledge, I've learned from Pond Inlet that there are polar bears that live on icebergs and they hunt from them. What affects will you have on them? (Line 2076)

Response:

The project proponent committed to providing information after the meetings.

Additional Response Information:

Polar bears rely on sea ice for movement and hunting. In the summer months when ice recedes polar bears migrate onto the land. It has been observed that due to increased warming from climate change polar bears are moving on land earlier in the season (Stirling & Parkinson, 2006). Polar bears are not solely marine animals and can haul out on either land or ice.

The seismic activity in this project is proposed for the late summer and early fall in offshore locations. The operation will be staying far from the coastlines and avoiding ice whenever possible. There are currently no reports addressing specific effects of seismic activity on polar bears that say it is unlikely they will interact with the seismic activity.

For more information on polar bears please see Section 6 of the 'Supplementary Report II'.

Source

Stirling, I., & Parkinson, C. L. (2006). Possible effects of climate warming on selected populations of polar bears (*Ursus maritimus*) in the Canadian Arctic. *Arctic*, 261-275.

15. Q: It was already brought up but Inuit traditional harvesting, what is your understanding of it from each individual community, at this point? (Line 2078)

Response:

The relationship between Inuit communities in Qikiqtani and traditional resources is much stronger than almost anywhere else in the Americas and it is probably the last place where this close relationship is seen. One of the reasons why the proponent has done more community engagement than the bare minimum is because they want to understand and develop a relationship with the communities. The use of traditional foods as a staple is much higher than in any other area found in the region.

The project proponent understands the importance of traditional harvesting food sources to Inuit communities throughout Nunavut. The proponent is committed to protecting the environment and the wildlife that Inuit communities rely on. Thus, the proponent has implemented a number of mitigation measures to alleviate any potential negative impact *(Please refer to the Environmental Assessment for a complete list of the mitigation measures for the project).*

In addition, the proponent is conducting an IQ Study to ensure that local knowledge is integrated into the proposed project. The IQ Study will cover important aspects of Inuit culture and

knowledge including traditional harvesting activities, harvesting geographical areas and species of interest in each of the communities.

16. Q: You've done -- I would say from my understanding, the company and the seismic or the two different consultants, they visited approximately 12 to 14 times. What have you learned in that time? (Line 2079)

Background: The project proponent and associated representatives have visited the communities on five different occasions in the last two years to begin discussion about this proposed project. Through the course of the visits comments, questions and concerns from communities were documented and responses provided.

Response:

The proponent has done more community engagement than the minimum requirement because they want to understand and develop a positive relationship with the communities. The use of traditional foods as a staple is greater than in any other area found in the region. That said, the proponent is not interested in trying to cause problems. It is not interested in doing anything that will jeopardize food supplies and these conversations have taken place in the past.

There are a lot of factors that influence changes that are being seen in the North. These include other development projects (such as mining operations), the increased use by other nations of the Northwest Passage because of climate change, and increased shipping; all of which are having an impact. The message seems to be: No change is the only acceptable change. This project is not trying to be the source of all the change. The real question is: Who gets to make the decision? That is outside of the scope of this project. That is an issue that takes place at another table but it is an important issue.

17. Q: What sub-lethal effects will you monitor afterwards? (after MKI has finished the seismic survey) (Line 2098)

Response:

The project proponent committed to providing information after the meetings.

Additional Response Information:

The operator will follow the 'Statement of Canadian Practice on the Mitigation of Seismic Sound in the Marine Environment' developed by Fisheries and Oceans Canada (DFO, 2007).

Source DFO. (2010). Statement of Canadian Practice with respect to the Mitigation of Seismic Sound in the Marine Environment. *Department of Fisheries and Oceans.* http://www.dfo-mpo.gc.ca/oceans-habitat/oceans/im-gi/seismic-sismique/pdf/statement-enonce_e.pdf

18. Q: Will you take that (traditional knowledge) into account? (Line 2106)

Response:

Yes, that is part of these meetings, listening to the community.

19. Q: So will you put in a new project design based on what you've heard this week, to the National Energy Board to decide? (Line 2109)

Response:

Considerations are made based on these discussions, the feedback provided from communities and fisheries, and from there the schedule and the timing of certain survey lines can be adjusted.

20. Q: But Inuit won't know this before the NEB decides -- what you've incorporated? And how are you going to incorporate that? How can you properly incorporate that? The NEB has a deadline of Friday for comments before it decides. How can that be? (Line 2111)

Response:

The community engagement process is ongoing; the company will be communicating with and responding to the community before, during and after operations.

21. Q: Will the actual company be going back besides the community liaison officer? (Line 2120)

Response:

Yes, that is correct. A person will be identified that the community feels is the proper person to speak for the community as a liaison.

Additional Response Information:

The engagement team will be going back to the communities with responses to the questions that have been asked during the National Energy Board meetings, as well as to complete an IQ study.

22. Q: Your communication with the company and how you interact with them afterwards, will it be the company? (Line 2124)

Response:

The company will communicate with the community.

23. Q: How much are you going to invest in this project for the first year? (Line 2133)

Response:

That will come out in the benefits plan that will be submitted to AANDC in terms of how much money is going to put forward.

24. Q: Who are the actual bodies behind that that are investing in that? You said there were two: TGS and PGS. So there's nobody beyond that? (Line 2138)

Response:

That is correct; PGS and TGS are taking all the risk.

25. Q: That's the biggest concern right now is: How can Inuit benefit? (Line 2145)

Response:

The Project proponent committed to providing information after the meetings.

Additional Response Information:

The proponent is committed to building a positive working relationship with the communities of Baffin Island. MKI will be employing Inuit as observers during the project; a Fisheries Liaison Officer will also be employed for the project and a Community Liaison Officer to represent each community for the duration of the project.

26. Q: And the way I read it there was one part where they say they have data, what was it? Anyway -- yeah, but I think I was more curious -- one of the things I wanted to know is if they got historical data can't that be used already? (Line 2163)

Response:

One of the reasons it mentions historical data in here is that there is not a lot of geophysical data available. Also, you can try and use old data to identify where to look, but as a comparison it would be the equivalent of an old black and white television versus a new high definition television. It makes a big difference when trying to identify where the oil could potentially be.

27. Q: So what kind of understanding was done -- or what kind of process or understanding happened with NIRB so that they're completely separate processes and it's not involved at all? (Line 2181)

Response:

For reference, see the last paragraph on page 3. The company had forwarded the project description to the Nunavut Planning Commission saying the project was outside the boundaries of the north Baffin regional land use plan and no conformity review was planned. Therefore, they did not forward the project to the Nunavut Impact Review Board. If they had deemed there to be trans-boundary affects they we would have started a dialogue. It is their responsibility to do that, and in this case they did not deem it applicable.

28. Q: Sorry, so you're saying that it was -- it's up to the planning commission to determine whether a project has trans-boundary impacts or not, and only under that circumstance will they forward it to NIRB? (Line 2186)

Response:

I think that's correct. That's their responsibility under the NSA under all the agreements.

29. Q: Which is when Canadian Environmental Assessment Agency (CEAA) was in place? (Line 2188)

Response:

Yes, in 2011.

30. CEAA was no longer in place in 2011? (Line 2192)

Response:

Yes, in 2011 it was in place. In 2012, CEAA was no longer in place.

31. Q: Other than what you've provided tonight, is there any other written materials for review that actually permits, you know, enough information to actually provide a written response other than having to do independent research? (Line 2214)

Response:

In response to the meetings, an extension may be issued to ensure that information from the communities is received. The other information collected from the company is all on the website (www.neb.com).

Supplementary Report IV

Follow-Up to the National Energy Board Letter dated May 31, 2013

Information provided in response to

Qikiqtarjuaq

TGS-NOPEC Geophysical Company ASA, Petroleum Geo-Services and Multi Klient Invest AS (TGS/PGS/MKI) Northeastern Canada 2D Seismic Exploration Survey.

August 22, 2013

Qikiqtarjuaq Questions

The following questions were asked during the National Energy Board's meeting in Qikiqtarjuaq, Nunavut on May 1, 2013. Each question and response is referenced to the report provided by the NEB, 'Public Review of the TGS-NOPEC Geophysical ASA (TGS), Petroleum Geo-Services (PGS) and Multi Klient Invest AS (MKI) Northeastern Canada 2D Seismic Survey Application, Volume 3'. Some original responses have been edited to ensure clarity. Verbatim responses can be found on the NEB website (www.neb.com).

Line numbers are referenced in brackets (Line xxxx).

To understand the context of each question, please refer to the Transcript Report for Qikiqtarjuaq on the National Energy Board website.

A list of acronyms used in this report can be found in Appendix A.

1. ***Q: Can you explain how strong is that sound coming out of that cannon and give an example of something we know out of a cannon? (Line 1325)***

Response:

The project proponent committed to providing information after the meetings.

Additional Response Information:

Statement from MKI in the meeting: "*Yeah, we've been asked that in the other community meetings so we're going to put together -- Troy here is going to put together an example video giving some demonstrations of the sound and how loud it would be comparative to other things that people would be familiar with."*

MKI believes that audio representation would be more effective than a video to best represent "seismic sound". We propose to present a "representation" recording of the seismic source sound in future meetings while supplementing it with the other deliverables such acoustic modelling, sound comparison tables, etc. (See Appendix D & E – Supplementary Report II)

2. ***Q: Do you have any studies that have been done on marine mammals with this that could be brought to everybody's attention? (Line 1343)***

Response:

Yes, in the environmental assessment documents there are references for other studies done on marine mammals and there is also information on sound modelling.

Additional Response Information:

Further information is available in the Environmental Assessment (LaPierre *et al*., 2011) and in Sections 2, 4 and 5 of the 'Supplementary Report II'.

Source

LaPierre, Tony., Arnott, Alexandra., Hawkins, Chris., Simpson, Kent., & Davis, Darlene.(2011). Environmental Impact Assessment For Marine 2d Seismic Reflection Survey Baffin Bay And Davis Strait Offshore Eastern Canada By Multi Klient Invest As. RPS Energy. Report No. HOPH417(B)

3. Q: But has it (seismic survey) been done on the Greenland? (Line 1353)

Response:

Yes, TGS and PGS have both done seismic surveys on in Greenland.

4. Q: Have they had any environmental feedback on what they've done (seismic in Greenland)? (Line 1362)

Response:

The project proponent committed to providing information after the meetings.

Additional Response Information:

There are no available public reports on environmental feedbacks from seismic surveys conducted in Greenland. Shell provided information on the whales and seals observed during their 2012 seismic survey in the Environmental Assessment for their 2013 seismic survey (Shell, 2013). Bowhead, beluga and narwhal whales were not seen during the transit to the survey area or in the survey area.

This report is further discussed in Section 2 of the 'Supplementary Report II' report.

Source:

Shell. (2013). Shell Greenland A/S 2013 Site Survey in Baffin Bay Blocks 5 (Anu) and 8 (Napu). Preliminary Environmental Impact Assessment

5. Q: Can that (environmental feedback from Greenland) be made available? (Line 1364)

Response:

The project proponent committed to providing information after the meetings.

Additional Response Information:

A renewed interest in oil exploration in Greenland in the 2000s has led to extensive seismic survey activity on the Greenland side of Baffin Bay. No reports on the environmental impact have been made available. If these reports are made available the proponent will ensure the information is provided to the communities.

6. ***Q: If I understand correctly what you were saying, do you have information when they did the surveying – seismic surveying in the Beaufort Sea? Do you have any information on that? (Line 1389)***

Response:

The project proponent committed to providing information after the meetings.

Additional Response Information:

There have been a number of published reports on the interactions of seismic surveys with whales and seals in the Beaufort Sea. There are more reports from seismic surveys occurring in other oceans. Due to community requests, reports are only included if they occur in Baffin Bay/Davis Strait and similar environments (i.e. Arctic).

These reports are summarized in Section 2 of the 'Supplementary Report II'.

Table 1 shows the seismic surveys that have occurred in the Beaufort Sea since 2008. Reports and documents that provide information on seismic surveys before 2008 are included with other seismic surveys on the land. Information was not available on the specific details of marine seismic surveys in the Beaufort Sea prior to 2008.

Table 1: Seismic surveys in the Beaufort Sea since 2008

7. ***Q: To continue on the same direction here, can you explain what do you know that we don't know – all of us, what is the impact on marine mammals that you know that we don't know? Please explain. (Line 1400)***

Response:

The project proponent committed to providing information after the meetings.

Additional Response Information:

Possible effects of seismic surveying on marine mammals are dependent on a number of factors such as the age, sex, physical state of the animal, the presence of offspring, prior experience with seismic surveying and others (Weilgart, 2007).

Interactions between seismic surveys and marine mammals range from whales and seals being curious and approaching the seismic vessel to displaying avoidance behaviour. There have been no documented cases of mortality in marine mammals due to seismic surveys (DFO, 2004; Abgrall, Moulton & Richardson, 2008).

The project proponent is committed to protecting the environment. As such, mitigation measures have been prepared to minimize potential effects from the seismic survey on marine mammals. There will be two experienced Marine Mammal Observers (MMOs) and two Inuit Observers working to identify marine mammals within a 500 m safety zone. It is the responsibility of the MMO to shut down the seismic source if a marine mammal is spotted within the 500 m safety zone.

For more detailed information on the effects of seismic sound on marine mammals, please refer to Sections 2 and 6 of the 'Supplementary Report II'. The projects mitigation measures can be found in the Environmental Assessment (LaPierre et al., 2011).

LaPierre, Tony., Arnott, Alexandra., Hawkins, Chris., Simpson, Kent., & Davis, Darlene.(2011). Environmental Impact Assessment For Marine 2d Seismic Reflection Survey Baffin Bay And Davis Strait Offshore Eastern Canada By Multi Klient Invest As. RPS Energy. Report No. HOPH417(B)

8. Q: But are these surveys were done at the same extent that you have in mind? (Line 1405)

Response:

Yes, and, in fact, they were more intensive surveys because they were 3D surveys whereas these are 2D surveys.

9. Q: With the same kind of equipment? (Line 1407)

Response:

Recently, yes.

10. Q: Do you know anything on the migratory runs of these in this area that you have in mind? (Line 1410)

Response:

The environmental assessments are compiling that information.

Additional Response Information:

Please refer to Section 6 in the 'Supplementary Report II' for information on the migratory patterns and general information of narwhal, bowhead, beluga, walrus, ringed seals, bearded seals and polar bears. The Environmental Assessment contains additional information on these and other species (LaPierre et al., 2011).

LaPierre, Tony., Arnott, Alexandra., Hawkins, Chris., Simpson, Kent., & Davis, Darlene.(2011). Environmental Impact Assessment For Marine 2d Seismic Reflection Survey Baffin Bay And Davis Strait Offshore Eastern Canada By Multi Klient Invest As. RPS Energy. Report No. HOPH417(B)

11. Q: How long would they be in the waters during the seismic testing? How long would it take? (Line 1416)

Response:

The plan for 2013 would take approximately 2 months. The testing is planned for September and early October.

12. Q: And also you said you all start from Grise, is the – are you starting from Grise or are you starting from south? Are you going up or coming down? (Line 1437)

Response:

It would of course depend on how much ice there is, but there needs to be flexibility in the plan whether it would start in the South or North. Feedback from the communities would help to determine where to start. Part of these processes here helps to formulate that plan.

Additional Response Information:

The map below illustrates the proposed survey area over a five year period (Figure 1). The proposed survey area does not go as far north as Grise Fiord. However, if the proposed survey is approved then there are a number of factors that will influence the survey schedule, including: ice conditions, weather, fishing vessels, and local community input regarding harvesting practices and marine mammal migration. It should be noted that although the proponent has applied to NEB for a five year approval, the results of the first year will dictate whether or not the proponent returns the following year. The proponent expects to collect the data in three years, that may or may not be consecutive.

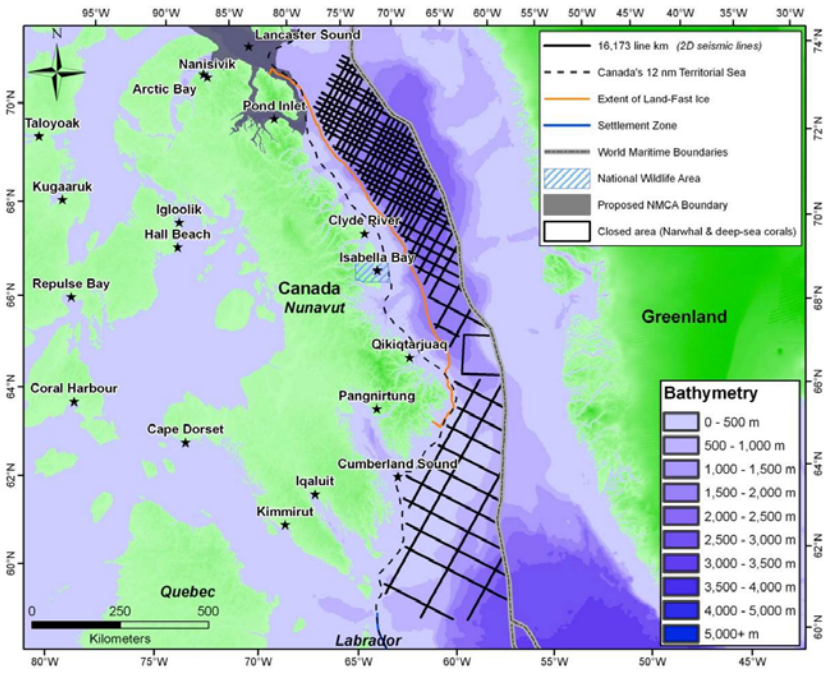

Figure 1: Proposed seismic survey project with survey lines over 5 years

13. Q: Okay. So let's say NEB approves your proposal and do the survey in September, October and for us if we notice a big difference on marine mammals in our area, who do we contact and tell them it's affecting our animals? Can that seismic survey stop? (Line 1439)

Response:

Contact should be made with the company via the Community Liaison Officer who is in direct contact with the vessel. Afterward, there would be a discussion about what exactly was the issue.

14. Q: Just to clarify, your graphic up here, your plan, should we understand that the line – the density of the lines is the density of the survey – of the seismic survey and there's less survey down south then north of Baffin? (Line 1444)

Response:

That map shows the entire five year plan. The map up here shows the density that would be started with.

15. Q: Oh, it's a five-year program, every year from September to October? (Line 1446)

Response:

The surveying months would change each year depending on the season and on the ice. The tentative three year schedule for acquisition would likely be mid-August to early October (up to 60 days).

16. Q: So should we understand that this is being done on five-year time? So everybody understand that this is for five years, they're going to be surveying and doing seismic sounding in the whole area for five years. Five years of mammal intrusion; is that the understanding? (Line 1448)

Response:

No, that is not it. The project will take five years to complete. The map shows the overall coverage; it will be done in stages.

Additional Response:

The results of year 1 will determine whether or not the proponent returns in future years. It should be noted that the program will take three years to collect and may not be collected in consecutive years.

17. Q: So every year – every year there'll be seismic- ? (Line 1450)

Response:

The density of coverage is not going to be the same every year, it will vary as the project progresses until the grid is gradually filled in.

Additional Response:

The results of year 1 will determine whether or not the proponent returns in future years. It should be noted that the program will take three years to collect and may not be collected in consecutive years.

18. Q: Okay fine. And you have no clue on marine mammal's life and migration routes on this area. You have no clue of that at this time or do you? (Line 1454)

Response:

That information is included in the Environmental Assessment document.

Additional Response Information:

Please refer to Section 6 of the 'Supplementary Report II' for information on the migratory patterns and general information of narwhal, bowhead, beluga, walrus, ringed seals, bearded seals and polar bears.

The Environmental Assessment contains additional information on these and other species (LaPierre *et al.*, 2011).

LaPierre, Tony., Arnott, Alexandra., Hawkins, Chris., Simpson, Kent., & Davis, Darlene.(2011). Environmental Impact Assessment For Marine 2d Seismic Reflection Survey Baffin Bay And Davis Strait Offshore Eastern Canada By Multi Klient Invest As. RPS Energy. Report No. HOPH417(B)

19. Q: And just to come back to Greenland, nobody was interested of seeing what Greenland had as reports on the environmental impact of those seismic testing in their country? Is there - like I'm saying, a study should be available from what they experienced. And nobody was interested of seeing what happened there? (Line 1460)

Response:

That information was collected in Greenland and was given to the regulatory authorities there.

20. Q: So – but you don't know? (Line 1464)

Response:
With regards to the information in Greenland, some of that information is public so you can look it up.

Additional Response Information:

Extensive research on reports relating to seismic surveys on the western coast of Greenland has been completed. There are no public reports[1] that assess the environmental impact of seismic activity in Greenland. If any such report becomes publically available, the project proponent is committed to providing it to the communities.

21. Q: But more specifically on environmental impact, do you have any information from Greenland on that you could share with us? (Line 1467)

Response:

The project proponent committed to providing information after the meetings.

Additional Response Information:

Extensive research on reports relating to seismic surveys on the western coast of Greenland has been completed. There are no public reports[2] that assess the environmental impact of seismic activity in Greenland. If any such report becomes publically available, the project proponent is committed to providing it to the communities.

22. Q: The airgun that you'll be using, according to that, there will be a difference within shallow and deep water – deeper water. Which one is louder, is it in the shallower or deeper water, or is the sound the same thing all the way? (Line 1477)

Response:

The sound does not change in shallower or deeper water. It may go longer distances, but the

[1] Shell's 2013 Environmental Assessment for a 2D seismic survey provided marine mammal sightings for their 2012 3D seismic survey in Baffin Bay. Please see Section 2 of the 'Supplementary Report II'.
[2] Shell's 2013 Environmental Assessment for a 2D seismic survey provided marine mammal sightings for their 2012 3D seismic survey in Baffin Bay. Please see Section 2 of the 'Supplementary Report II'.

actual sound from the source is the same.

23. ***Q: Even the sound – even if it's shallow, have you done any study how far it goes under the sea bed? Whether a shallow or deep, what study have you done that it will be the same before you reach the depth or the seabed? What's – how is it? If it's very deep and the seabed is very deep, how many metres is it and how many metres does it go down even if it's in shallow waters? (Line 1480)***

Response:
This is the reason why the seismic survey is being done. The goal is to map and see the substructures beneath the sea floor because companies don't know, and that's why these surveys are done. How the sound is reflected back up will depend on the geology underneath the sea floor, and so it will vary. That is the kind of data that has to be analyzed after the project. This kind of information can take up to a year to analyze.

Additional Response Information:

In marine surveys, seismic waves can penetrate up to 6000 metres below the seafloor (CAPP, 2005).

Source
CAPP (Canadian Association of Petroleum Producers. (2005) SEISMIC SURVEYS The search for Oil and Gas In Offshore Atlantic Canada. Retrieved From: www.capp.ca/getdoc.aspx?DocID=90917

24. ***Q: So if I go back to the map again, the density that is shown in the deep portion, 5,000 metres are closer to each another because it's deeper. Is that correct? No? (Line 1493)***

Response:

Those lines were determined by geologists because of certain formations in the geological substructure that may be an area of interest.

25. ***Q: So if you're deep or not deep, it's the same distance between the lines. That's what you are saying to me? (Line 1495)***

Response:

The distance can vary, depending on the geology. Some areas require more attention that others, and therefore a denser grid.

26. ***Q: So the distance of the lines is the interest of the area. Is that right? That means there's more – there's more seismic movement there in those areas? (Line 1498)***

Response:

It means there is more potential for investigation.

27. Q: So that means more sounding in those areas? (Line 1500)

Response:

If we do more lines, there will be more sound, yes.

28. Q: So more closer together, probably? (Line 1502)

Response:

The work will be done over time, in phases. Once a line in done it is not done again.

29. Q: In between let's say. You'll go in between the lines? (Line 1505)

Response:

Yes, in the next phase.

30. Q: And you have no idea on the migratory routes of these marine mammals? (Line 1508)

Response:

We have baselines through DFO and other studies, which have been factored into the EA. The other big component is gathering traditional knowledge through the communities, as there also exits information on that.

Additional Response Information:

Please refer to Section 6 of the 'Supplementary Report II' for information on the migratory patterns and general information of narwhal, bowhead, beluga, walrus, ringed seals, bearded seals and polar bears.

The Environmental Assessment contains additional information on these and other species (LaPierre *et al.*, 2011).

Source

LaPierre, Tony., Arnott, Alexandra., Hawkins, Chris., Simpson, Kent., & Davis, Darlene.(2011). Environmental Impact Assessment For Marine 2d Seismic Reflection Survey Baffin Bay And Davis Strait Offshore Eastern Canada By Multi Klient Invest As. RPS Energy. Report No. HOPH417(B)

31. Q: Are you aware that there's a box (protected area) around the Cape Dwyer? You'll definitely stay away from that? (Line 1514)

Response:

Yes, the proponent will not go into the protected area.

32. Q: How come you have not invited environmental people that have the knowledge on seismic sounding? And you are supposed to be the advocate and the protection of the environment. How come? Explain to us. (Line 1540)

This question was asked to representatives from the National Energy Board

Response:

NEB Response: "When a company, such as MKI, applies to do seismic testing they must file an Environmental Assessment, among other things. That EA requires the company to bring us the most recent information. Once we have reviewed it we hear from communities and then ask the company what they are doing to mitigate potential impacts. This is part of that process".

33. Q: So why are you (the project proponent) here today? (Line 1564)

Response:

NEB Response: "They (*MKI)* are part of the process of evaluation of their application to get a licence. The company is here today to answer questions from the community".

Additional Response:

It should be noted that MKI was originally invited to the meetings as observers, and they would only be required to answer operational questions. Had MKI be advised that they would be required to answer a broader range of questions they would have sent up additional resources.

34. Q: CLO, community liaison officer, fishery liaison officers, and marine mammal observers, how many of each are you employing and for how long? (Line 1576)

Response:

The project proponent committed to providing information after the meetings.

Additional Response Information:

For this proposed project there will be four Community Liaison Officers (one for each community), two experienced Marine Mammal Observers and two Inuit Observers and one Fisheries Liaison Officers for the duration of the program.

The MMOs and FLOs will be working five weeks on, five weeks off for the duration of the project (this is dependent on weather and ice). The Community Liaison Officer will be working to help build capacity within the communities, and to keep the community and proponent updated on the project.

35. Q: What is the safe distance that he (person) can go diving while you're doing your survey? (Line 1586)

36.

Response:

The surveying would be taking place far away from where people would be diving. The general distance from a seismic vessel is anywhere from 500 to 1500 metres.

Additional Response:
The International Association of Diving Contractors has worked with the International Association of Geophysical Contactors and has created a minimum guideline of between 500 and 1500 meters for divers to be near seismic activity.

37. Q: Because this is a five-year program, is it going to be 2D the whole time or will there be 3D seismic acquisition during that time? (Line 1591)

Response:

Only 2D surveys are to be conducted.

38. Q: So AFA requests that the phrase 'near any harvesting area' be clarified. How will this native harvest area be identified? What will the defined minimum safe distance be? At what distance will the seismic vessel circumvent active fishing gear? (Line 1601)

Response:

Most of the questions that you have in here and most of the practices that you would like to do in here are what we do elsewhere, so we do this in Labrador and Newfoundland with the FLOs on board the boat, the fishing liaison officers, the MMOs, and also through the process here.

And the way that we've laid out the survey lines as such is to do most of this avoidance and, you know, what I've seen here, I think the way our survey is laid out and with the communications that you wold like to do from the FLO to the other fishers that are out in the area, that's not an issue.

You know, we have—email reports can be done on a daily basis. That's routine for us to do and for the FLO to send those in to the communities. So we really—I don't see any issue in any of this.

And its standard practice for us, what you put in here. So that's part of our procedures that we use when conducting surveys.

We will be in discussions with the fisheries organizations and look at scheduling, to address how we will schedule the survey activities. The seismic operations does not want to get around any type of fixed fishing gear or any type of fishing vessels that might have gear out. Therefore, knowing where fishing activity is going to occur during what time period is a very important aspect of determining the schedule for the seismic activity.

Additional Response Information:

Section 5.2 (7) the location of the seismic activity associated with this project will not take place in the vicinity of any native harvest area. Native Harvest areas are identified by those being within the Inuit Settlement Zone.

All proposed program activities will occur seaward of Canada's 12 nautical mile boundary, to the east of the land-fast ice limit. No Geophysical data will be recorded within the Land Fast Ice Zone.

Information related to commercial fishing is provided in Section 5.2 of the Environmental Assessment.

MKI will define the minimum safe distance ~ 12 km buffer (for seismic vessel turning radius) from the land-fast ice and territorial sea boundaries, to the western end of the seismic lines.

Fishers have noted that good communications, exchange of plans and gear locations, understanding of fishing practices and co-operation at sea are the keys to addressing this issue. MKI will establish advance communications with representatives of any fisheries and DFO survey teams that may be present in the survey area. Open lines of communication between the commercial fishery and the proposed seismic survey program should prevent potential adverse effects. Prior to the commencement of the program a "Notice to Mariners" is issued by the Survey Vessel and the Fisheries Liaison Officer initiates and maintains radio communications between fishing vessels throughout the project. There is not specific distance.

39. Q: So we – actually we are asking for better clarification, so you just said that it's (fisheries concerns) not an issue. So what does this mean? (Line 1614)

Response:

The scheduling of the survey activities and the location means they should not conflict with any native harvesting. Also, the presence of the fisheries liaison officer will make it known if any fishing activates taking place near the area.

Additional Response:

The scheduling of the survey acquisition will not conflict with any native harvesting within the Land Fast Ice Area. Furthermore with the employment of the FLO onboard the seismic vessel this will ensure communication with the commercial fleet to avoid any other potential conflict. The presence of the FLO will make it known if any fishing activities are taking place.

40. Q: So I mean – what I mean – can we get feedback from you in writing according to what we said here? (Line 1621)

Response:

There are no issues with this kind of communication. Between the fisheries liaison officers and the community liaison officers there will be constant contact with the industry and the community to ensure that everyone knows what is being done and where. If there is activity going on in the area where the survey is taking place then changes can be made to accommodate that.

41. ***Q: If that happened, the catch rate is reduced, what kind of compensation you had put in place? (Line 1628)***

Response:

That would be looked into on a case-by-case basis. There would have to be considered where the vessel was in relation to the fishing, and the communications received from the community.

42. ***Q: Do you know if we would be able to receive the VMS data? (Question from proponent to AFA). (Line 1646)***

Response:

Yes, catch rates and daily data can be shown. A comparison can be made from last year, before the activity taking place, and this year, if it is happening.

43. ***Q: His question was – the way I understood him – if it's going to hurt the fishing industries for the four fishing companies, are they going to be compensated? (Line 1651)***

Response:

Trying to pinpoint the reason for a decline in a fishery is a complex subject that includes multiple and interrelated variables. It is almost impossible to lay blame in one place. In terms of compensation between industries, a lot of discussion and communication needs to happen in order to negotiate outcomes.

44. ***Q: How often would you do seismic testing in one evening? I mean, one day, how many seismic shots would you do within a day? (Line 1666)***

Response:

It would be an impulse every 15 to 20 seconds during the day while recording is being done on the survey line.

Additional Response

This may actually be as frequent as 10- 15 seconds.

45. ***Q: And what kind of feedback did you get from Pond and Clyde? How did they feel? (Line 1681)***

Response:

Every time I've gone to communities in the past, each community has asked what the other community thinks and the same response has always been given: the opinions of each community is respected, but it is not appropriate to say what others think. That may best be communicated between the communities themselves.

NEB Response: And I'm sure you can appreciate that we respect that so I will say the same thing. In this case, the comments of each community will be on the NEB's website but I think the principles of engagement are that each community's information is theirs and should be respected.

46. Q: Why don't we take it one year at a time, find out first? (Line 1690)

Response:

The project proponent committed to providing information after the meetings.

Additional Response Information:

The results of the first year will determine whether or not the proponent will return in subsequent years.

47.* Q: *If I was a diver here in Qikiqtarjuaq would I hear the sound of that cannon that is about, I would say, 200 km away? (Line 1692)

Response:

Other communities have also asked for models of how the sound dissipates with distance. This information can be provided. In the EA, there is a table of model distances over which the sound dissipates.

Additional Response Information:

The sound from the survey can travel for hundreds of kilometres; however, the sound dissipates as it travels further from the source. The International Association of Diving Contractors guidelines specify a safe operating distance of between 500 and 1500 m (1.5 km) near seismic activity. At a distance of 200 km it is unlikely that a diver could hear the seismic activity.

48. Q: So you can't tell me now if I'm going to hear it or not, if I'm underwater? (Line 1696)

Response:

The International Association of Diving Contractors has worked with the International Association of Geophysical Contractors and has created a minimum guideline of between 500 and 1500 metres for divers to be near seismic activity.

49. Q: So if there's activity in front of Clyde River, it should have no effect in this (Qikiqtarjuaq) area? (Line 1701)

Response:

No, not typically.

50. Q: Have you done a model of the channel here – that is here, at 3,000, 4,000 metres, in length like that and how would it react? (Line 1703)

Response:

Yes, that is part of the standard Environmental Assessments.

51. Q: With CEAA changing and you acknowledging that an environmental assessment is not required under CEAA, what is the process moving forward because this is an operation permit for one year? How about moving forward? So moving forward, how will the communities communicate with the NEB? (Line 1712)

Response:

The company has applied for a five year permit. The National Energy Board can approve it for the full five years, or for one year, subject to annual approvals. If the one year permit is awarded they are required to report back annually all matters to the community at the end of the year.

52. Q: How much timeframe do they have to report back to the community? Like what I have learned in the past, some organizations report back six months after what they did or some of them over a year. Do they have certain days to report back to the community? (Line 1727)

Response:

The permit would require them to report annually, so they would have one year between reports. The board could condition them to report on a more frequent basis.

53. Q: You mentioned that 1,500 metres for a diver, what effect would that have at 1,500 metres, lethal, sub-lethal? (Line 1731)

Response:

The project proponent committed to providing information after the meetings.

Additional Response Information:

The International Association of Diving Contractors has worked with the International Association of Geophysical Contractors and has created a minimum guideline of between 500 and 1500 metres for divers to be near seismic activity.

54.* Q: *What is the safety zone for those divers (Gulf Coast), and is there any hearing protection required or special hearing protection to mitigate? (Line 1733)

Response:

If there is diving going on in the area, you can contact the diving superintendent and they will give the minimum distances wanted for operations. Generally, that is between 500 and 1500 metres.

55.* Q: *Do you (TGS and PGS) have board members? Like your company, does it have board members? (Line 1738)

Response:

Yes, TGS and PGS are publically traded companies and with board members.

56.* Q: *Like if the hunters notice a big difference in marine mammals are you guys going to listen? (Line 1741)

Response:

The project proponent committed to providing information after the meetings.

Additional Response Information:

The project proponents are committed to building relationships with the communities. The proponent wants to ensure that the line of communication remains open between the community and themselves, and it is for this reason that the Community Liaison Officer position was created. The Community Liaison Officer will work in each individual community and report back to the proponent on any topics of interest, observations or questions the community may have.

57. Q: And are you going to listen to HTO, their concerns? (Line 1748)

Response:

The project proponent committed to providing information after the meetings.

Additional Response Information:

MKI sees the issues of the HTO as important. The project proponents are committed to building relationships with the communities. The proponent wants to ensure that the line of communication remains open between the community and themselves, and it is for this reason that the community liaison officer position was created. The Community Liaison Officer will work in each individual community and report back to the proponent on any topics of interest, observations or questions the community may have.

58. Q: What kind of plan do you have for the loss of food if it should happen? Do you have any kind of plan for compensation or – to replace what we lost? (Line 1763)

Response:

There is no set plan in place at the moment. The community liaison officers will ensure that if people are seeing changes that information will go into the project. The company is trying to figure out the best way to make sure there is no change in the food supply.

59. Q: Can you talk about how many times – you mentioned Labrador and Newfoundland a project that happened last year – how many times the MMO officer required a shutdown? (Line 1778)

Response:

The project proponent committed to providing information after the meetings.

Additional Response Information:

Environmental reports from Newfoundland and Labrador 2012 survey is attached as Appendix C

60. ***Q: How can you ensure that you get people with the right knowledge, the right training process – "constitution" and I mean that they have a lot of power to shut down the boat and have the construction to actually follow through with that? (Line 1782)***

Response:

Part of the training process is to be aware of the procedures that have to be adhered to.

61. ***Q: Any animals that die, like halibut and other animals, do you have plans to avoid killing type of animal? (Line 1790)***

Response:

There has been research around the world done on the effects of seismic surveys on marine wildlife. If an animal is exposed to super intense sound at some point an effect would be seen. That kind of high intensity and focused sound is not what will happen in these surveys. The purpose of this project is to gather geological data having as minimal impact as possible on the local wildlife. That is why so much research goes into this subject area.

62. ***Q: How is the company proposing to select the fisheries liaison officer for the project? How is the process of you – have you negotiated or are you working out to hire that individual? (Line 1811)***

Response:

Candidates that are proposed to us will be considered and then they will go through a selection process from there.

63. ***Q: Proposed (fisheries liaison officer candidates) by who? (Line 1814)***

Response:

By the community.

64. ***Q: So that means – so I had understanding that three communities will be select – will send their candidates when the boat is adjacent to the community? (Line 1817)***

Response:

Yes, there would be crew changes taking place at intervals during the survey and a candidate would be onboard the vessel.

65. Q: So correct me if I'm wrong; there will be – there will be four marine mammal observers; correct, three on the ship, the seismic ship, and one on the support ship? (Line 1823)

Response:

That is correct. There will be four Marine Mammal Observers, 2 on the seismic vessel and 2 on the support vessel.

Additional Response Information:

There will two experienced Marine Mammal Observers and two Inuit Observers employed for the duration of the project.

66. Q: And they will be rotated every five weeks? (Line 1825)

Response:

That is correct.

67. Q: There will be one Fishery Liaison Officer for the five weeks and then one for the second five weeks? (Line 1827)

Response:

Correct.

68. Q: And there'll be a Community Liaison Officer in each community as well? (Line 1829)

Response:

Yes.

69. Q: It's still not clear to me who would consult with to hire (Fisheries Liaison Officer). (Line 1834)

Response:

Communities will be invited to propose candidates.

70. Q: Can you clarify the MMO? Who is training the MMO? (Line 1839)

Response:

The project proponent committed to providing information after the meetings.

Additional Response Information:

The project proponent sponsored a MMO training class in Iqaluit at the Arctic College in 2011. The proponent will employ two Inuit Observers for this project.

71. Q: Oh. So it (training MMO's) hasn't started yet, naturally, no? (Line 1841)

Response:

A class at the Arctic College has been sponsored and has already trained people.

72. Q: And those (MMO training) companies are under contract, under you? (Line 1845)

Response:

No, they are not. The training was done through the Arctic College and the MMO training companies are not associated with the proponent.

73. Q: Okay compared to a sonar system, the seismic locator or the seismic sound, how does that compare to the – a typical boat sonar, for example? How strong is it or how much stronger is it or is it comparable? It's (sonar) not comparable? (Line 1850)

Response:

The project proponent committed to providing information after the meetings.

Additional Response Information:

Please see Appendix D & E for a discussion on sound and the terms used to describe sound: frequency and intensity.

Sonar and seismic are similar in a variety of ways, but there are significant differences, which justify individual consideration (Table 2). Both methods use a sound source to create energy waves in the water. When these waves encounter objects or materials they send back reflective waves, which are received and interpreted to understand characteristics of surrounding areas.

Table 2: Sonar vs seismic survey comparison

	Sonar	**Seismic Survey**
Sound Source	Electro-acoustic sound source	Air pressure pistons
Frequency	Low-frequency (<1000 Hz); mid-frequency (1-20 kHz); and high frequency (>20 kHz)	5-300 Hz
Directionality	Horizontal	Vertical
Sound intensity 1 m from sound source	Military usage (Low Frequency Array): 235 dB re 1 µPa	235-240 dB re 1 µPa
	Commercial/Personal usage (mid to high frequency): 150-235 dB re 1 µPa	

Source

Hildebrand, J. (n.d.) Impacts of Anthropogenic Sound on Cetaceans. *International Whaling Commission.*
BCMEM. (2003). Sonar Versus Seismic: What are the Differences? British Columbia Ministry of Energy and Mines.

74. Q: Has there been studies done on echolocation mammals like bull whales or narwhals or belugas with this type of seismic study? (Line 1859)

Response:

The project proponent committed to providing information after the meetings.

Additional Response Information:

Beluga and other toothed whales hear best at frequencies of 20-100 kHz (LGL Ltd., 2012). The hearing threshold of these species increase progressively (poor hearing) outside of this 20-100 kHz range. Belugas are capable of hearing seismic and vessel-generated sounds at lower frequencies, but these sounds are not within their best hearing range. Sounds need to be at or above hearing threshold to be readily detectable. Sounds must also be at or greater than ambient noise levels in order to be detected.

Beluga whales have been observed to change behaviour as far as 20 km from seismic activity (Miller *et al.*, 2008; Harris *et al.*, 2007). It has been estimated that beluga whales received sound level at 150 dB re 1µPa rms (LGL Ltd., 2012).

Belugas and narwhal generally summer in coastal areas, and their wintering grounds are not near the seismic survey area. It is unlikely they will come into contact with the seismic activity.

It is important to note that there will be a marine mammal observer on board the vessel at all times and will have the authority to halt operations if any marine mammal is spotted within the 500 m safety zone.

For more detailed information on the known effects of sound from seismic surveys on narwhal, bowhead, beluga, walrus, ringed seals, bearded seals and polar bears, please refer to Section 6 of the “Supplementary Report II”. The Environmental Assessment contains additional information on these and other species (LaPierre *et al*., 2011).

75. Q: But just to come back to my question, there has been no studies done with the seismic on these echo sounding animals? (Line 1864)

Response:

The short answer is yes and that is part of the environmental impact assessment. In the impact assessments, there is an assessment of the different species in the bay, their migration, the signs on impact of seismic on those species or comparable species and then an assessment of the risk.

And there were also some issues brought up in some of the previous meetings, I understand, and more information has been provided subsequent to that, to complete the picture as with respect to impacts.

So it's there and it's unfortunate that we didn't bring the marine biologists here today with us. We apologize for that and that is why we have a bit of a hard time giving you specific information on the impacts right now but I can assure you that it's part of the assessment that is also being looked at by the NEB now. And we've tried to address all concerns as best we can there and in subsequence communications.

76. Q: Can we give you our concern and ask you to come to the community to hear the concerns? (Line 1873)

Response:

The project proponent committed to providing information after the meetings.

Additional Response Information:

The project proponent is committed to ensuring effective communication is maintained with communities throughout this project. The proponent will be hiring community liaison officers in each community as a means of ensuring that both the community and proponent are updated on any project developments. The proponents want to continue a dialogue with the communities not only leading into the start of the project but during the project.

77. Q: If a community find a problem and if they want a vessel or the seismic study to be stopped right away and if we were to write a letter to you in regards to our concern and wanting the ship to be hauled or stopped from doing its study, would you be able to? (Line 1888)

Response:

Yes, any concern, complaint or anything brought to the proponent's attention would be addressed. It would be investigated and if it was serious enough, or put into risk the safety of the community or the environment, the project can be stopped.

78. Q: Do you have any idea of the counts of mammals and behaviors that are occurring in the Strait here? Is there any assessment done at the present time on that? Do we know how many bowhead whales? Do we know how many narwhals? Do we know

how many species and the counts on that that is occurring and their migration routes? Do we know anything of all that at the moment? (Line 1894)

Response:

The project proponent committed to providing information after the meetings.

Additional Response Information:

It is estimated that between 60, 000 – 80, 000 narwhal frequent the High Arctic, Baffin Bay and Davis Strait (Pierre, 2007). Due to historical commercial whaling, less than 450 bowheads remain in the Baffin Bay-Davis Strait population. The ranges, migration routes and other information on these marine mammals, and others, can be found in the Environmental Assessment (LaPierre *et al.*, 2011), however, some of the data sources are proprietary and cannot be revealed.

Please refer to Section 6 in the 'Supplementary Report II' for information on the migratory patterns and general information of narwhal, bowhead, beluga, walrus, ringed seals, bearded seals and polar bears. The Environmental Assessment contains additional information on these and other species (LaPierre *et al*., 2011).

NOAA. (2012). Bowhead Whale (Balaena mysticetus). Office of Protected Resources. Retrieved from: http://www.nmfs.noaa.gov/pr/species/mammals/cetaceans/bowheadwhale.htm#population

79. Q: The Fisheries and Ocean don't even know the belugas and the only time -- this is the only year that they're doing this study, first time. But you said you knew. Now, you don't know? (Line 1908)

Response:

The project proponent committed to providing information after the meetings.

Additional Response Information:

To clarify, this is an area of expanding research. DFO conducts research on population estimates, migration routes and behavioural patterns of marine mammals (along with fish, invertebrates and other marine life). The large distribution and abundance of marine mammals across Canada makes completing research on a yearly basis difficult. There is available information on the majority of marine mammals in Canada. However, some of the information may be several years old.

Through this project, Marine Mammal Observers will collect additional information on marine mammals seen in the study area. This information can be used in collaboration with Inuit knowledge and scientific knowledge to inform decisions on marine mammal management.

80. Q: How will this affect the narwhal? ... What's going to be the observation? Is it going to be a visual observation on the ocean of how many mammals are going around or is it going to be a sonar or you know, interpretation of what's in the water? What is the whole story here? (Line 1920)

Response:

The project proponent committed to providing information after the meetings.

Additional Response Information:

Available research indicates that narwhal remain in their summering grounds throughout the summer (July and August) to have babies and eat. Narwhal eat a variety of marine species during the summer while they remain in their summering grounds.

It is unlikely that narwhal will be in the survey area during July and August. At this time, narwhal are present along the coast of Baffin Island and in the many fjords and bays of Baffin Island and Ellesmere Island. It appears that narwhal begin their migration to their overwintering grounds beginning in September and continuing until October. Narwhal that undergo a longer migration (travelling south down Baffin Island) begin their migration earlier compared to narwhal that travel directly offshore to their overwintering grounds.

Based on available information, it appears that in Eclipse Sound, Admiralty Inlet and Somerset Island narwhal will enter the survey area beginning in October. However, this may change as narwhal are spending more time in the fjords and bays as the ice around Baffin Island has begun to freeze later in the year.

It is unlikely that the proposed seismic survey will interact with narwhal in August or September. Once narwhal migrations begin in September, based on satellite tracking, narwhal may enter the survey area in October. At this time, based on available information the 500 m marine mammal safety zone will help limit negative effects to narwhal. Due to the lack of available studies and/or reports, the change, if any, of narwhal behaviour to seismic sound is not known.

For more information on the effects of seismic surveying on narwhal and other marine mammals, please refer to Section 6 of the 'Supplementary Report II'. The Environmental Assessment contains additional information on these and other species (LaPierre *et al*., 2011).

81. Q: And maybe, you know, we could ask ourselves the question, why are -- maybe part of our plan is being screwed up in many ways and many species are being disturbed and, you know, it's maybe a lot of impact of a lot of things. But maybe this is part of an impact, you know? (Line 1928)

Response:

The project proponent committed to providing information after the meetings.

Additional Response Information:

The project proponent is very committed to protecting the environment. There are mitigation measures in place to limit the amount of impact the survey will have on the environment and wildlife.

Please refer to the Environmental Assessment for a description of mitigation measures for the project (LaPierre *et al.,* 2011). Community members can report any changes in marine mammal behaviour to the Community Liaison Officer. The Community Liaison Officer will maintain communication with the proponent throughout the project providing a direct link between the community and the company.

MKI has contracted NEXUS Coastal Resource Management to produce the attached "Interaction Assessment" which has been used to inform the "Acquisition Plan".

Supplementary Report V

Follow-Up to the National Energy Board Letter dated
May 31, 2013

Information provided in response to

Pond Inlet

TGS-NOPEC Geophysical Company ASA, Petroleum Geo-Services and Multi Klient Invest AS (TGS/PGS/MKI) Northeastern Canada 2D Seismic Exploration Survey.

August 22, 2013

Pond Inlet Questions

The following questions were asked during the National Energy Board's meetings (afternoon and evening) in Pond Inlet, Nunavut on April 29, 2013. Each question and response is referenced to the report provided by the NEB, 'Public Review of the TGS-NOPEC Geophysical ASA (TGS), Petroleum Geo-Services (PGS) and Multi Klient Invest AS (MKI) Northeastern Canada 2D Seismic Survey Application, Volume 1'. Some original responses have been edited to ensure clarity. Verbatim responses can be found on the NEB website (www.neb.com)

Line numbers are referenced in brackets (Line xxxx).

To understand the context of each question, please refer to the Transcript Report for Pond Inlet on the National Energy Board website.

A list of acronyms used in this report can be found in Appendix A.

1. ***Q: The wildlife in our area, if there were any damages or if they're dying off, where can we turn to ask people of Pond Inlet if there's any damages, if we were to see another strange things happening? (Line 96)***

Response:

The project proponent committed to providing information after the meetings.

Additional Response Information:

The project proponent is committed to protecting the environment. There are mitigation measures in place to limit the amount of impact the survey will have on the environment and wildlife. Please refer to the Environmental Assessment for a complete list of mitigation measures (LaPierre *et al*., 2011).

Community members can report observations to the Community Liaison Officer. The Community Liaison Officer will maintain communication with the proponent throughout the project serving as a direct link between the community and the company. Community members can also report observations directly to the Department of Fisheries and Oceans and/or the National Energy Board.

LaPierre, Tony., Arnott, Alexandra., Hawkins, Chris., Simpson, Kent., & Davis, Darlene.(2011). Environmental Impact Assessment For Marine 2d Seismic Reflection Survey Baffin Bay And Davis Strait Offshore Eastern Canada By Multi Klient Invest As. RPS Energy. Report No. HOPH417(B)

Q: ***Do you have any precautions that would least affect these areas where seabird nest? (Line 106)***

Response:

The Marine Mammal Observers are trained to look for seabirds as well, but all of the work is being done offshore, a long distance from any shoreline bird colony. Each community will have a Community Liaison Officer to who will communicate with the vessel in order to know what is going on when and where

2. Q: What contingency plans do you have to further protect the food? (Line 113)

Response:

In order to go to certain latitudes the vessel has to comply with Canadian Coast Guard regulations. It also goes through yearly inspections from Det Norske Veritas, one of the major inspection agencies. This means that it has to comply with international and Canadian requirements. There is also a pollution plan and insurance.

3. Q: What other things could you do if that were – if the cable were to snap? (Line 120)

Response:

The cable is equipped with 'retrievers' which are basically flotation devices that would bring the cable up to the surface if it snapped. A support vessel, in advance of the actual survey ship, is used to monitor for sea ice. Satellite imagery is used as well. Ice is avoided whenever possible to minimize potential risks.

4. Q: So if there was to be an oil spill, my question would be: How long about would it take to get it cleaned up in the bottom of the sea? Because we still can see the bottom of the sea, from that testing, it's still there and they pretended to clean it up with different types of chemicals and they're poisonous. (Line 150)

Response:

The project proponent committed to providing information after the meetings.

Additional Response Information:

There are a number of ways oil can occur in the marine environment. Oil can be naturally occurring in the environment (Elders have described seeing oil seeps in Scott Inlet), or from vessels, and oil production and extraction. This Project does not include oil production or extraction.

The project proponent has protocols in place to prevent and clean up environmental damage caused by a vessel. These protocols adhere to international standards and regulations. The *Arctic Shipping Pollution Prevention Act* and the Arctic Shipping Pollution Prevention Regulators develop the protocols for having a vessel in Arctic waters. The vessel will have contingency plans and safety management systems on board. Also, the vessel will avoid areas of ice, as the survey cannot be completed near ice. This will reduce the chance of collision with an iceberg or ice floe.

5. ***Q: First of all, the question I'd like to pose is that project that you want to do is in Arctic obviously, where the ice -- where there's ice. Have you ever experienced and worked on the same scenario in different world or other countries? (Line 173)***

Response:

Yes, we've worked extensively throughout Greenland, and the partners we have contracted here have also conducted work in Greenland, the Russian Arctic and off Norway. We have both recent and long term experience in the arctic region.

6. ***Q: If you can tell me relatively true, while you're doing this project which animal would have the most effect -- which negative effect have you noticed most on animals during your projects? (Line 178)***

Response:

The project proponent committed to providing information after the meetings.

Additional Response Information:

It is difficult to determine which animal species would potentially be the most affected by surveying activities. Responses to seismic activity by marine mammals are highly variable ranging from interest to avoidance. These responses can depend on a variety of factors including the age and sex of the animal, its physical state, the presence of offspring, prior experiences with seismic surveying and other environmental factors (Weilgart, 2007).

While there are no documented cases of marine mammal mortality due to seismic surveying (DFO, 2004; Abgrall, Moulton & Richardson, 2008), there are a wide range of behavioural responses to seismic sound, including startle, fright, avoidance and changes in physical behaviour and vocalization (Gordon *et al.,* 2003; Weilgart, 2007; McDonald *et al*., 1995). Marine Mammal Observers will be on board the survey vessel and can stop the survey if marine mammals enter the 500 m safety zone.

For more detailed information on the effects of sound on marine mammals, please refer to Sections 2 and 6 of 'Supplementary Report II'.

7. ***Q: I understand I will be getting an answer in the future, but when? (Line 186)***

Response:

The project proponent committed to providing information after the meetings.

Additional Response Information:

The answers to all the community questions are based on the best scientific and Inuit information accessible and will be provided back to each community as provided in this document. The answers will be provided to the National Energy Board and posted on their website.

8. ***Q: It seems there are documents stating there are reserves, many, many reserves. And not too long ago I had asked within the Legislative Assembly about the sea near Clyde River in the ocean, the ocean sea, and you stated you didn't know whether there were any reserves and further clarification after you're done dealing with this, then what? (Line 188)***

Response:

These seismic surveys are done to help map the sub-surface geology beneath the water. This information is used by the oil and gas companies to do the drilling. The seismic surveys are done first and the information collected is used by the oil and gas companies to assess whether this area has potential for them to come and drill for the oil and gas. The seismic survey allows for a more educated analysis and better decision making as to where to drill and where not to drill.

9. ***Q: After you're done with this project, you had stated that perhaps after four or five years -- I think it was five years -- the information you collect, who do you then sell -- who do you then sell this information -- who will you sell this information to, to oil companies? (Line 198)***

Response:

If oil and gas lease blocks are released offshore here, companies could potentially express interest to use the information to determine if they interested in working here. This is still in development and at this time it is undetermined who would potentially want to use the information.

10. ***Q: What -- from your study surveys (in Greenland, Russia, etc) did you find that you were not expecting? (Line 206)***

Response:

The biggest thing was weather changes as surveys could be taken later into the season than expected.

11. Q: First of all, my question is especially for the sea mammals or for whales. When you do -- when you do the seismic, how -- have you done studies to find out how much your seismic numbers affect the marine wildlife, like narwhal? (Line 217)

Response:

The project proponent committed to providing information after the meetings.

Additional Response Information:

Seismic surveying uses air pressure to create sound that is capable of penetrating under the seafloor (this does not harm the seafloor, no holes are created). The effects of sound produced from seismic surveys noise on marine mammals have been studied, and no documented cases of mortality have been recorded (DFO, 2004; Abgrall, Moulton & Richardson, 2008). Observations from past seismic surveys have demonstrated that marine mammals do demonstrate a wide range of behavioural responses including startle, fright, avoidance and changes in physical behaviour and vocalization (Gordon *et al*., 2003; Weilgart, 2007; McDonald *et al*., 1995).

There are few reports describing how long it takes marine mammals to return to the normal behaviour as displayed before the seismic survey began. One report indicated that whale behavioural patterns often resumed 24 hours after the seismic survey left the area (Mosbech *et al*., 2000). Another report documented that bowhead whales resumed normal behaviour one hour after the seismic survey stopped (Ljungblad *et al*., 1988).

Researchers have recommended guidelines for seismic surveys based on existing reports and studies on whale and seal responses to the sound levels received from seismic surveys. For exposure to multiple sound pulses (like seismic surveys), permanent threshold shift (loss of hearing, not recoverable) is assumed to occur if the sound exposure level is exceeded:

- Cetaceans (whales): approximately 198 dB re 1µPa²
- Pinnipeds (seals): approximately 186 dB re 1µPa²

DFO prepared the *Statement of Canadian Practice with Respect to the Mitigation of Seismic Sound in the Marine Environment* (DFO, 2010). The Statement of Canadian Practice formalizes and standardizes the mitigation measures in Canada with respect to the conduct of seismic surveys in the marine environment.

As stated in the Environmental Assessment for the project, the received sound level at 500 m from the sound source is 180 dB (LaPierre *et al*., 2011). Therefore, based on available information, whales and seals should not be permanently affected from the proposed seismic survey. However, changes in behaviour may be observed, and these are thought to be temporary based on previous reports and studies.

For more information on the effects of the sound on marine mammals refer to Sections 2 and 6 of the ‘Supplementary Report II’.

LaPierre, Tony., Arnott, Alexandra., Hawkins, Chris., Simpson, Kent., & Davis, Darlene.(2011). Environmental Impact Assessment For Marine 2d Seismic Reflection Survey Baffin Bay And Davis Strait Offshore Eastern Canada By Multi Klient Invest As. RPS Energy. Report No. HOPH417(B)

12. Q: When they know this information already, why do you need to do further studies in this area? (Line 225)

Response:

The seismic information is much higher quality and allows the companies to pin point exactly where to drill. Although they may already have previous information telling them there is oil in the area, this seismic survey would help prevent companies from having to drill exploratory wells to try and find exactly where the reserves are located.

13. Q: Mr. Speaker, I want to ask, the seismic testing, do they bring their poppers like seismic equipment? (Line 233)

Response:

The project proponent committed to providing information after the meetings.

Additional Response Information:

The seismic vessel will bring all necessary equipment to conduct the survey. The equipment will include a seismic survey vessel, a sound source, hydrophone cables (streamer), and a supply vessel.

14. Q: From there, for example, I will use as an example on asking about it, that this ship from there starts popping seismic activity, firing its seismometer, how long -- how far would the sound carry? (Line 236)

Response:

This information has been compiled and is available through the National Energy Board. Basically there is a 10-50 kilometre radius where the sound level is above the background noise in the ocean. This area is not lethal or necessarily harmful.

15. Q: Water -- sound travels differently through water than sound. How far away would the sound reach; would it reach Greenland? How many kilometres can the sound reach in water? (Line 237)

Response:

The project proponent committed to providing information after the meetings.

Additional Response Information:
Sound travels further in the water than in the air. Noise from other boats, and natural events, like earthquakes and rain[1] can be heard throughout the ocean. This constant background noise is present throughout the ocean.

The sound source will be pointed at the bottom of the ocean. However, there will be some sound that travels outwards from the sound source and sound will bounce off the ocean floor to be reflected back to the survey equipment.

The effect of the seismic survey in a distance, will contribute to this background noise, but only for a short period of time.

Appendix D & E

16. Q: Who has the authority to stop this? Maybe the NBA (sic), who holds the -- the authority to say 'yes' or 'no'? (Line 265)

Response:

The project proponent committed to providing information after the meetings.

Additional Response Information:

The proposed seismic survey is occurring in the offshore of Baffin Bay and Davis Strait, which is outside of the 12 nautical mile territorial sea boundary. As a result, the regulatory authority for this project is the National Energy Board (NEB). Based on a review of the proponent's application, the NEB has the authority to approve or decline the application. The communities will not have a vote for approval or rejection. However, the community does have the right to voice their concerns, have the right to be informed and provide input.

Nunavut is a territory, thus distributing much of the power to the federal government. That is what the UN Declaration of the Rights of Indigenous Peoples is all about. Often the communities look at the company as the other side. Building relationships with companies can strengthen the community's interest with external organizations and agencies.

[1] Rain can increase background noise in the ocean by up to 35dB across a range of frequencies from 100Hz to more than 20kHz. (Wilson *et al*., 1985 *in* Hildebrand, J. (2004) Impacts of Anthropogenic Sound on Cetaceans. *International Whaling Commission* 32p.

17. Q: Twenty-two (.22) short -- long rifles -- that air gun? (Line 280)

Response:

A comparison table will be provided to indicate how a .22 rifle sounds next to the sounds of the actual seismic source, that way a visual and numerical comparison can be made.

Additional Response Information:

MKI believes that audio representation would be more effective than a video to best represent "seismic sound". We propose to present a "representation" recording of the seismic source sound in future meetings while supplementing it with the other deliverables such acoustic modelling, sound comparison tables, etc. (Appendix D & E)

Q: Again, Troy, how long would that (sound modelling) take to happen as well? Is that a long project or something you could do within a fairly short time frame? (Line 284)

Response:

One or two weeks to ensure that the proper information is provided to the community.

18. Q: My first question perhaps: Baffin Bay, if you went into all the survey in Baffin Bay, where would you start? From the north or from the south and work your way up? What's the plan? Where would you start? (Line 307)

Response:

That is still undecided. First, the feedback from the communities is collected. Then the planning incorporates the local knowledge received and an actual route for the survey is decided upon based on all the information.

19. Q: Why do you want to do your survey during the fall? (Line 312)

Response:

In order to avoid ice and bad weather.

20. Q: If you would follow the exact routes, you'd have a very long distance to travel. I don't understand this 8 kilometre. When you do a project this big, you will travel 8 kilometres a day, however, would you finish your project in five years, at 8 kilometres per day? (Line 317)

Response:

The 8 kilometres is actually the length of cable the vessel tows. It is constantly moving and travels at a speed of 8 kilometres per hour.

21. Q: It would be possible to finish this project in five year at 5 kilometres per hour? (Line 322)

Response:

Yes, models show that with 5000 sail line kilometres to be surveyed it can be finished within a 60 day period.

22. Q: Which map are you – will you be using the two years ago original map or this one or that one? (Line 330)

Response:

The maps have changed because of input from the communities. The hope is to achieve in 2013 what is shown on the most recent map.

23. Q: This year alone, you'll be doing that and I heard – overheard five-year project? (Line 335)

Response:
Yes, the permission would be for a five year project.

24. Q: If you have the basic information with one year, first year, why more studies within the next five years once you have the basic information? (Line 337)

Response:

The idea is to do a coarse grid at first in order to get a base map of the area, and then to fill in the gaps to try and get a better resolution by surveying between previous survey lines.

25. Q: Can you give us more information, in more detail, with first, second, third, fourth and five year plan with your proposal? (Line 342)

Response:

Yes, a model of those survey lines can be made based on project goals and provide an estimate on the timing.

26. Q: You gave us, two year ago, I notice South Baffin had less line and, as of today, with the National Energy Board map, I see there's more lines than two years ago. Why is this? (Line 345)

Response:

The lines are actually a polygon representation of the grid. This is an area, and not survey lines. The previous information we provided shows the survey lines.

27. Q: Two years ago, the gentleman right here proposed this map to us to Hamlet Council and the National Energy Board map is this one and there's more lines with National Energy Board and two years ago there was less lines with South Baffin. Why am I seeing more lines today? (Line 348)

Response:

The lines are actually a polygon representation of the grid. This is an area, and not survey lines. The previous information we provided shows the survey lines.

28. Q: My question is, first question is once we finish this consultation, after you finish the community consultation, when would you (NEB) have to decide on this project or proposed project? (Line 361)

Response:

NEB Response: After the community consultations, all the information that the proponent has been committed to provide will be collected, considered and reviewed so that recommendations can be made. Then the full board will make a decision whether to approve, approve with conditions or deny the proposed project. The reviewed report will go to the board in mid-to-late May. The company would like to start work in July, so the final decision will be made public before that time.

29. Q: I have two questions; the people who are going to do a seismic study, have you included any person to go on your ship, traditional Inuit? (Line 390)

Response:

Yes, there will be local people from the communities on the vessels as observers and also people who will liaison from each of the communities so that you are able to keep in touch with the vessel and vice versa.

30. Q: Divided to a statements here, community liaison officer and marine mammal observer, community member of Pond Inlet, whether they will be getting an employee or will you get an employee from outside the community. I want clarification, thank you. (Line 406)

Response:

Yes, we would like to have an employee from inside the community. There has been training done at the university here to give people the background on Marine Mammal Observations and weather reporting.

31. Q: Is the marine mammal observer or the liaison officer notice a big attack, what kind of authority does that person will have? Will he able to stop the project? (Line 409)

Response:

Yes, if a marine mammal enters the mitigation zone the Marine Mammal Observer will have the right to stop the surveying.

32. ***Q: Here in Nunavut, they don't have a ship like Coast Guard ships. If you guys had an accident or the ship had hit a piece of ice, what mitigation emergency plans do you have for the nearest community? Would you wait for the Coast Guard at the nearest community or would the Coast Guard ship go with the St. John's oceans? Would you be dragged in to St. John's oceans? What would be the set-up? (Lines 411-413)***

Response:

PGS has mitigation measures that involve adhering and complying with everything required from a regulatory point of view. There is a support vessel that is important for mitigation and emergency measures. There is also an emergency response plan in place long before the surveying starts that contains all the contacts needed for issues from medical to mechanical.

33. Q: If you had an incident in Baffin Bay, do I just ignore your help call while I have my 60-foot boat? Do I just ignore your big ship if there was an incident? (Line 418-419)

Response:

That depends on the situation and the conditions. The hope would be for any possible help to come, and in the opposite situation, if something were to happen to a community member's boat the survey team would be happy to come and assist.

34. Q: My other question would be: As we all know, Arctic is a unique place in Canada and there's a lot of information, data within scientific area. How could these scientific data's be more accurate to us as a community member? (Line 424)

Response:

Any information that is not proprietary data will be shared. This includes information about marine mammals, fish, sea birds, sea state fishing activity, etc.

35. Q: How can Nunavut be part of National Energy Board Member? (Line 436)

Response:

Currently there are no members of the National Energy Board from Nunavut, however there are open positions for 'Temporary Board Member' and the information on where to apply for those positions can happily be provided.

36. Q: My question is the fisheries -- haven't you got any documentation from Fisheries Coalition? That's my first question. You got any comments from them? (Line 510)

Response:

There have been several meetings with the Baffin Fisheries Coalition in Iqaluit, Halifax and St. John's. Contact has been maintained with them at all stages of the community engagements about where and when they are fishing. That information has been passed on to the company.

37. Q: As you know, I have talked to you before and my second question is, there are -- is it okay if you guys do this type of study where there's lots of wildlife? (Line 513)

Response:

The timing of the study is done to have the least potential impact on wildlife migration and fishing activity. The Marine Mammal Observers on the vessel are there so that if marine mammals are observed they can shut down operations and wait for the mammals to pass through the mitigation zone.

38. Q: There's lots of oil and they will -- the oil companies will want the oil that you said you'll just do site testings, and you said you have to look for oil through seismic testing. Are you going to explain it properly and define it about -- define the seismic testing that we can understand, now, right now? (Line 518)

Response:

The project proponent committed to providing information after the meetings.

Additional Response Information:

Marine seismic surveys are conducted to determine geologic features below the seafloor. The seismic survey process includes the following steps:

1. A piston (sound source) generates a sound when it quickly releases compressed air into the water. The sound source is towed by the research vessel 6-10 metres (18-30 feet) below the surface of the water.
2. The sound generated by the source travels through the water as a sound wave to the seafloor. Some of the sound will bounce off different layers (types) of sediments and rocks and return back to surface of the water.
3. The sound that returns to the surface of the water is detected by hydrophones. Hydrophones will be towed by the vessel on a cable that is 6-12 kilometres (18,000- 36,000 feet) long. The cable is also called a streamer.
4. The information collected is analyzed using computer programs that can produce an image of the different rock layers beneath the seafloor.

39. Q: How can you understand this (referring to oil spill cleanup), that we need food too? (Line 522)

Response:

The project proponent committed to providing information after the meetings.

Additional Response Information:

The project proponent understands the importance of traditional food sources to communities throughout Nunavut. The proponent is committed to protecting the environment and the wildlife that Inuit rely on. Thus, the proponent has prepared mitigation measures to minimize potential negative impacts (please refer to the Environmental Assessment for the complete list of mitigation measures). In addition, the proponent is conducting an IQ Study to ensure that local knowledge is integrated into the proposed project. The proponent has committed to installation of Passive Acoustic Monitoring onboard the seismic vessel to listen for mammals.

Source

LaPierre, Tony., Arnott, Alexandra., Hawkins, Chris., Simpson, Kent., & Davis, Darlene.(2011). Environmental Impact Assessment For Marine 2d Seismic Reflection Survey Baffin Bay And Davis Strait Offshore Eastern Canada By Multi Klient Invest As. RPS Energy. Report No. HOPH417(B)

40. Q: How are you going to supply us with food if it had such a negative impact in our waters? How can you help us if you -- if there was a big impact to our wildlife? (Line 523)

Response:

The project proponent committed to providing information after the meetings.

Additional Response Information:

Food security in northern communities is a complex issue, which is affected by multiple factors, not all of which are fully understood. Even if the proposed project did not occur there are still a variety of issues, which could affect arctic food sources. The effects of increased shipping, fallout from atmospheric pollution, decreasing nutrient abundance, climate change effects or changes in water quality would all still occur. These changes could also affect the health or abundance of a species in a given year.

To address issues related to this project, the company will continue to have ongoing discussions with the communities. This will help identify community concerns and observations. There will be a Community Liaison Officer (CLO) in each community. The CLO will serve as a link between the community and project proponent throughout the duration of the proposed project. Any concerns or observations in a community can be brought forward to the CLO who will pass the information on to the project proponent.

Two experienced Marine Mammal Observers and two Inuit Observers will be employed onboard the vessels for the duration of the project, looking for marine mammals within the 500 m safety zone. If a marine mammal comes within the safety zone, the seismic source will shut down as per the Statement of Canadian Practice.

Fisheries Liaison Officer maintains daily communication with the fishing fleets in Baffin Bay and Davis Strait.

For more information on the known effects of sound from seismic surveys on marine mammals, please refer to section 2 in the ‘Supplementary Report II’. The complete list of mitigation measures for the project can be found in the Environmental Assessment (LaPierre *et al*., 2011).

Source

LaPierre, Tony., Arnott, Alexandra., Hawkins, Chris., Simpson, Kent., & Davis, Darlene.(2011). Environmental Impact Assessment For Marine 2d Seismic Reflection Survey Baffin Bay And Davis Strait Offshore Eastern Canada By Multi Klient Invest As. RPS Energy. Report No. HOPH417(B)

41. Q: That what I've heard before that in our waters -- between Clyde River and Pond Inlet, in our waters, in the low land areas, that there's a oil gushing all the time. You know about that; right? Or …? Do you know about that or are you going to look for more oil even though you know about that oil gushing out all the time? (Line 552-553)

Response:

Yes, we are aware of the oil seeps. The objective of the study is to determine the geology of the area, and to identify the exact location of the oil deposits. Although the oil may seep out in one location, the actual deposit may be some distance away due to sub-surface geology.

42. Q: When you first started from your first seismic testing and when we object to it you guys stopped. So you haven't done anything else or any testing with the vessel at all since the last time when we object to the testing? Are you going to go on or are you here to clarify everything, whether you're going to do the testing or not? (Line 562-563)

Response:

The testing has not started. Right now the proponent is seeking approval (from the NEB) to do the testing. To receive approval, the project has to be able to justify the effects it would have, and any mitigation measures which would be taken in the case approval was granted.

43. Q: Did you do any seismic testing last year? (Line 569)

Response:

This company has never done any testing in Baffin Bay.

44. Q: According to your comment and that they'll be an observer on the ship, how many miles are you going to do the air gun or shoot to the bottom of the sea? How many minutes or how often? (Line 573-574)

Response:

The seismic shots are done according to the vessel speed. Generally there is a pop done every 15-20 seconds.

Additional Response Information:

There are 16,173 km of survey lines that would be completed over five years. Whether or not the proponent returns in subsequent years will depend on the results of the first year. It should be noted this data will be collected in three years that may not be consecutive. The first year plan is to collect approximately 5000km of data.

45. Q: On one of the previous slides that had the more detailed lines, are those the actual routes that you're planning on testing? (Line 598)

Response:

Some of the maps we have put up have polygons on them which do not represent the survey lines, they are depicting an area. The map with the survey lines can be found in the discussion paper.

46. Q: And the boat that you're planning on using, that's not a boat you own; correct? That's a boat you rent? (Line 609)

Response:

The vessel is under a long term charter agreement to PGS and MKI. It is run by Sanco Shipping out of Norway.

47. Q: I'm wondering what year you rented the boat specific for this test? (Line 612)

Response:

It is not rented specifically for this test. It is a long term charter. The vessel has also worked off Newfoundland and Labrador, Brazil and West Africa.

48. Q: What is the planned approval date for this project? (Line 617)

Response:

I will be making a recommendation to the board in mid-May, and after that the board will make a decision. The work, if approved, is planned to start in July so the approval would come before.

49. Q: Just wondering from the environmental aspect, what studies have you investigated and what things have you taken into consideration from previous studies done? And amongst that, what changes have you made to your proposed testing as a result of those studies, any studies that you may have read or done. (Line 622-623)

Response:

The communities will be provided with studies on the known effects of sound on marine mammals, as well as, the sound generated by the whales themselves in order to give an idea of the comparison and how far sound travels, etc. All of this information is in previous studies, which will be forwarded to the communities.

50. Q: If this testing does go ahead and for some strange reason we happen to see whale beachings, what are your plans with that? (Line 631)

Response:

That is part of the rationale behind the mitigation zone (*500 m marine mammal safety zone)*, to avoid those kinds of circumstances. The relationship between the community and the company is very important. People can report in to try and find out what has caused it. In some cases there may be other causes, but keeping open lines of communication is what is important.

51. Q: And I'm just wondering like, what most people are saying is a lot of reluctance when it comes to this going ahead. I'm wondering if it's the same kind of feeling, same vibe you're getting from the members of all the other communities that you've been in? (Line 637)

Response:

That is a question asked in each community, and the goal is not to pit community against community. In each location there are people who are in favour of it and people who are concerned about it. In all cases there is a mix of opinions.

52. Q: As you were talking, when that you would stop the ship if there were any marine mammals coming up, what kind of a gun -- airgun do you have or dynamite would you use? (Line 647)

Response:

The source ray uses compressed air to create the sound. The elements have compressed air in them and a piston inside moves to release the air.

53. Q: Are they going to affect the crustacean on the seabed because they are the food for the other marine mammals? (Line 653)

Response:

The project proponent committed to providing information after the meetings.

Additional Response Information:

There are no known cases of invertebrate mortality due to exposure to seismic surveying in field conditions (DFO, 2004), however, in experimental conditions (less than 5 m) lethal and/or sub-lethal effects have been observed (LaPierre, 2011). Studies have been conducted on the effects of seismic sound on Snow Crab (DFOC, 2004; Christian *et al*., 2003) and Dungeness Crab (Pearson *et al*., 1994). The results of these studies have not shown any long term or serious pathological, physiological or behavioural effects. It is unlikely that crustaceans will be negatively affected by this project.

Pearson, W., J. Skalski, S. Sulkin, and C. Malme. 1994. Effects of seismic energy releases on the survival and development of zoeal larvae of Dungeness crab (*Cancer magister*). Marine Environmental Research 38:93-113.
LaPierre, Tony., Arnott, Alexandra., Hawkins, Chris., Simpson, Kent., & Davis, Darlene.(2011). Environmental Impact Assessment For Marine 2d Seismic Reflection Survey Baffin Bay And Davis Strait Offshore Eastern Canada By Multi Klient Invest As. RPS Energy. Report No. HOPH417(B)

54. Q: And you had a -- when the Whaling Committee was here, the study area that you want to do is calving ground for bowhead whales and other whales; are they going to be affected? (Line 654)

Response:

The project proponent committed to providing information after the meetings.

Additional Response Information:

It is unknown as to the exact calving locations of bowhead whales. Inuit have observed bowhead calves in Isabella Bay and north of Isabella Bay (NWMB, 2000). Calves are frequently seen in the Arctic Bay area (NWMB, 2000). Bowhead whales are thought to give birth during the summer months up until August (NWMB, 2000). Based on where the seismic survey activity will take place and where known bowhead calving areas are, it is unlikely that bowhead calving areas will be affected.

In order to limit the disturbance of the surveying on any marine mammal species there will be a Marine Mammal Observer on the vessel at all times who will have the authority to shut down the source if any marine mammals are spotted in the 500 m safety zone.

For more information the known effects of seismic surveying on whales and other marine mammals please refer to Section 2 of the 'Supplementary Report II'.

Source

Nunavut Wildlife Management Board. 2000. Final Report of the Inuit Bowhead Knowledge Study. Nunavut, Canada.

55. Q: In deeper waters, does the sound wave travel -- does it spread, the sound wave when you're doing testing? (Line 673)

Response:

The sound travels out in all directions, but it gets fainter the farther it moves away. Sound travels further in water than air, but the decibel levels (or level of sound intensity) are not the same. This is the kind of information will be passed onto the communities.

Additional Response Information:

Appendix D & E

56. Q: And who is going to monitor the ship activities? (Line 677)

Response:

The ship is monitored by the company from shore 24 hour, seven days a week. There is also the community liaison and shore representatives who can be brought into the community.

57. Q: Want to talk about a little bit of the ship: Where would the ship start discharging the -- discharge water going up to the site? (Line 681)

Response:

All the ballast water is contained onboard, as per regulations. Nothing is discharged. Dirty oil and other materials are stored onboard until they can be discharged at a port capable of handling those types of materials.

58. Q: Like there's always packs of ice, and even the little ices, can they bounce back the sound waves, like, bounce them back down? (Line 685)

Response:

Operationally ice is avoided as it can damage the equipment. Everything possible is done to avoid the ice. First, there is a support vessel that goes out in front. Also, all the latest satellite data is used. Local knowledge will also be used. Available tools and sources of information will be used to try and avoid ice.

Additional Response Information:

The seismic survey vessel will try to avoid all areas with ice present as it impedes the vessel's progress, presents the potential for damaged equipment and can lower data quality. In order to avoid the areas with ice present several methods are used. The support vessel scouts ahead of the survey vessel, satellite imagery is used and local knowledge from the communities will be sought. It is not always possible to avoid ice, as it often moves freely in the water.

59. Q: And can I -- I'd like to know more about passive acoustic monitoring or did we talk about that too? (Line 691)

Response:

There are two types of monitoring used for marine mammals that can be used during a seismic survey. The first is using Marine Mammal Observers to visually observe for marine mammals that surface at the top of the water. The second is the use of passive acoustic monitoring which uses a hydrophone to listen for whales communicating under the water. Even when the ship is not running the seismic source it is monitoring for whales by listening for them in the water.

60. Q: What if commercial quantities are not found, what then, what good the drilling would be if they even find the commercial quantities of oil and gas? (Line 696)

Response:

The project proponent committed to providing information after the meetings.

Additional Response Information:

The purpose of this survey is to locate areas where there are high probability of oil and gas.

There will be no exploratory drilling or extraction during this project. This project is to complete 2D Seismic Survey. Any future project would require proponents to apply for permits and complete the required tasks associated with the application.

Communities will have the opportunity to be involved in future projects occurring in Baffin Bay and Davis Strait.

61. Q: With the change in CEAA (Canadian Environmental Assessment Act), what opportunity will the communities have to express any kind of concerns with this project if it goes ahead beyond this hearing? What is the process moving forward in the future? (Line 702-703)

Response:

NEB Response: Now that the CEAA has been repealed for seismic activity a similar process will be continued where companies are asked to waive their confidentiality for environmental matters. Going forward all questions and concerns regarding environmental matters go on the public registry, as it would have under CEAA. In a way there is still a commitment to an EA whether there is a CEAA or not. There is a mandate under the *Canada Oil and Gas Operations Act* to ensure there is environmental protection for all projects authorized under the act.

62. Q: When you have an environmental assessment, you look at what the communities or whatever, the affected people what do they value the most. And I'd like to know from the environmental assessment what Pond Inlet values from -- you've mentioned that you've been to this community I think three or four times now. So I'd like to know what you've learned from Pond Inlet and how you've incorporated it into your environmental assessment because that's what they want to know. (Line 708-709)

Response:

The environmental assessment was performed by another consulting company. As for what people value, there are three main things that come up in community meetings; traditional food sources, the environment and the ability to have a say in the project. All of these things are being included in the design of this project.

63. Q: If all the wildlife moved away from this area, how are we going to have food? Because of the seismic testing, because they're not good for animals and we have the best nutrition food in the North. (Line 723)

Response:

The project proponent committed to providing information after the meetings.

Additional Response Information:

The project proponent understands the importance of traditional food sources to Inuit communities throughout Nunavut. The proponent is committed to protecting the environment

and the wildlife that Inuit communities rely on. Thus, the proponent has implemented a number of mitigation measures to alleviate any potential negative impact.

Food security in northern communities is a complex issue, which is affected by multiple factors, not all of which are fully understood. Even if the proposed project did not occur there are still a variety of issues, which could affect arctic food sources. The effects of increased shipping, fallout from atmospheric pollution, decreasing nutrient abundance, climate change effects or changes in water quality would all still occur. These changes could also affect the health or abundance of a species in a given year.

For more information on the effects of seismic surveying on marine mammals, please refer to Sections 2 and 6 of the 'Supplementary Report II'. Mitigation measures for the project can be found in the project's Environmental Assessment (LaPierre et al., 2011)

Source:

LaPierre, Tony., Arnott, Alexandra., Hawkins, Chris., Simpson, Kent., & Davis, Darlene.(2011). Environmental Impact Assessment For Marine 2d Seismic Reflection Survey Baffin Bay And Davis Strait Offshore Eastern Canada By Multi Klient Invest As. RPS Energy. Report No. HOPH417(B)

64. Q: In June -- and you said that you could change or you're going to start doing the testing in June? (Line 733)

Response:

The project proponent committed to providing information after the meetings.

Additional Response Information:

The proponent is unable to begin the survey until approval has been received from the National Energy Board. Upon approval the proponent will be coordinating the survey schedule with feedback from the communities, fisheries organizations and government. The survey will only be operating in the ice-free months, the acquisition plan provided is from mid-August to mid-September.

65. Q: Are you not going to have any study done beside a boat or a vessel (aerial survey)? (Line 738)

Response:

An aerial survey using a plane has been considered but the weather conditions in Nunavut can limit the ability to travel by plane, while still allowing for marine transit.

66. Q: The sea mammals -- polar bears, walrus, whales, seals, square flippers -- are you going to stop this testing just for these animals? And now, think about the sea ducks, sea birds who eat from the underwater, the different type of seabirds? (Line 739)

Response:

With respect to the marine mammals that are out there, it is not just whales that would stop the surveying. Any mammal, such as a polar bear or dolphin, regardless of the species would stop the operation.

67. Q: The animals at the seabed I don't want them harmed, and also the fish in the seabed that doesn't come up for air, that stays in the water. Maybe have they made us understand or have they make you understand that turbot -- where turbot -- where they go at certain months, especially in the fall, through the deep water on the seabed? That they know where they migrate at which month maybe if you know about that, can you answer this question? (Line 748-749)

Response:

Yes, there are two ways; one is scientific surveys done to assess the resource. There is also the fisheries liaison officer who works to ensure that there is communication between the fishing industry and the survey vessel.

68. Q: I heard that there will be an Inuit observer on the ship looking for animals. There will be more than one Inuk on the ship? (Line 754)

Response:

The project proponent committed to providing information after the meetings.

Additional Response Information:

The proponent is committed to protecting the environment and wildlife. The proponent has developed mitigation measures to limit potential negative impact (please refer to Environmental Assessment, Mitigation Measure Section).

Two experienced Marine Mammal Observers and two Inuit Observers will be employed for the duration of the project. The observers onboard the vessels are looking for marine mammals. MMOs will keep a detailed log of what species are observed, and where and when they were observed. If a marine mammal is seen within the 500 m-safety zone the seismic source shuts down. Once MMOs no longer see a marine mammal within the 500 m-safety zone for 30 minutes, the 20-minute ramp up procedure will begin. (As per the Statement of Canadian Practice)

Source

LaPierre, Tony., Arnott, Alexandra., Hawkins, Chris., Simpson, Kent., & Davis, Darlene.(2011). Environmental Impact Assessment For Marine 2d Seismic Reflection Survey Baffin Bay And Davis Strait Offshore Eastern Canada By Multi Klient Invest As. RPS Energy. Report No. HOPH417(B)

69. Q: Can you answer it? If not, you cannot. If they have a federal government and Greenland had agreement? (Line 758)

Response:

Some work has been done in Greenland in the past, and it would need to be confirmed to see if some of the information on the agreements with the Greenland government and the authorities over there could be released. There are a lot of things that are confidential in those documents and, to tell the truth, it would need to be checked to see if that would be releasable.

70. Q: If you do testing in the lower water or near the sea bed, are they going to have the same sound or the strength? (Line 762)

Response:

The source makes the same noise no matter how deep or shallow the water is. The effects it has when it reaches the floor in deeper water will be different, but they do not turn it up or down based on water depth.

71. Q: Do you know the percentage of how much spill there is? (Line 770)

Response:

This project is not about drilling for oil, it is about seismic surveys.

Additional Response Information:

This project is only conducting the seismic surveying operations required to locate potential oil reserves under the sea floor. There will be no drilling as part of this project; nothing will be going down to the seafloor that could release any oil. The only potential for a spill comes from the surveying vessel itself. This vessel carries approximately 500, 000 litres of fuel but has a full safety plan, as legally required. There is also a support vessel on hand that has containment equipment onboard sufficient to deal with the unlikely possibility of a catastrophic event occurring to the vessel and causing a spill.

72. Q: So what you're saying is it's 50/50 percent chance? So if it would spill, do you have a proper -- proper safety plan? (Line 777-778)

Response:

The ship has to have a safety plan and everything is in place in the documents submitted to the NEB and the authorities. The ship itself only carries fuel oil. There is nothing going down to the bottom that could release any oil.

73. Q: My question is due to the high current and all that, it would spread, maybe rapidly. Would the ship be able to keep up with a spill? (Line 783)

Response:

That would depend on the type of spill it would have. The only oil that could spill would be due to a catastrophic event onboard the vessel. The vessel has a full safety plan. There is also a support vessel on hand that has containment equipment onboard. The amount of fuel that could spill would be about 500, 000 liters.

74. Q: And would you still drill if it's -- even if it's a small rate of oil? (Line 787)

Response:

There is no drilling involved in this project. All we do is test the ocean floor with sound waves, looking for formations in the rock. Nothing actually goes into the ocean floor.

75. Q: So my last question is, since you're testing, does that mean you're planning to drill some day? (Line 789)

Response:

No, the project proponent does not drill, that is up to the oil companies. The information acquired here would go to companies and to the government and they would decide if it was viable to drill for oil or not. Depending on the results it could be decided to drill for oil, or not to drill for oil.

76. Q: It is written down here that the National Energy Board will review an assessment done -- it's written under that as an assessment -- what I understand is that we are asking for permission or not? (Line 802)

Response:

The project proponent committed to providing information after the meetings.

Additional Response Information:

The proposed seismic survey would occur offshore of Baffin Bay and Davis Strait in an area that falls outside of the 12 nautical mile territorial sea boundary. As a result, the regulatory authority for this project is the National Energy Board. The NEB will review the application and decide if the project can or cannot proceed. The communities will not have a vote for approval or rejection. However, the community does have the right to voice their concerns, have the right to be informed and provide input to the project.

Nunavut is a territory, thus distributing much of the power to the federal government. That is what the UN Declaration of the Rights of Indigenous Peoples is all about. Often the communities look at the company as the other side. Building relationships with companies can strengthen the community's interest with external organizations and agencies.

77. Q: And can you make agreement if there is approval that you can compensate the North for a trillion dollars for loss of animals? (Line 806)

Response:

NEB Response: As part of the approval of a seismic survey, if it is approved, there needs to be a benefit plan and that is not something that the NEB approves. That is something that the government, your government, has to work out with the company.

The company has to have approval of a benefit plan by the government of Canada and AANDC, have to approve that benefit agreement. NEB has no say in that. That is an agreement between the government and the company.

Additional Response Information:

The project proponent will seek benefit approval from the necessary authorities. The project proponent is committed to building a positive working relationship with the communities of Baffin Island.

78. Q: When you make an explosion, whatever dies, will you be counting the dead animals; for example, walrus? (Line 827)

Response:

The source of the sound is not actually an explosion, it uses compressed air. Also, any observations about animals, dead or alive, would be reported to the community. If there was a animal dead in the water that was caused by some other source, it would be reported to the community as well.

79. Q: Do you own the vessel? (Line 833)

Response:

The vessel is on a long term lease charter agreement, and it is crewed by people from the company.

80. Q: Is that the one (reference to page 3, Figure 1 of the package)? How long is that thing that is dragging by the ship? (Line 839)

Response:

Yes, it is. It is 8100 metres in length.

81. Q: And how deep is that thing underneath the water? (Line 841)

Response:

The cable that records the information is 8100 metres in length and is towed at 25 metres under water. The source is 14 metres in length and is towed at 9 metres under water.

82. Q: That's safe enough for the ice to go by? (Line 849)

Response:

Yes, it is enough for the ice to go by. As mentioned earlier, operations will avoid ice. There is a scout vessel that goes ahead to look out for ice. Satellite data is also used.

83. Q: The streamer, like with the icebergs, would you have to stop for a while if there was to be an iceberg on your way, a huge iceberg? (Line 851)

Response:

Yes, in the event of ice the course of the vessel would be adjusted to avoid it.

84. Q: The testing area, if there was -- even if there's too much ice build-up, do you just continue doing seismic testing? (Line 853)

Response:

No, if there is too much ice the course is adjusted for an area where there is no ice.

85. Q: The testing area that you did, do you go back to do anymore study to see if you've missed anything or when you have to go to another location? (Line 855)

Response:

The surveying process provides real time feedback, so if there are problems or if anything was missed it would be known right away.

86. Q: Your airgun, does it go straight down? And once it touched -- so it takes back the information from the seabed to your cable? (Line 858)

Response:

Yes, the source sends the pulse straight down and the sound reflections (echos) return to the sensors located on the cable being pulled behind the boat. There are compasses and monitors on the sensors so their locations are known in relation to the boat. This allows the vessel and gear to move out of the way of obstacles, such as icebergs.

87. Q: The airgun, is it very loud under water, say every half hour? (Line 863)

Response:

As mentioned before, the sound goes out about every 15-20 seconds into the water.

88. Q: Say you have eight hours a day and all that time for the eight hours, you do this testing or do you take a break at all if there's any -- or if there's too much ice in the area where you want to do the study? (Line 866)

Response:

The breaks occur at the end of the survey lines, indicated by the black lines on the slide. If ice is encountered, operations would stop and turn around, or move out of its way.

89.* Q: *The square lines, how large are they each, is it one mile, two miles? (Line 869)

Response:

The lines vary in length, but to put it in perspective, the space between these lines is approximately 100 kilometres. If the first line were finished, in order to do the second line it would take approximately 15 hours to travel the distance between the lines.

90. Q: You're going to get pretty close to Lancaster Sound. Have you done anything there, Button Point? Since you're going to go near Lancaster Sound, when you're doing the testing, do you go near the land or can you see the land? (Line 873, 874)

Response:

No, the vessel will be far enough offshore that land cannot be seen.

91. Q: My first question is do you guys know what the maximum decibel that a marine mammal can take? (Line 884)

Response:

This information has been collected and is being forwarded to the communities.

92. Q: Can we not try to get the gas that are already seeping out to see if there's any other oil and make fitted tunnels? (Line 916)

Response:

The project proponent committed to providing information after the meetings.

Additional Response Information:

The project proponent is aware of naturally occurring oil seeps, such as the one in Scott Inlet. While it is helpful to know where these locations are, formations in the substructure may cause seeps to occur at great distances from the source. The purpose of the survey is to gain a broad understanding of the geology of the entire area to see where oil reserves are located.

93. Q: How can we lower the sound of the air gun or decimal sound? Maybe you can find out through the satellite where the oils are? Maybe there's a technology? (Line 925)

Response:

The project proponent committed to providing information after the meetings.

Additional Response Information:

No method for surveying deep marine geology has been developed that is more accurate, time efficient, or has fewer environmental impacts than the use of a towed air source array and hydrophones contained in a long streamer.

94. Q: How can you do type of any activity without doing a huge effect, negative effect? (Line 928)

Response:

The project proponent committed to providing information after the meetings.

Additional Response Information:

Mitigation measures have been prepared to limit potential effects a project may have on the environment. This project will implement the following mitigation measures:

- Community Liaison Officer: maintain communication with the project proponent to provide updates to the Hamlet Council, Hunters and Trappers Organizations and community on the project.

- Fisheries Liaison Officer: will maintain communication with all fishing vessels near the vicinity of the seismic survey. The officer will update the survey vessel on known fishing activities in the area and will provide relevant information to DFO.

- Marine Mammal Safety Zone: a safety zone of 500 m (1640.42 feet) from the sound source has been established. If a whale, seal, polar bear or walrus (any species of mammal) is identified within the safety zone, the seismic source will be shut down.

- Marine Mammal Observer: are on the vessels looking for marine mammals. MMOs will keep a detailed log of what species are observed, and where and when they were observed. If a marine mammal is seen within the 500 m safety zone, the seismic source shuts down. Once MMOs do not see a marine mammal within the 500 m safety zone for 30 minutes, the 20-minute ramp up procedure will begin.

- Ramp up Procedure: is when the survey vessel gradually increases the intensity of the air source (sound) over 20 minutes. This procedure is used to allow for fish and marine mammals to move away from the survey area.

- Statement of Canadian Practice with respect to the Mitigation of Seismic Sound in the Marine Environment: The project proponent is following the "Statement of Canadian Practice with respect to the Mitigation of Seismic Sound in the Marine Environment" in order to avoid or minimize the impacts on marine life. The Statement of Practice outlines the necessary and appropriate mitigation measures for seismic surveys.

95. Q: MKI, I think it's important for Inuit to know who is coming here to work, what companies are paying for this work. So that's my question. (Line 935)

Response:

The program is a joint venture between PGS and TGS. MKI is a division of PGS. The permit is going under MKI but the program is shared as a joint venture between the two companies. PGS and TGS will be funding and operating this program.

96. Q: What is the -- what are you -- what is the rush of this meeting? (Line 941)

Response:

The meeting is being sponsored by the National Energy Board because they are responsible for reviewing the application and making a decision on whether to approve or deny the project. This project has been ongoing since 2011, and MKI and its partners have been holding community consultations for two or three years now. An environmental assessment is being provided and now communities are being asked to give feedback. The company has been invited to this meeting to answer any questions. It was advertised in newspapers, on the radio and on posters in the community. Apologies if it appears the meeting has been too fast for some, but advanced advertising of this meeting was done in the best possible manner.

Supplementary Report VI

Follow-Up to the National Energy Board Letter dated May 31, 2013

Information provided in response to

Clyde River

TGS-NOPEC Geophysical Company ASA, Petroleum Geo-Services and Multi Klient Invest AS (TGS/PGS/MKI) Northeastern Canada 2D Seismic Exploration Survey.

August 22, 2013

Clyde River Questions

The following questions were asked during the National Energy Board's (NEB) meeting in Clyde River, Nunavut on April 30, 2013. Each question and response is referenced to the report provided by the NEB, 'Public Review of the TGS-NOPEC Geophysical ASA (TGS), Petroleum Geo-Services (PGS) and Multi Klient Invest AS (MKI) Northeastern Canada 2D Seismic Survey Application, Volume 1'. Original responses have been edited to ensure clarity. Verbatim responses can be found on the NEB website (www.neb.com)

Line numbers are referenced in brackets (Line xxxx).

To understand the context of each question, please refer to the Transcript Report for Clyde River on the National Energy Board website.

A list of acronyms used in this report can be found in Appendix A.

1. ***Q: How do you know that's the area for that (closed area, narwhal in deep-sea corals)? Did you study it and find narwhals there or is there a study based on that? (Line 1013)***

Response:

The area is designated by the Department of Fisheries and Oceans based on their information.

Additional Response Information:

Since 1998, fishing effort restrictions have been in place to limit the time spent by vessels fishing for Greenland halibut (turbot) in NAFO Div. 0A (sub-zone 2.1) in an area identified as a narwhal overwintering area. In 2006, DFO Fisheries Management, following discussions with DFO Science, decided that a significant portion of the southern narwhal overwintering grounds that includes deep-water coral locations should be closed to all Greenland halibut fishing (fixed and mobile gears) (DFO, 2007). Contributing factors for this decision included the status of "special concern" of the narwhal that use this area, the importance of halibut in its diet during the winter, concerns over narwhal entanglement in gillnets, and the presence of deep-sea corals, which may play an important role in this ecosystem (DFO, 2007).

DFO. (2007). Development of a Closed Area in NAFO 0A to protect Narwhal Over-Wintering Grounds, including Deep-sea Corals. *DFO Canadian Science Advisory Secretariat Science Response. 2007/002.*

2. ***Q: Is there another reason besides exploration activities that you're going to use it for? (Line 1017).***

Response:

No, the intent of the activity is for exploration of oil deposits.

3. ***Q: Beside that box on page 4, do you know of other feeding areas? (Line 1023)***

Response:

The Project proponent committed to providing information after the meetings.

Additional Response Information:

Whales and seals are often found in locations for one of three reasons: calving, mating and feeding. While some animals return to the same location year after year, others may rotate between several preferred locations. These locations often have similar geographic and oceanic characteristics (for example, fjords with a similar water depth and water temperature) which provide a suitable habitat for the animal. For example, narwhals in the High Arctic visit multiple fjords and bays during the summer months, while there are some beluga populations, such as the Cumberland Sound population, that remain in Cumberland Sound throughout the entire year. Reports from both Inuit and scientific researchers have identified that there is suitable habitat for bowhead whales along the eastern coast of Baffin Island.

Studies and observations of where marine mammals tend to be during specific months of the year do not guarantee that is where they will be found in future years. Whales and seals are opportunistic foragers and will eat at times and locations where food is available. There are areas where whales are frequently found, such as Lancaster Sound, Cumberland Sound, Narwhal and Deep-Sea Coral Closed Area and the many fjords and bays around Baffin Island. However, whales and seals are not present in these locations year-round. They may only spend one week or several weeks at a particular location depending on the availability of food.

The proposed survey will likely take place during the months of September and October. During this time whales and seals are finishing up their summer activities and preparing to migrate to their wintering grounds. The summering grounds for many of these animals occur in coastal regions around Baffin Island and in the High Arctic. The wintering grounds for the whales and seals are widely dispersed and include the North Water, the west coast of Greenland, Baffin Bay, Foxe Basin, Hudson Bay and at the floe edge south of Davis Strait.

The timing and path of the fall migration for whales and seals are different for each species. Please see Section 6 in the “Supplementary Report II” for a comprehensive analysis.

4. ***Q: For mammals, halibuts and turbot won't be included in there (500 m marine mammal safety zone) eh? (Line 1030)***

Response:

No, fish will not be included. It will include marine mammals within the mitigation (*500m marine mammal safety zone)* zone.

5. ***Q: Us, people from Nunavut, are we not in Canada? Is that not our water? That's my first question. (Line 1041)***

Response:

The Government of Nunavut regulates the waters within 12 nautical miles, whereas the federal government regulates anything outside 12 nautical miles. For oil and gas exploration this means the National Energy Board has responsibility. The ocean waters inside the 12 nautical mile limit and outside the 12 nautical mile limit are Canadian waters, the different areas are used only to differentiate between the areas where the different levels of government have responsibility.

6. ***Q: When there's a -- when we feel that there's going to be activities happening in our area because we have to live with -- we have to live and buy food with money, especially in the ocean, and if we lose our food source would you take over our land and forget about the communities? (Line 1053)***

Response:

This question refers to the fundamental relationship between Indigenous Peoples and the Government of Canada, and is beyond the scope of the project.

7. ***Q: If this project was to proceed, would you -- would there be any benefits to us? (Line 1058)***

Response:

One benefit will be the Community Liaison Officer for the operation while it is going on.

Additional Response Information

Two Inuit Marine Mammal Observers and the Fisheries Liaison Officers will be hired from Nunavut communities.

8. ***Q: Once you start the seismic testing the whales are probably going to move to other locations. Are there going to be any effect on our mammals? Are there going to be any effect on our mammals or not? (Line 1063)***

Response:

Marine mammal observers will be onboard the boats and operations will comply with regulations. They will have the ability to call the control room and stop the operation if marine mammals are sighted in the mitigation zone (*500m marine mammal safety zone)*.

9. ***Q: Who is supporting you within Nunavut? (Line 1079)***

Response:

There is no way of saying that one community is in favour of the project and another community is against it. In all communities you find people who are excited about the opportunities presented by projects like this, and others who have concerns.

10. ***Q: And someone mentioned that there would be observer on the ship or vessel if something should happen? (Line 1087)***

Response:

Yes, there will be marine mammal observers on board and they will comply with the regulations.

11. ***Q: My question is about the benefits plan: Have you discussed the benefits plan with Inuit? (Line 1098)***

Response:

Yes, we have started to discuss the benefits plan. There will be follow-up meetings with each of the communities to discuss these benefits, which will include more than fiscal benefits; such as employment opportunities, and the benefits of mutual relationships.

12. ***Q: And who is the requirement for you to discuss it with? Is it the communities? Is it a central organization? (Line 1106)***

Response:

NEB Response: For clarification, the National Energy Board has no say in the benefits plan, however, it cannot issue the licence until the benefits plan has been agreed upon. So far, the Hamlet offices are the initial focus for discussions but advice from other umbrella organizations will also be taken into consideration.

13. Q: And have they (Nunavut Tunngavik Inc.) discussed it (benefits plan) with the community? (Line 1116)

Response:

This is unclear at this time as it is an internal matter for Nunavut Tunngavik Inc (NTI).

14. Q: And it's very interesting that -- who gets to determine on what pace and how development happens? (Line 1119)

Response:

The Project proponent committed to providing information after the meetings.

Additional Response Information

It is hard to determine exactly what pace development occurs at. Projects could be approved quickly if there are no problems with a proposed project, or it could take a long time to get to a point where all stakeholders are satisfied with a project. How development happens is determined by guidelines and procedures that are followed by the regulatory organization.

For this project, involving offshore seismic surveys, regulation falls under the jurisdiction of the National Energy Board. Other federal departments, such as Natural Resources Canada, Fisheries and Oceans Canada, Environment Canada, and Parks Canada are notified of the project to determine if they may have a responsibility or interest in the proposed activities.

The environmental assessment process (for this project) involves discussions with federal government, territorial government, and local Inuit people and organizations. These discussions are an important part of approving development projects. For the proposed seismic survey, community engagement helps to identify Inuit use and knowledge of the area so that the proposed project will not impact or have minimal impact on traditional and current use of marine space and resources.

15. Q: That looking at the map -- is that -- all the described areas in the squares is the whole thing that you're planning? (Line 1129)

Response:

Yes, that would be the total program over multiple years.

16. Will there be a way to clean that (oil spills from drilling) up? (Line 1147)

Response:

Drilling is not our expertise, and although this is a valid question it is better posed to one of the major oil companies that do the drilling (reiteration of the point that the project is not an oil exploration project but a seismic survey).

17. Q: Is there something that we can do as a community? There's a question to NEB. You know we can talk and say our feelings about this and all that, but what can we do in legal terms to stop this as a community? Can we -- is there a way for us to complain and say: "That little box is not the only area where narwhals eat"? What legal -- something legal that we can use to stop them? Is there anything? (Line 1153)

Response:

NEB Response: In terms of the responsibilities of the National Energy Board, we have to ensure that the activity that Multi Klient Invest AS (MKI) is proposing can be done safely for communities, workers, the people who fish in the area and to protect the environment. It is our responsibility under law to ensure that the company complies with everything they have said they are going to do, taking into account any comments, conditions or recommendations that are made by any of the communities. If the company does not meet these conditions, or cannot prove they can meet these conditions, their application will be denied.

18. Q: Can you elaborate a little bit more on those? I don't understand the writing on there (page 10, "Non-Seismic Data Collection Activities"). (Line 1166)

Response:

Generally, passive acoustic monitoring is used in conjunction with observer sightings from the MMOs (Marine Mammal Observer) to better understand where the marine mammals are located. The gravity metre is a listening device, or a passive recording instrument, located in the hull of the ship. It measures differences in the gravity of the Earth and does not make any noise.

19. Q: Wouldn't their information be -- would they be getting different information than what Geological Survey is going to get? (Line 1173)

Response:

The Geological Survey is looking for geohazards like earthquakes, not oil. They would need the same level of approval undertake a survey to look for oil.

20. Q: So their equipment (for a Geological Survey) cannot penetrate like the seismic testings? (Line 1177)

Response:

My understanding is that it is in very shallow water, it's not a survey that looks at the offshore areas proposed here.

21. Q: Why don't we get an example of -- why didn't we get a sample of the sound before you started coming here? You probably know how it effects the marine mammals. (Line 1180)

Response:

A lot of work has been done with seismic surveys in other places and a lot of that information is used in doing the environmental assessment. The document has been submitted by the companies to the NEB for the approval process. It has a section on marine mammals and the effects on marine mammals.

Additional Response Information:

Additional information on the known effects of sound from seismic surveys to marine mammals can be found in Section 6 of the 'Supplementary Report II'.

Appendix D & E

22. Q: Is there a monitor in the ship to see how much fish there are in the area that you're surveying? (Line 1181)

Response:

As standard procedure, there have been interactions with the Baffin Fisheries Coalition and the Arctic Fisheries Alliance to make sure the vessel does not go through at the same time the fishing vessels are operating. There is also Fisheries Liaison Officers who will communicate with the fishing industry and a Community Liaison Officer who will communicate with the community, so there is constant interaction.

23. Q: I mean regulatory bodies are in Calgary and in the middle of Canada. Why are there over there and not on Baffin Island where they're closer? (Line 1191)

Response:

NEB Response: The National Energy Board is based in Calgary. There are office employees in the Northwest Territories, but not in Nunavut. If this application is approved, inspectors and monitors would be coming to ensure that the company is complying with all the conditions.

24. Q: And I think it would be -- make it a lot easier if they had a -- even if you don't speak Inuktitut, even if you Qallunaat, at least you'll be present in the -- in this area. We're talking to you even if we don't speak Qallunaat. Can you answer that? (Line 1195)

Response:

NEB Response: Your question and written comments will be taken to the Chairman of the National Energy Board and put to the board to see if they would be interested in having an employee here.

25. Q: So I'd like to ask the company if they could just confirm for the people of Clyde River, if the application was approved, how many marine mammal observers would you have from each community, how would they be selected, how many Fishery liaison officers would you have on the ship and where would they come from and how would -- how are you -- would you choose the community liaison officers for the communities? (Line 1209)

Response:

So far, MKI and TGS have taught marine mammal (*observer)* classes, which have trained 12 people here.

Additional Response Information:

MKI has providing MMO training to two classes of Environmental Students at Iqaluit Arctic College. There will two experienced Marine Mammal Observers and two Inuit Observers employed for the duration of the project. Typically there is one FLO employed for the duration of the project. First opportunity for these positions will be given to local Nunavut residents that show an interest and prove to be qualified candidates. The Community Liaison officer will be selected from each community which continue to be identified through community engagement team (NEXUS Coastal Resource Management).

26. Q: How many Fishery Liaison Officers and Community Liaison Officers, if there are some and the same? (Line 1224)

Response:

There would be one Community Liaison Officer for each community and Fisheries Liaison Officers.

27. Q: And I think there's a requirement or the company will have committed and may be required, if it gets approved, that they would report through the community liaison officers back to the communities annually, if not any time. Is that -- I'd like to confirm that because that would be a requirement that you are committed to do. (Line 1242)

Response:

Yes, that is -- that is correct. Communication would go through the Community's Liaison Officer.

28. Q: From seismic testing you've done in the Atlantic and Labrador region, has there ever been mammals dying, seals or narwhals or beluga, anything like that? (Line 1249)

Response:

No deaths have been recorded. The company keeps record of all mammal observations while the vessel is conducting seismic surveys. For the recent surveys off of Newfoundland and Labrador, observation reports were submitted to Newfoundland Petroleum Board. There is a comprehensive report on all the observations and daily logs combined from both the FLOs and the MMOs (marine mammal observers) on board the boat, as well as the Inuit MMOs that on board. These reports may not be public yet but if they are they can be accessed from the Newfoundland Petroleum Board.

Additional Response Information:

There have been no documented cases of marine mammal (whales, seals and walruses) mortality or permanent loss of hearing upon exposure to oil and gas exploration seismic surveys (DFO, 2004; Abgrall, Moulton and Richardson, 2008). We have summarized reports and journal articles, which assess the effect of sound from seismic surveys on whales and seals in northern waters. This information can be found in Section 2 of the 'Supplementary Report II'. Available Marine Mammal Observer reports from seismic surveys in Labrador and Newfoundland waters are found in Section 3 of the 'Supplementary Report II'.

Sources

Abgrall, P., V.D. Moulton, and W.J. Richardson. (2008). Updated review of scientific information on impacts of seismic survey sound on marine mammals, 2004-present. Canadian Science Advisory Secretariat.

29. Q: What monitoring program do you have afterwards to determine if you've affected any animals? (Line 1251)

Response:

There are no continued observations after the survey is complete.

30. ***Q: So when you're done with the surveying and oil companies want to buy the results, is there like an estimate for how much you would sell it for? (Line 1253)***

Response:

That information is not released to the public, as it is confidential contractual information between both the partners.

31. ***Q: Then the benefits agreement you said you were -- you didn't say you were negotiating but you were talking with organizations. What would that be based on, the numbers there? (Line 1255)***

Response:

Yes, that goes with the discussions with each one of the communities.

32. ***Q: So as a community would we say we want $10 billion; does it work like that? (Line 1257)***

Response:

The benefits are made up of different things; including jobs as community liaison officers, marine mammal observers. The community can also take advantage of support service job opportunities, and the expertise that the project brings to the region. That is some of the basis of the benefits plan.

33. ***Q: The project you are proposing, proposing to use airguns seems like it's already approved and it has pictures. What's going to happen? (Line 1260).***

Response:

The use of airguns is included in the proposal to the National Energy Board, however the project has not been approved yet. This is part of the process right now.

Supplementary Report

TGS NOPEC Geophysical Company ASA, Petroleum GeoServices and Multi Klient Invest AS
Northeastern Canada 2D Seismic Exploration Survey

November 2012

Supplementary Report

This report has been prepared in response to comments brought forward during community information sessions held in June and October, 2012. All sources referenced throughout the report will be available at the hamlet office, or provided by email, upon request.

This report provides a summary of information compiled from past research. It will not address unsubstantiated concerns expressed by some environmental organizations regarding development of natural resources in general.

Seismic Surveys

Marine seismic surveys are conducted to determine geologic features below the seafloor. The seismic survey process includes the following steps:

1. A piston (sound source) generates a sound when it quickly releases compressed air into the water. The sound source is towed by the research vessel 6-10 metres (18-30 feet) below the surface of the water.
2. The sound generated by the source travels through the water as a sound wave to the seafloor. Some of the sound will bounce off different layers (types) of sediments and rocks and return back to surface of the water.
3. The sound that returns to the surface of the water is detected by hydrophones. Hydrophones will be towed by the vessel on a cable that is 6-12 kilometres (18,000- 36,000 feet) long. The cable is also called a streamer.
4. The information collected is analyzed using computer programs that can produce an image of the different rock layers beneath the seafloor.

Marine Fish

Much of the research and knowledge of Arctic marine fish is restricted to Arctic cod due to its ecological importance and to Greenland halibut due to its economic importance. It is understood that there are two types of possible effects from high intensity sound on fish:

- Physical Effects: includes any changes in the fish itself, which may include death.
- Behavioural Effects: can result in changes in swimming direction and location.

There have been no documented cases of fish mortality upon exposure to sound from seismic air sources under field operating conditions (DFO, 2004) and airguns cause no physical damage to fish at distances greater than 12 metres (36 feet) (Gausland, 2000).

Behavioural effects on fish from seismic surveys are understood to be short term, with the duration of the effect less than the duration of the exposure (DFO, 2004). Behavioural effects on fish may affect commercial fisheries catch rates, however those rates are also dependent on many environmental factors. A Norwegian study observed a 132% increase in gillnet catches for Greenland Halibut, while long line catches decreased by 16% during the seismic survey

(Lokkeborg, Ona, Vold & Salthaug, 2012). To limit the potential effect of sound on commercial fisheries, mitigation measures provided by DFO (2010) will be followed.

The potential impact of a 3D seismic survey killing fish larvae and eggs in a fish population (0.18% per day) is below the naturally mortality (5-15% per day) observed in a fish population and, therefore is within the natural variability of fish and larvae mortality (Saetre & Ona, 1996 in LaPierre et al., 2011).

Whales and Seals

Information sources which inform management and policy decisions on seismic surveys with respect to marine mammals include the following:

- Captive Studies: have been used to measure auditory sensitivity, auditory function and the effects of noise exposure. However general behavioural changes in animals due to their captivity may affect natural responses to sound.
- Field Studies: opportunistic observations made by vessels on the behaviour of whales in the observable vicinity of a seismic survey vessel.
- Modelling: computer programs are used to predict the effect of sound on whales ears.
- Tracking devices: uses instruments attached to seals and whales to track individuals and document their underwater behaviour, physiological responses and obtain information on the environment.

Potential effects from seismic surveys on whales and seals include the following:

- Mortality and physical effects: stranding/mortality, hearing impairment and non-auditory effects (for example, ship strikes).
- Direct behavioural effects: displacement, migratory diversion, changes in dives and respiratory patterns, and changes in social behaviour and vocalization patterns.

There is very little information on the following effects of seismic surveys on whales and seals: functional consequences of physical and behavioural effects, chronic effects and indirect effects.

Physical Effect of Acoustic Sounds on Marine Mammals

There have been no documented cases of marine mammal mortality (whales, seals and walruses) upon exposure to oil and gas exploration seismic surveys (DFO, 2004; Abgrall, Moulton & Richardson, 2008).

Behavioural Effect of Acoustic Sounds on Marine Mammals

In field studies, behavioural responses to sounds[1] have been recorded for a few whale species in a limited range of conditions (Gordon et al. 2003; Weilgart, 2007; McCauly et al., 1998;

[1] sounds for this study include seismic surveys, drilling platforms and rigs, airplanes , sonar, commercial shipping, recreational boating

McDonald et al., 1995). Responses include startle and fright, avoidance, and changes in behaviour and vocalization patterns. However, behavioural observations are variable, some findings are contradictory, and the biological significance of these effects has not been measured.

The primary cause of physical and behavioural effects on marine mammals caused by seismic surveys is the intensity of sound, measured in decibels (dB), produced by the seismic source. Responses to noise can be highly variable, depending on species, individuals, age, sex, physical state, presence of offspring, prior experience, characteristics of the noise source, and other factors (Weilgart, 2007).

There are two categories to qualify the effect of sound on marine mammals hearing:

- Permanent Threshold Shift (PTS): permanent reduction in hearing sensitivity.
- Temporary Threshold Shift (TTS): temporary hearing loss (completely recoverable over time spans of minutes to hours).

The United States National Marine Fisheries Service and Department of Fisheries and Oceans have identified, that for high intensity sounds, whales and seals should not be exposed to impulsive sounds (such as those produced by seismic surveys) with levels greater than 180dB and 190dB respectively (Abgrall et al., 2008). This information has been incorporated into the "Statement of Canadian Practice with Respect to the Mitigation of Seismic Sound in the Marine Environment" (DFO, 2010). For this project, the anticipated sound intensity at 500 metres (approximately 1500 feet) from the sound source is 180dB. Therefore, if a marine mammal is observed within the 500 metre safety zone, the seismic survey will stop operating.

To date, there has been no specific documentation that TTS or PTS occurs when marine mammals are exposed to sequences of airgun pulses under realistic field conditions (Gordon, 1998; DFO, 2004; Abgrall et al., 2008).

Whales and seals that may interact with the proposed seismic survey project include narwhal, beluga, bowhead, ringed seal, bearded seal, harp seal, and hooded seal.

Studies on the effects of sound on specific species are as follows:

- Narwhal
    - There are no known studies specifically on the effects of sound on narwhal. From conversations with hunters and elders, it was explained that narwhals are sensitive to sound. However, it is unknown what sound level would negatively affect narwhals.
- Beluga
    - Generally exhibited avoidance behaviour when swimming less than 1.5 km away from the sound source at a level of 163 dB (Awbrey and Stewart, 1983).

    - Observed to exhibit avoidance of seismic survey vessels of 10 to 20 km when sound levels reach 150 dB (Abgrall et al., 2008).
- Bowhead
    - Summering bowheads showed no detectable avoidance of seismic surveys, no change in general activities or call activities (Richardson et al., 2007 in Weilgart 2007).
    - Overt avoidance behaviour at ranges of 6-8km, swimming away from the vessels and air source (Gordon et al., 2003).
    - A pattern of shorter surfacing, shorter dives, few blows per surfacing, and longer intervals between blows when exposed to anthropogenic noise (Hildebrand, 2004).
    - Changes in call detection rates in response to airgun activity have been found for bowhead whales (Stone & Tasker, 2006).
- Ringed and Bearded Seals
    - A study observed the following behaviour of those seals sighted when the seismic airgun was operational (Harris et al., 2001):
        - 18% looked, 2% approached, 5% swam parallel to the boat's track, 36% dove, and 39% swam away
        - Seals might reduce exposure to the sounds by remaining at the surface
        - No seals were observed to leave the general area of operation during seismic activity
- Harp Seal
    - There are no known studies of the impact of seismic surveys on harp seals.
- Hooded Seal
    - There are no known studies of the impact of seismic surveys on hooded seals.

Mitigation Measures

The project proponent will implement the following mitigation measures:

Community Liaison Contact

The Community Liaison Officer will maintain communication with the project proponent to provided updates to the Hamlet Council, Hunters and Trappers Organization and community on the project. As well, they will work closely with the Hamlet on developing proposals, projects, and reports to advance economic development opportunities and build capacity within the community.

Fisheries Liaison Officer

The Fisheries Liaison Officer will maintain communication with all fishing vessels near the vicinity of the seismic survey. The officer is solely responsible for communicating with the fishing industry. The officer will update the survey vessel on known fishing activities in the area and will provide relevant information to DFO.

Marine Mammal Safety Zone

A safety zone of 500m (1500 feet) from the sound source has been established. If a whale, seal or walrus is identified within the safety zone, the seismic survey stops.

Marine Mammal Observer

Marine Mammal Observers (MMOs) are on the survey vessel looking for marine mammals. MMOs will keep a detailed log of what species are observed, and where and when they were observed. If a marine mammal is seen within the 500m-safety zone, the seismic survey stops. Once MMOs do not see a marine mammal within the 500m-safety zone for 30 minutes, the 20-minute ramp up procedure will begin.

Ramp Up Procedure

The ramp up procedure is when the survey vessel gradually increases the intensity of the air source (sound) over 20 minutes. This procedure is used to allow for fish and marine mammals to move away from the survey area. If a marine mammal enters the 500m-exclusion zone during this 20-minute 'ramp up' procedure, the airguns will be shut down. The ramp up procedure occurs each time the air source is turned on.

Statement of Canadian Practice with respect to the Mitigation of Seismic Sound in the Marine Environment

The project proponent is following the "Statement of Canadian Practice with respect to the Mitigation of Seismic Sound in the Marine Environment" in order to avoid or minimize the impacts on marine life. The Statement of Practice outlines the necessary and appropriate mitigation measures for seismic surveys.

* This series documents the scientific basis for the evaluation of fisheries resources in Canada. As such, it addresses the issues of the day in the time frames required and the documents it contains are not intended as definitive statements on the subjects addressed but rather as progress reports on ongoing investigations.

* La présente série documente les bases scientifiques des évaluations des ressources halieutiques du Canada. Elle traite des problèmes courants selon les échéanciers dictés. Les documents qu'elle contient ne doivent pas être considérés comme des énoncés définitifs sur les sujets traités, mais plutôt comme des rapports d'étape sur les études en cours.

Research documents are produced in the official language in which they are provided to the Secretariat.

Les documents de recherche sont publiés dans la langue officielle utilisée dans le manuscrit envoyé au Secrétariat.

ABSTRACT

This document provides an updated review of recent scientific information on the effects of seismic survey sound from airgun(s) on marine mammals. It reviews conclusions in the Canadian Science Advisory Secretariat (CSAS) Habitat Status Report 2004/002 and describes published information that has become available since 2004 (through February 2008). The types of impacts reviewed closely follow those outlined in the original CSAS Habitat Status Report and include mortality and physical effects, direct behavioural effects, functional consequences of physical and behavioural effects, chronic effects, and indirect effects.

The review of ***mortality and physical effects*** considers strandings/mortality, hearing impairment, and non-auditory effects. There is no conclusive evidence that airgun pulses cause stranding or death in marine mammals, or non-auditory effects (e.g., gas bubble formation). However, incidents involving beaked whale strandings near naval exercises which used mid-frequency sonar suggest a need for caution in conducting seismic surveys in areas occupied by beaked whales. A key paper (Southall et al. 2007) provides new recommendations for injury criterion in marine mammals exposed to sound. Permanent threshold shift (PTS) in hearing is recommended as an injury criterion. On a SEL (sound exposure level) basis, there is a risk of PTS when received sound levels exceed 15 dB above the SEL which may elicit temporary threshold shift (TTS) in hearing. On a peak pressure basis, sounds might cause immediate PTS if received sound levels exceed 6 dB above TTS_{peak} threshold. For exposure to multiple pulses like those from airgun(s), PTS is assumed to occur if either of the following SEL or peak pressure criterion are exceeded:

- Cetaceans: ~198 dB re 1 $\mu Pa^2 \cdot s$ or 230 dB re 1 µPa (peak)
- Pinnipeds: ~186 dB re 1 $\mu Pa^2 \cdot s$ or 218 dB re 1 µPa (peak)

The ***direct behavioural effects*** considered include displacement and migratory diversion, changes in dive and respiratory patterns, changes in social behaviour, and changes in vocalization patterns. Baleen whales generally tend to avoid at least the immediate area around operating airguns, but avoidance radii are quite variable. Bowhead and gray whales in summer feeding habitat often exhibit only localized avoidance of airgun sources. Dolphins show variable responses to seismic surveys but seem more responsive than suspected earlier. Beluga whales exhibited 10-20 km avoidance of a seismic vessel; received sound levels were estimated at 150-130 dB re 1 µPa (rms). In contrast, there is little evidence that sperm whales avoid seismic surveys and a study of ringed seals concluded that they showed very limited avoidance of an operating airgun array. Dive and respiratory patterns vary in response to seismic exposure. Some preliminary analyses suggest that foraging attempts by sperm whales in the Gulf of Mexico decrease during seismic exposure. There are also variable results reported for changes in vocalization patterns of marine mammals in response to seismic sounds. Some baleen and toothed whales continued calling in the presence of seismic operations while others stopped calling and resumed after the survey.

Very little information addresses the potential for ***functional consequences of physical and behavioural effects***, ***chronic effects***, and ***indirect effects*** of seismic survey sound on marine mammals. Masking effects of pulsed sounds on marine mammal calls another natural sounds are expected to be limited, although there are very few specific data on this.

RÉSUMÉ

Le document offre une évaluation actualisée des renseignements scientifiques relatifs aux effets sur les mammifères marins du bruit que produisent les canons à air employés pour les levés sismiques. Ses auteurs reviennent sur les conclusions du Rapport sur l'état des habitats 2004/002 du Secrétariat canadien de consultation scientifique (SCCS) (MPO, 2004a) et décrivent les renseignements parus depuis 2004 (jusqu'en février 2008). Les types d'incidences examinés suivent de près ceux décrits dans le Rapport sur l'état des habitats du SCCS. Ils comprennent la mortalité et les effets physiques, les effets comportementaux directs, les conséquences fonctionnelles des effets physiques et comportementaux, les effets chroniques et les effets indirects.

L'analyse de l'aspect ***mortalité et effets physiques*** porte sur les échouements et les morts, la perte d'audition et les effets extra-auditifs. On n'a pas de preuve concluante que les impulsions de canon à air provoque l'échouement ou la mort des mammifères marins, ni qu'elles ont des effets extra-auditifs (p. ex. la formation de bulles gazeuses). Cela dit, l'échouement de baleines à bec au voisinage de sites d'exercices navals qui mettaient en jeu des sonars à moyenne fréquence appelle à la prudence lorsqu'il s'agit d'effectuer des levés sismiques dans des zones fréquentées par cette espèce. Un article fondamental (Southall *et al.*, 2007) recommande de nouveaux critères relatifs aux atteintes physiologiques chez les mammifères marins exposés au bruit. Les auteurs recommandent d'inclure la perte d'audition permanente, ou déplacement permanent de seuil (PTS, de l'anglais *permanent threshold shift*), parmi les critères. Du point de vue du niveau d'exposition sonore (SEL – *sound exposure level*), il y a risque de PTS lorsque le niveau sonore perçu dépasse de 15 dB le SEL susceptible de produire une perte d'audition temporaire, ou déplacement temporaire de seuil (TTS, de l'anglais *temporary threshold shift*). Du point de vue de la pression de crête, il peut y avoir perte d'audition permanente immédiate, si le niveau sonore perçu dépasse de 6 dB la limite inférieure du $TTS_{crête}$. Dans le cas d'une exposition à des impulsions multiples comme celles émises par des canons à air, on suppose que le PTS survient si soit le critère de SEL, soit le critère de pression de crête qui suivent sont dépassés :

- Cétacés : ~198 dB re 1 $\mu Pa^2 \cdot s$ ou 230 dB re 1 µPa (crête);
- Pinnipèdes : ~186 dB re 1 $\mu Pa^2 \cdot s$ ou 218 dB re 1 µPa (crête).

Les ***effets comportementaux directs*** pris en considération comprennent le déplacement et la déviation des voies migratoires, ainsi que la modification des régimes de plongée et de respiration, du comportement social et des vocalisations. Les baleines à fanons évitent généralement les parages immédiats des canons à air en activité, mais le rayon d'évitement varie beaucoup. Les baleines boréales et les baleines grises qui se trouvent dans leurs aires d'alimentation estivales n'ont souvent qu'une réaction d'évitement localisé. Les dauphins ont des réponses variées aux levés sismiques, mais ils semblent réagir davantage qu'on le soupçonnait. Les bélugas étudiés ont évité les navires sismiques dans un rayon de 10 à 20 km; les niveaux sonores perçus étaient estimés à entre 150 et 130 dB re 1 µPa (rms). Par contre, il y a peu d'indications que le cachalot macrocéphale évite les tirs sismiques, et une étude sur des phoques annelés a conclu qu'ils manifestaient une réaction très limitée d'évitement face à une batterie de canons à air en activité. Les régimes de plongée et de respiration varient en réaction à l'exposition à des bruits sismiques. D'après certaines analyses préliminaires, la quête de nourriture de cachalots macrocéphales dans le golfe du Mexique diminue durant les tirs. On rapporte des résultats variés pour ce qui est des changements dans les vocalisations des mammifères marins en réponse aux bruits sismiques. Certaines baleines à fanons et baleines à dents ont continué leurs appels au cours d'opérations sismiques, tandis que d'autres les ont interrompus pour les reprendre quand les levés se sont terminés.

On a très peu de renseignements sur les ***conséquences fonctionnelles des effets physiques et comportementaux***, les ***effets chroniques*** et les ***effets directs*** éventuels des bruits sismiques sur les mammifères marins. On suppose que les effets de masque des impulsions sur les appels des mammifères marins et sur d'autres sons naturels sont limités, mais il y a peu de données précises sur le sujet.

INTRODUCTION

The following document provides an updated review of recent scientific information on the effects of seismic survey sound from airgun(s) on marine mammals (i.e., data that became available from 2004 through early 2008). It reviews conclusions in the Canadian Science Advisory Secretariat (CSAS) Habitat Status Report 2004/002 (DFO 2004a) and describes published information that has become available since 2004. Lawson and McQuinn (2004) highlighted much of the background information relating to the effects of seismic sounds on marine mammals up to 2004. Due to the limited information on the subject, conference abstracts, papers, and other unpublished or "grey literature" that have often not been externally or peer-reviewed are included, in addition to peer-reviewed literature. Also, in some instances, literature published prior to 2004 is cited for contextual purposes. Additional recent reviews of the effects of sound from seismic surveys, and sources of anthropogenic noise in general, on marine mammals can be found in Gordon et al. (2004), NRC (2005), Nowacek et al. (2007), Southall et al. (2007), Weilgart (2007), and Tyack (2008).

INTRODUCTION

Le présent document offre une évaluation actualisée des renseignements scientifiques relatifs aux effets sur les mammifères marins du bruit que produisent les canons à air employés pour les levés sismiques. Ses auteurs reviennent sur les conclusions du Rapport sur l'état des habitats 2004/002 du Secrétariat canadien de consultation scientifique (SCCS) (MPO, 2004a) et décrivent les renseignements parus depuis 2004 et jusqu'au début de 2008. Lawson et McQuinn (2004) ont considéré une bonne partie des renseignements de base concernant les effets des ondes sismiques sur les mammifères marins jusqu'en 2004. Comme les informations sur le sujet sont peu nombreuses, nous incluons, outre les publications évaluées par les pairs, une « littérature grise » qui, souvent, n'a pas fait l'objet d'un examen externe ou d'une révision par des spécialistes – résumés de conférence, communications et d'autres documents non publiés. Parfois, pour fournir un contexte, nous citons des documents publiés avant 2004. D'autres analyses documentaires ont été faites récemment des effets du bruit produit par les levés sismiques, et des bruits anthropiques en général, sur les mammifères marins. Citons Gordon *et al.* (2004), NRC (2005), Nowacek *et al.* (2007), Southall *et al.* (2007), Weilgart (2007) et Tyack (2008).

IMPACTS OF SEISMIC SOUND ON MARINE MAMMALS

Mortality and Physical Effects

Strandings and Mortality

DFO (2004a) concluded that "although whale strandings have been linked to exposure to anthropogenic sound, exposure to seismic sound is considered unlikely *to cause direct marine mammal mortality".*

Marine mammals close to underwater detonations of high explosives can be killed or severely injured, and the auditory organs are especially susceptible to injury (Ketten et al. 1993; Ketten 1995). Airgun pulses are less energetic and have slower rise times, and there is no proof that they can cause serious injury, death, or stranding even in the case of large airgun arrays. However, the association of mass strandings of beaked whales with naval exercises and, in one case, a seismic survey, has raised the possibility that beaked whales exposed to strong "pulsed" sounds may be especially susceptible to injury and/or behavioural reactions that can lead to stranding.

Strandings and mortality may be due to various noise-related causes, including (1) swimming in avoidance of a sound into shallow water; (2) a change in behaviour (such as a change in dive profile, staying at depth longer than normal, or remaining at the surface longer than normal) that might contribute to tissue damage, gas bubble formation, hypoxia, cardiac arrhythmia, hypertensive hemorrhage or other forms of trauma; (3) a physiological change such as a vestibular response leading to a behavioural change or stress-induced hemorrhagic diathesis, leading in turn to tissue damage; and (4) tissue damage directly from sound exposure, such as through acoustically mediated bubble formation and growth or acoustic resonance of tissues. There are

IMPACT DES BRUITS SISMIQUES SUR LES MAMMIFÈRES MARINS

Mortalité et effets physiques

Échouements et morts

Le MPO (2004a) conclut que « même si les échouements de baleines ont été liés à l'exposition à des sons anthropiques, on considère qu'il est peu probable que l'exposition à des bruits sismiques cause la mortalité directe de mammifères marins ».

Les mammifères marins qui se trouvent à proximité d'une détonation sous-marine d'explosifs peuvent en mourir ou être gravement blessés, et leurs organes auditifs sont particulièrement fragiles (Ketten *et al.,* 1993; Ketten, 1995). Les impulsions des canons à air sont moins puissantes et ont un temps de montée plus long; rien ne prouve qu'elles peuvent entraîner des blessures graves, la mort ou l'échouement, même lorsque de grosses batteries sont employées. Cependant, l'association d'échouements massifs de baleines à bec avec des exercices navals et, dans un cas, avec une étude sismique, a montré la possibilité que l'exposition à de forts signaux sonores « impulsionnels » rende ces cétacés particulièrement vulnérables à des atteintes physiologiques et/ou comportementales qui peuvent les amener à s'échouer.

Diverses causes attribuables à des perturbations sonores peuvent expliquer les échouements et les morts : (1) les animaux nagent vers les eaux peu profondes pour s'éloigner de la source; (2) la perturbation provoque un changement de comportement (par exemple, le profil de plongée se modifie, les animaux restant en profondeur ou à la surface plus longtemps que d'habitude) susceptible de provoquer divers traumatismes – lésion des tissus, embolie gazeuse, hypoxie, arythmie cardiaque, hémorragie hypertensive ou autres; (3) un changement physiologique, telle une réaction du système vestibulaire, amenant une modification du comportement ou une diathèse hémorragique induite par le stress, laquelle amène une lésion des tissus; (4) des lésions directement imputables à l'exposition sonore, en raison des bulles de gaz

increasing indications that gas-bubble disease, induced in supersaturated tissue by a behavioural response to acoustic exposure, could be a pathologic mechanism for the strandings and mortality of some deep-diving cetaceans exposed to sonar, although the evidence of a causal connection remains circumstantial (Cox et al. 2006; Southall et al. 2007).

qui se forment et augmentent ou de la résonance acoustique dans les tissus. Il y a de plus en plus d'indications que l'embolie gazeuse, qui se constitue dans un tissu sursaturé par suite d'une réaction comportementale à une exposition acoustique, pourrait être un mécanisme pathologique de l'échouement et de la mort de certains cétacés à plongées profondes exposés à des sonars, bien que les preuves d'un lien causal demeurent circonstanciels (Cox *et al.*, 2006; Southall *et al.*, 2007).

Of concern for cetaceans, particularly beaked whales, is that tissue damage and live strandings may be induced at received sound levels that are lower than had previously been anticipated and, in particular, at levels lower than those that induce auditory damage (e.g., reviewed in Dolman and Simmonds 2006). The growing evidence that mid-frequency sonar is associated with certain strandings and mortality of beaked whales (Cox et al. 2006; D'Spain et al. 2006) has raised concern about the possibility that seismic surveys might at times have similar effects.

Ce qui préoccupe chez les cétacés, en particulier chez les baleines à bec, est que les lésions des tissus et les échouements d'animaux vivants seraient provoqués par des niveaux sonores captés plus faibles que prévu et, en particulier, plus faibles que ceux qui produisent des dommages auditifs (voir notamment l'analyse de Dolman et Simmonds, 2006). Devant les preuves s'accumulant qu'un sonar à moyenne fréquence aurait joué un rôle dans l'échouement et la mort de baleines à bec (Cox *et al.*, 2006; D'Spain *et al.*, 2006), on craint que les levés sismiques puissent parfois avoir des effets analogues.

Seismic pulses and mid-frequency sonar signals are quite different. Sounds produced by airgun arrays are broadband impulses with most of the energy below 1 kHz. Typical military mid-frequency sonars emit non-impulse sounds at frequencies of 2–10 kHz, generally with a relatively narrow bandwidth at any one time (though the frequency may change over time). Thus, it is not appropriate to assume that there is a direct connection between the effects of military sonar and seismic surveys on marine mammals. However, evidence that sonar signals can, in special circumstances, lead (at least indirectly) to physical damage and mortality (e.g., Jepson et al. 2003; Fernández et al. 2004, 2005a; Cox et al. 2006) suggests that caution is warranted when dealing with exposure of marine mammals to any high-intensity pulsed sound.

Les impulsions sismiques et les signaux sonars de moyenne fréquence sont très différents. Les sons produits par les batteries de canons à air sont des impulsions large bande, dont l'essentiel de l'énergie est émise sous 1 kHz. Les sonars militaires de moyenne fréquence émettent habituellement des signaux non impulsionnels à des fréquences d'entre 2 et 10 kHz, en général dans une bande plutôt étroite à un moment donné (mais la fréquence peut changer avec le temps). Ainsi, il ne convient pas de présumer qu'il y a un lien direct entre les effets des sonars militaires et ceux des dispositifs sismiques sur les mammifères marins. Cela dit, les indications selon lesquelles les signaux sonars peuvent mener, dans des circonstances particulières, du moins indirectement, à des dommages physiques et à des décès (voir notamment Jepson *et al.*, 2003; Fernández *et al.*, 2004, 2005a; Cox *et al.*, 2006) incitent à la prudence lorsqu'il est question d'exposer les mammifères marins à toute impulsion sonore de forte

There is no conclusive evidence of cetacean strandings as a result of exposure to seismic surveys. Speculation concerning a possible link between seismic surveys and strandings of humpback whales in Brazil (Engel et al. 2004) was not well founded (International Association of Geophysical Contractors [IAGC] 2004; International Whaling Commission [IWC] 2007). In September 2002, there was a stranding of two Cuvier's beaked whales in the Gulf of California, Mexico, when the Lamont-Doherty Earth Observatory (L-DEO) seismic vessel R/V Maurice Ewing was operating a 20-airgun, 8490-in^3 airgun array in the area. It is uncertain when the whales came ashore and thus, how close the seismic vessel had been when the whales stranded. However, the seismic vessel was on a survey line approaching the stranding site and had a closest point of approach of 33.3 km around the time the live-stranded beaked whales were discovered by fishermen (Hildebrand 2005). The link between the stranding and the seismic surveys was inconclusive and not based on any physical evidence (Hogarth 2002; Yoder 2002). Nonetheless, that plus the incidents involving beaked whale strandings near naval exercises involving use of mid-frequency sonar suggests a need for caution in conducting seismic surveys in areas occupied by beaked whales.

Hearing Impairment

DFO (2004a) determined that the significance of TTS effects, were they to occur, are likely to be unimportant, unless it resulted in PTS; or other threats that normally could be avoided by acoustic means, such as those from predators or entanglement in fishing gear, occur concurrently.

Temporary or permanent hearing

intensité.

Il n'y a pas de preuve concluante que des cétacés se seraient échoués après avoir été exposés à des bruits sismiques. L'hypothèse d'un lien possible entre des levés sismiques et l'échouement de rorquals à bosse au Brésil (Engel *et al.*, 2004) n'était pas bien fondée (International Association of Geophysical Contractors [IAGC], 2004; International Whaling Commission [IWC], 2007). En septembre 2002, deux baleines à bec de Cuvier se sont échouées dans le golfe de Californie, sur les côtes mexicaines, au moment où le navire sismique *Maurice Ewing* de l'observatoire terrestre Lamont-Doherty (L-DEO) effectuait des tirs au moyen d'une batterie de 20 canons à air de 8 490 po^3 dans le secteur. On ne sait pas avec exactitude quand les baleines se sont échouées et donc à quelle distance se trouvait le navire sismique. Toutefois, celui-ci se trouvait sur une ligne de levé approchant le site d'échouement et son point de rapprochement maximal était de 33,3 km vers le moment où des pêcheurs ont découvert les baleines échouées encore vivantes (Hildebrand, 2005). Le rapport établi entre l'échouement et les études sismiques n'était pas concluant, et aucune preuve matérielle ne le corroborait (Hogarth, 2002; Yoder, 2002). Néanmoins, cet incident et les échouements de baleines à bec dans les parages de sites d'exercices navals faisant appel à des sonars de moyenne fréquence incitent à la prudence lorsqu'on effectue des levés sismiques dans des secteurs occupés par des baleines à bec.

Perte d'audition

D'après le MPO (2004a), le degré d'importance des effets d'élévation temporaire du seuil auditif, s'ils se produisent, est probablement insignifiant, à moins qu'ils résultent en un déplacement permanent du seuil ou que se matérialisent au même moment d'autres menaces que les mammifères marins évitent normalement par des moyens acoustiques, notamment des prédateurs ou des engins de pêche dans lesquels ils s'enchevêtrent.

Une perte temporaire ou permanente d'audition

impairment is a possibility when marine mammals are exposed to very strong sounds (Goold and Coates 2006), and temporary threshold shift (TTS) has been demonstrated and studied in certain captive odontocetes and pinnipeds exposed to strong sounds (reviewed in Southall et al. 2007). However, there has been no specific documentation that TTS let alone PTS occurs when marine mammals are exposed to sequences of airgun pulses under realistic field conditions. Current U.S. National Marine Fisheries Service (NMFS) policy regarding exposure of marine mammals to high-level sounds is that, for situations under U.S. jurisdiction, cetaceans and pinnipeds should not be exposed to impulsive sounds with received levels ≥180 and 190 dB re 1 μPa_{rms} respectively (NMFS 2000). Those criteria have been used in establishing the safety (=shutdown) radii for numerous seismic surveys in both U.S. and Canadian waters. However, those criteria were established before there was any information about the minimum received levels of sounds necessary to cause auditory impairment in marine mammals. As discussed below,

- the 180-dB criterion for cetaceans is probably quite precautionary, i.e. lower than necessary to avoid temporary threshold shift (TTS), let alone permanent auditory injury, at least for delphinids and similar species for which TTS measurements are available;

- the 190-dB criterion for pinnipeds may not be as precautionary, at least for harbour seals; there are indications that the TTS threshold in the harbour seal is lower than in odontocetes (Southall et al. 2007:443);

- the level associated with the onset

est possible quand les mammifères marins sont exposés à des sons très forts (Goold et Coates, 2006). On a montré et étudié un déplacement temporaire de seuil (ou TTS, de l'anglais *temporary threshold shift*) chez certains odontocètes et pinnipèdes en captivité qui avaient été exposés à des sons forts (analyse de Southall *et al.*, 2007). Cela dit, on ne trouve aucune indication précise dans la documentation d'une perte d'audition temporaire et encore moins permanente chez les mammifères marins exposés à des séquences d'impulsions provenant de canons à air dans des conditions réalistes d'emploi. La politique en vigueur du National Marine Fisheries Service (NMFS) des États-Unis concernant l'exposition des mammifères marins à des niveaux sonores élevés précise que, dans les situations qui ressortissent aux États-Unis, les cétacés et les pinnipèdes ne devraient pas être exposés à des impulsions sonores dont les niveaux perçus seraient respectivement de ≥ 180 et 190 décibels rapportés à une pression efficace de 1 micropascal (expression notée dB re 1 μPa_{rms}) (NMFS, 2000). Ces critères ont servi à définir le rayon de sécurité (= arrêt) de nombreux levés sismiques dans les eaux canadiennes et américaines. Cependant, ils ont été établis avant qu'on dispose d'informations sur les niveaux sonores minimaux de réception nécessaires pour occasionner une perte d'audition chez les mammifères marins. Comme il est indiqué plus bas,

- Le critère de 180 dB pour les cétacés est probablement très prudent, c.-à-d. inférieur au niveau nécessaire pour éviter un TTS, à plus forte raison une perte d'audition permanente, du moins chez les delphinidés et espèces similaires pour lesquelles on dispose de mesures de TTS.

- Le critère de 190 dB à l'égard des pinnipèdes n'est peut-être pas aussi prudent, du moins pour les phoques communs; il semble que le TTS se produise à un niveau inférieur chez le phoque commun que chez les odontocètes (Southall *et al.*, 2007:443).

- Le niveau à partir duquel se produit un

of TTS is often considered to be a level below which there is no danger of permanent damage; TTS is a normal and temporary phenomenon occurring when animals (and humans) are exposed to strong sounds, and it does not constitute injury (e.g., Kryter 1985; Southall et al. 2007).

- the minimum sound level necessary to cause permanent threshold shift (PTS) is higher, by a variable and generally unknown amount, than the level that induces barely-detectable TTS; the actual PTS threshold is likely to be well above the level causing onset of TTS (Southall et al. 2007).

NMFS is developing new noise exposure criteria for marine mammals that account for the available scientific data on TTS, the expected offset between the TTS and PTS thresholds, differences in the acoustic frequencies to which different marine mammal groups are sensitive, and other relevant factors. Preliminary information about this process, and about the possible structure of the new criteria, was given by NMFS (2005); D. Wieting in http://mmc.gov/sound/plenary2/pdf/plenary2summaryfinal.pdf; and Miller et al. (2005b). Detailed recommendations for new science-based noise exposure criteria for marine mammals, frequency weighting procedures, and related matters were published in early 2008 (Southall et al. 2007).

Southall et al. (2007) suggest that thresholds for injury (and behavioural responses) should be examined separately for five functional hearing groups: low-frequency cetaceans (mysticetes, for which the functional

TTS est souvent considéré comme un niveau en deçà duquel il n'y a pas de danger de dommage permanent; le TTS est un phénomène normal et provisoire qui se produit lorsque des animaux (et des humains) sont exposés à des bruits forts, et il ne constitue pas une lésion (voir notamment Kryter, 1985; Southall *et al.*, 2007).

- Le niveau sonore minimal nécessaire pour entraîner un déplacement permanent de seuil (ou PTS, de l'anglais *permanent threshold shift*) est plus élevé – la différence varie et elle est mal connue – que le niveau qui provoque un TTS à peine décelable; en réalité, la limite inférieure de la perte d'audition permanente est vraisemblablement beaucoup plus élevée que celle d'une perte d'audition temporaire (Southall et *al.*, 2007).

Le NMFS définit de nouveaux critères d'exposition au bruit chez les mammifères marins qui tiennent compte des informations scientifiques dont on dispose maintenant sur le TTS, l'écart attendu entre le niveau d'apparition d'une perte d'audition temporaire et celui d'une perte permanente, les différences de fréquences acoustiques auxquels divers groupes de mammifères marins sont sensibles et d'autres facteurs pertinents. le NMFS (2005), D. Wieting (http://mmc.gov/sound/plenary2/pdf/plenary2summaryfinal.pdf) et Miller *et al.* (2005b) ont donné les renseignements préliminaires sur la démarche et sur la structure possible des nouveaux critères. Des recommandations détaillées ont été publiées au début de 2008 (Southall *et al.*, 2007) au sujet des nouveaux critères scientifiques d'exposition au bruit chez les mammifères marins, des procédés de pondération des fréquences et de sujets connexes.

Selon Southall *et al.* (2007), les valeurs limites conduisant à des atteintes physiologiques (et à des modifications de comportement) devraient être examinées séparément pour cinq groupes d'acuité auditive : cétacés basse fréquence (mysticètes, dont le champ fonctionnel

hearing range is concluded to be 7 Hz to 22 kHz); mid-frequency cetaceans (the majority of odontocetes, 150 Hz to 160 kHz); high-frequency cetaceans (remaining odontocetes, 200 Hz to 180 kHz); pinnipeds in water (75 Hz to 75 kHz) and pinnipeds in air (75 Hz to 30 kHz). This review discusses low-frequency cetaceans (mysticetes), mid- and high-frequency cetaceans collectively, under "odontocetes", and pinnipeds in water. Seismic surveys are assumed to be of little relevance to "pinnipeds in air".

d'audibilité se situerait entre 7 Hz et 22 kHz), moyenne fréquence (la plupart des odontocètes; champ entre 150 Hz et 160 kHz) et haute fréquence (le reste des odontocètes; champ entre 200 Hz et 180 kHz), les pinnipèdes dans l'eau (entre 75 Hz et 75 kHz) et les pinnipèdes dans l'air (entre 75 Hz et 30 kHz). Nous examinons les cétacés basse (mysticètes), moyenne et haute fréquences collectivement dans la catégorie « odontocètes » ainsi que les pinnipèdes dans l'eau. Nous supposons que les levés sismiques touchent peu les « pinnipèdes dans l'air ».

Several aspects of the monitoring and mitigation measures that are now often implemented during seismic survey projects are designed to detect marine mammals occurring near the airgun array, and to avoid exposing them to sound pulses that might, at least in theory, cause hearing impairment (e.g., Barlow and Gisiner 2006; Holst et al. 2006; McCauley and Hughes 2006; Weir and Dolman 2007). In addition, many cetaceans show some avoidance of the area with ongoing seismic operations (see Displacement and Migratory Diversion section, below). In these cases, the avoidance responses of the animals themselves will reduce or (most likely) avoid the possibility of hearing impairment.

Plusieurs aspects des mesures de surveillance et d'atténuation des effets qui sont maintenant souvent appliquées au cours des campagnes sismiques sont destinés à déceler la présence de mammifères marins près des batteries de canons à air et à éviter d'exposer ces animaux à des impulsions sonores qui pourraient, du moins en théorie, causer une baisse d'audition (voir notamment Barlow et Gisiner, 2006; Holst *et al.*, 2006; McCauley et Hughes, 2006; Weir et Dolman, 2007). En outre, de nombreux cétacés évitent la zone des tirs sismiques (voir plus bas la section « Déplacement et déviation des voies migratoires »). Dans ces cas, la réaction d'évitement des animaux réduira ou (très probablement) annulera la possibilité d'une perte d'audition.

Temporary Threshold Shift (TTS).—TTS is the mildest form of hearing impairment that can occur during exposure to a strong sound (Kryter 1985). While experiencing TTS, the hearing threshold rises and a sound must be stronger in order to be heard. At least in terrestrial mammals, TTS can last from minutes or hours to (in cases of strong TTS) days. For sound exposures at or somewhat above the TTS threshold, hearing sensitivity in both terrestrial and marine mammals recovers rapidly after exposure to the noise ends. TTS is not considered an injury (Southall et al. 2007). Few data on sound levels and durations necessary to elicit mild TTS have been obtained for marine mammals,

Déplacement temporaire de seuil (TTS) – le TTS est la forme la plus légère de déficit auditif que peut produire l'exposition à un son fort (Kryter, 1985). Il s'agit d'une élévation récupérable du seuil d'audition; le son doit alors être plus fort pour être entendu. Chez les mammifères terrestres, du moins, le TTS peut durer des minutes ou des heures, voire (dans les cas d'un TTS prononcé) des jours. Chez les mammifères terrestres et marins, si le bruit est égal ou légèrement supérieur à celui qui provoque la perte temporaire d'audition, la sensibilité auditive est rapidement récupérée une fois que l'exposition au bruit cesse. Le TTS n'est pas considéré comme une atteinte physiologique (Southall *et al.*, 2007). On a obtenu peu de données sur les niveaux et les durées du son nécessaires pour produire un

and none of the published data concern TTS elicited by exposure to multiple pulses of sound. Available data on TTS in marine mammals are reviewed in some detail by Southall et al. (2007).

faible TTS chez les mammifères marins, et aucune information publiée ne concerne le TTS provoqué par l'exposition à des impulsions sonores multiples. Southall *et al.* (2007) analysent dans un certain détail les données disponibles sur le TTS chez les mammifères marins.

Mysticetes: There are no data, direct or indirect, on levels or properties of airgun (or other) sounds that are required to induce TTS in mysticetes. The frequencies to which mysticetes are most sensitive are lower than those to which odontocetes are most sensitive, and natural background noise levels at those low frequencies tend to be higher. As a result, auditory thresholds of baleen whales within their frequency band of best hearing are believed to be higher (less sensitive) than are those of odontocetes at their best frequencies (Clark and Ellison 2004). From this, it is suspected that received levels causing TTS onset may also be higher in mysticetes than in odontocetes. In any case, Southall et al. (2007) conclude that it would be precautionary to assume that TTS would not occur in mysticetes at received levels any lower than those causing TTS in odontocetes.

Mysticètes : Il n'y a pas de données, directes ou indirectes, sur les niveaux ou les propriétés des sons produits par des canons à air (ou d'autres sources) qui produiront un TTS chez les mysticètes. Les fréquences auxquelles les mysticètes sont le plus sensibles sont inférieures à celles auxquelles les odontocètes sont le plus sensibles, et les niveaux sonores de fond à ces basses fréquences tendent à être plus élevés. Par conséquent, on croit que les seuils d'audition des baleines à fanons dans la plage des fréquences qu'ils entendent le mieux sont plus élevés (sensibilité moindre) que les seuils des odontocètes aux fréquences qu'elles entendent le mieux (Clark et Ellison, 2004). Ce qui amène à présumer que les niveaux perçus qui occasionnent un TTS pourraient aussi être plus élevés chez les mysticètes que chez les odontocètes. En tout cas, Southall *et al.* (2007) concluent qu'il serait prudent de supposer que le TTS ne se produira pas chez les mysticètes à un niveau perçu plus faible que celui qui cause un TTS chez les odontocètes.

Odontocetes: There are empirical data on the sound exposures that elicit onset of TTS in captive bottlenose dolphins and belugas. The majority of these data concern non-impulse sound, but there are some limited published data concerning TTS onset upon exposure to a single pulse of sound from a watergun (Finneran et al. 2002). A detailed review of these data can be found in Southall et al.(2007). The following summarizes some of the key results.

Odontocètes : Il existe des données empiriques sur les expositions au bruit qui provoquent le TTS chez les dauphins à gros nez et les bélugas en captivité. L'essentiel des données porte sur les bruits non impulsionnels, mais quelques données ont été publiées sur le TTS provoqué par l'exposition à une seule impulsion provenant d'un canon à eau (Finneran *et al.*, 2002). Southall *et al.* (2007) font un examen détaillé de ces données. Voici un résumé des principaux résultats.

There is recent information corroborating earlier expectations that the effect of exposure to strong transient sounds is closely related to the total amount of acoustic energy that is received. Finneran et al.(2005) examined the effects of tone duration on TTS in bottlenose dolphins.

Des informations récentes corroborent les prévisions antérieures que l'effet de l'exposition à de forts bruits transitoires est étroitement lié à la quantité totale d'énergie acoustique captée. Finneran *et al.* (2005) ont examiné les effets de la durée du signal sonore sur le TTS chez les dauphins à gros nez. Les dauphins à gros nez

Bottlenose dolphins were exposed to 3 kHz tones for periods of 1, 2, 4 or 8 s, with hearing tested at 4.5 kHz. For 1-s exposures, TTS occurred with SELs of 197 dB, and for exposures >1 s, SEL ≥195 dB resulted in TTS. (SEL is equivalent to energy flux, in dB re 1 $\mu Pa^2 \cdot s$) At an SEL of 195 dB, the mean TTS (4 min after exposure) was 2.8 dB. Finneran et al. (2005) suggested that an SEL of 195 dB is the likely threshold for the onset of TTS in dolphins and beluga exposed to mid-frequency tones of durations 1-8 s (i.e., TTS onset occurs at a near-constant SEL, independent of exposure duration). That implies that a doubling of exposure time results in a 3 dB lower TTS threshold.

ont été exposés à des signaux de 3 kHz pour des périodes de 1, 2, 4 ou 8 secondes, et on a testé leur ouïe à 4,5 kHz. Le TTS se produisait à un niveau d'exposition sonore (SEL – *sound exposure level*) de 197 dB à 1 seconde. Dans le cas d'expositions plus longues (>1 s), un SEL ≥195 dB produisait un TTS. (Le SEL équivaut au flux d'énergie en dB re 1 $\mu Pa^2 \cdot s$). À un SEL de 195 dB, le TTS moyen (4 minutes après l'exposition) était de 2,8 dB. Finneran *et al.* (2005) ont avancé qu'un SEL de 195 dB est le niveau probable d'apparition du TTS chez les dauphins et les bélugas exposés à des signaux sonores de fréquence moyenne et d'une durée d'entre 1 et 8 secondes (c.-à-d. que le TTS se produit à un SEL presque constant, indépendamment de la durée d'exposition). Ainsi, doubler la durée d'exposition abaisse de 3 dB le seuil de perte d'audition temporaire.

Mooney *et al.* (2005) exposed a bottlenose dolphin to octave-band noise ranging from 4 to 8 kHz at SPLs of 160 to 172 dB re 1 µPa for periods of 1.8 to 30 min. Recovery time depended on the shift and frequency, but full recovery always occurred within 40 min. Consistent with the results of Finneran et al.(2005) based on shorter exposures, Mooney *et al.* reported that to induce TTS in a bottlenose dolphin, there is an inverse relationship of exposure time and SPL; as a first approximation, as exposure time was halved, an increase in noise SPL of 3 dB was required to induce the same amount of TTS. In other words, for toothed whales receiving single short exposures to non-impulse sound, the TTS threshold appears to be, to a first approximation, a function of the total energy received (Finneran et al. 2002, 2005).

Mooney *et al.* (2005) ont exposé un dauphin à gros nez à des niveaux sonores par bandes d'octaves d'entre 4 et 8 kHz à un niveau de pression acoustique (SPL – *sound pressure level*) de 160 à 172 dB re 1 µPa pour des périodes de 1,8 à 30 min. Le temps de récupération dépendait du décalage et de la fréquence, mais la récupération était toujours complète dans les 40 minutes. Mooney *et al.* ont indiqué que pour produire le TTS chez le dauphin à gros nez, il y avait un rapport inverse entre la durée d'exposition et le SPL, ce qui vient confirmer les résultats de Finneran *et al.* (2005) obtenus après des expositions plus courtes; comme approximation première, en réduisant de moitié la durée d'exposition, il fallait augmenter la pression acoustique de 3 dB pour provoquer le même TTS. En d'autres mots, dans le cas des baleines à dents soumises à une exposition courte à des signaux non impulsionnels, le seuil de perte d'audition temporaire semble être, à première approximation, fonction de l'énergie totale perçue (Finneran *et al*., 2002, 2005).

The TTS threshold for odontocetes exposed to a single impulse (from a watergun) appeared to be somewhat lower than for exposure to non-impulse sound. This was expected, based on evidence from terrestrial mammals showing that broadband pulsed sounds

Chez des odontocètes exposés à une impulsion unique (d'un canon à eau), le TTS se serait produit à un niveau un peu inférieur que dans le cas d'une exposition à un signal non impulsionnel. C'est ce que laissaient présager les données obtenues à l'égard de mammifères terrestres, qui indiquaient que les impulsions en

with rapid rise times have greater auditory effect than do non-impulse sounds (Southall *et al.* 2007). The received energy level of a single seismic pulse that caused the onset of mild TTS in the beluga, as measured without frequency weighting, was ~186 dB re 1 $\mu Pa^2 \cdot s$ or 186 dB SEL (Finneran et al. 2002)[1]. Given that the rms level of an airgun pulse (in dB re 1 µPa measured over the duration of the pulse) is typically 10–15 dB higher than the SEL for the same pulse, a single airgun pulse might need to have a received level of ~196–201 dB re 1 μPa_{rms} in order to produce brief, mild TTS. Exposure to several strong seismic pulses that each have received levels near 190 dB_{rms} (175–180 dB SEL) could result in cumulative exposure of ~186 dB SEL and thus slight TTS in a small odontocete, assuming that the TTS threshold upon exposure to multiple pulses is (to a first approximation) a function of the total received pulse energy.

bande large avec front de montée rapide ont un effet plus grand sur l'audition que des signaux non impulsionnels (Southall *et al.*, 2007). Le niveau d'énergie perçu d'une impulsion sismique unique ayant causé un léger TTS chez le béluga, mesuré sans pondération de fréquence, était de ~186 dB re 1 $\mu Pa^2 \cdot s$ ou de 186 dB SEL (Finneran *et al.*, 2002)[1]. Comme le niveau efficace (ou niveau rms, de l'anglais *root mean square*) d'une impulsion de canon à air (en dB re 1 µPa mesuré sur la durée de l'impulsion) est habituellement plus élevé de 10 à 15 dB que le niveau d'exposition sonore (SEL) pour la même impulsion, pour qu'une unique impulsion de canon à air produise un léger et bref TTS, il faudrait peut-être que le niveau perçu soit d'environ 196 à 201 dB re 1 μPa_{rms}. L'exposition à plusieurs impulsions sismiques fortes dont chacune aurait un niveau perçu approchant 190 dB_{rms} (175-180 dB SEL) pourrait donner une exposition cumulée de ~186 dB SEL et donc produire un léger TTS chez un petit odontocète, en supposant que la valeur d'apparition d'une perte d'audition temporaire sous l'effet d'une exposition à des impulsions multiples est (en première approximation) fonction de l'énergie impulsionnelle totale captée.

Insofar as we are aware, there are no published data confirming that the auditory effect of a sequence of airgun pulses received by an odontocete is a function of their cumulative energy. Southall et al. (2007) consider that to be a reasonable, but probably somewhat precautionary, assumption. It is precautionary because, based on data from terrestrial mammals, one would expect that a given energy exposure would have somewhat less effect if separated into discrete pulses, with potential opportunity for partial auditory recovery between pulses. However, as

Pour autant que nous sachions, aucune donnée n'a été publiée confirmant que l'effet auditif d'une séquence d'impulsions de canon à air perçues par un odontocète soit fonction de leur énergie cumulée. Southall *et al.* (2007) considèrent l'hypothèse raisonnable, bien que probablement un peu prudente. Prudente, parce que, d'après les données sur les mammifères terrestres, on s'attendrait à ce que l'exposition à une énergie donnée ait un effet moindre si on la divise entre des impulsions distinctes, avec possibilité de récupération partielle de l'audition entre les impulsions. Cependant, la vitesse de récupération du TTS chez les mammifères marins a encore été très

[1] *If the low-frequency components of the watergun sound used in the experiments of Finneran et al. (2002) are downweighted as recommended by Miller et al. (2005a) and Southall et al. (2007) using their M_{mf}-weighting curve, the effective exposure level for onset of mild TTS was 183 dB re 1 $\mu Pa^2 \cdot s$ (Southall et al. 2007).*

[1] *Si on sous-pondère les éléments basse fréquence du signal émis par le canon à eau dans les expériences de Finneran et al. (2002), comme le recommandent Miller et al. (2005a) et Southall et al. (2007) au moyen de leur courbe de pondération M_{mf}, le niveau effectif d'exposition provoquant un léger TTS était de 183 dB re 1 $\mu Pa^2 \cdot s$ (Southall et al., 2007).*

yet there has been little study of the rate of recovery from TTS in marine mammals, and in humans and other terrestrial mammals the available data on recovery are quite variable. Southall et al. (2007) conclude that - until relevant data on recovery are available from marine mammals - it is appropriate to not to allow for any assumed recovery during the intervals between pulses within a pulse sequence.

peu étudiée, et les données disponibles pour les humains et d'autres mammifères terrestres varient beaucoup. Southall *et al.* (2007) ont conclu qu'il convient – jusqu'à ce qu'on dispose des données utiles sur la récupération chez les mammifères marins – de ne pas supposer qu'il y a récupération dans les intervalles entre les impulsions d'une séquence.

The above TTS information for odontocetes is derived from studies on the bottlenose dolphin and beluga. There is no published TTS information for other types of cetaceans. However, preliminary evidence from a harbour porpoise exposed to airgun sound suggests that its TTS threshold may have been lower (Lucke et al. 2007).

Les informations précitées au sujet du TTS chez les odontocètes proviennent d'études sur le dauphin à gros nez et le béluga. Il n'y a pas de renseignements publiés au sujet du TTS chez d'autres types de cétacés. Néanmoins, les indications préliminaires de l'exposition d'un marsouin commun aux signaux d'un canon à air laissent à penser que la valeur limite du TTS pourrait être plus basse (Lucke *et al.*, 2007).

Additional data are needed to determine the received sound levels at which small odontocetes would start to incur TTS upon exposure to repeated, low-frequency pulses of airgun sound with variable received levels. At the present state of knowledge, it is necessary to assume that the effect is directly related to total energy even though that energy is received in multiple pulses separated by gaps.

Il faut recueillir plus d'informations pour déterminer la limite d'apparition d'un TTS chez des petits odontocètes exposés à des impulsions basse fréquence répétées d'un canon à air, étant donné des niveaux perçus variés. En l'état actuel des connaissances, il faut supposer que l'effet est directement lié à l'énergie totale, même si cette énergie est reçue sous forme d'impulsions multiples séparées par des intervalles.

Pinnipeds: In pinnipeds, TTS thresholds associated with exposure to brief pulses (single or multiple) of underwater sound have not been measured. Initial evidence from more prolonged (non-pulse) exposures suggested that some pinnipeds (harbour seals in particular) incur TTS at somewhat lower received levels than do small odontocetes exposed for similar durations (Kastak et al. 1999, 2005; Ketten et al. 2001). Kastak et al. (2005) reported that the amount of threshold shift increased with increasing SEL in a California sea lion and harbour seal. They noted that, for non-impulse sound, doubling the exposure duration from 25 to 50 min (i.e., a +3 dB change in SEL) had a greater effect on TTS than an increase of 15 dB (95 vs. 80 dB) in

Pinnipèdes : On n'a pas mesuré chez les pinnipèdes le seuil de perte d'audition temporaire associé à l'exposition à de brèves impulsions sonores (uniques ou multiples) sous l'eau. Selon les premières données disponibles sur des expositions plus longues à des signaux non impulsionnels, certains pinnipèdes (le marsouin commun en particulier) éprouvent un TTS à un niveau perçu légèrement inférieur à celui qui provoque une perte d'audition temporaire chez de petits odontocètes exposés pour une durée analogue (Kastak *et al.*, 1999, 2005; Ketten *et al.*, 2001). Kastak *et al.* (2005) indiquent que le déplacement du seuil avait augmenté en même temps que le niveau d'exposition sonore chez une otarie de Californie et un marsouin commun. Ces auteurs ont remarqué que, dans le cas de

exposure level. Mean threshold shifts ranged from 2.9–12.2 dB, with full recovery within 24 hr (Kastak et al. 2005). Kastak et al. (2005) suggested that, for non-impulse sound, SELs resulting in TTS onset in pinnipeds may range from 183 to 206 dB re 1 $\mu Pa^2 \cdot s$, depending on the absolute hearing sensitivity.

signaux non impulsionnels, doubler la durée d'exposition de 25 à 50 minutes (c.-à-d. une augmentation du SEL de +3 dB) avait un plus grand effet sur le TTS que l'augmentation de 15 dB (95 dB plutôt que 80) du niveau d'exposition. Les déplacements moyens de seuil allaient de 2,9 à 12,2 dB, l'ouïe se rétablissant complètement dans les 24 heures (Kastak *et al.*, 2005). Kastak *et al.* (2005) avancent que, dans le cas de signaux non impulsionnels, les SEL qui provoquent l'apparition de TTS chez les pinnipèdes se situeraient entre 183 et 206 dB re 1 $\mu Pa^2 \cdot s$, le niveau variant selon la sensibilité auditive absolue.

As noted above for odontocetes, it is expected that—for impulse sound—the onset of TTS would occur at a lower cumulative SEL given the assumed greater auditory effect of broadband impulses with rapid rise times. The threshold for onset of mild TTS upon exposure of a harbour seal to impulse sounds has been indirectly estimated as being an SEL of ~171 dB re 1 $\mu Pa^2 \cdot s$ (Southall et al. 2007). That would be equivalent to a single pulse with received level ~181–186 dB re 1 μPa_{rms}, or a series of pulses for which the highest rms values are a few dB lower.

Comme dans le cas précité des odontocètes, on s'attend à ce que le TTS apparaisse, sous l'effet d'impulsions, à un SEL cumulatif inférieur, puisqu'on prête aux impulsions en bande large, dont le temps de montée est très bref, un plus grand effet sur l'audition. On a estimé indirectement le niveau d'exposition sonore à partir duquel apparaît un léger TTS chez un phoque commun exposé à des signaux impulsionnels à SEL de ~171 dB re 1 $\mu Pa^2 \cdot s$ (Southall *et al.*, 2007). Voilà qui équivaudrait à une impulsion unique avec niveau perçu de ~181–186 dB re 1 $\mu Pa_{rms,}$ ou à une série d'impulsions pour lesquelles les valeurs efficaces les plus fortes sont inférieures de quelques décibels.

At least for non-impulse sounds, TTS onset occurs at appreciably higher received levels in California sea lions and northern elephant seals than in the harbour seal (Kastak et al. 2005). Thus, the first two species would presumably need to be closer to airgun array before TTS would be a possibility. Insofar as we are aware, there are no data to indicate whether the TTS thresholds of other pinniped species are more similar to those of the harbour seal or to those of the two less-sensitive species.

Au moins dans le cas des signaux non impulsionnels, le TTS apparaît à des niveaux perçus sensiblement plus élevés chez l'otarie de Californie et l'éléphant de mer boréal que chez le phoque commun (Kastak *et al.*, 2005). Ainsi, il faudrait sans doute que les deux premières espèces soient plus près de la batterie de canons à air pour qu'un TTS soit possible. Pour autant que nous sachions, on ne dispose pas de données indiquant si la valeur limite du TTS chez d'autres espèces de pinnipèdes s'approche davantage de celles du phoque commun que de celles des deux espèces moins sensibles.

Fissipeds: There are no available data on TTS in sea otters and polar bears. However, TTS is considered unlikely to

Fissipèdes : Il n'y a pas de données sur le TTS chez les loutres de mer et les ours blancs. Cela étant, on considère peu probable qu'ils

occur in sea otters or polar bears if they are on the water surface, given the pressure release effect at the water's surface. Furthermore, sea otters tend to inhabit shallow coastal habitats whereas marine seismic surveys are generally conducted within deeper offshore areas.

Likelihood of Incurring TTS from Airgun Pulses: DFO (2004a) concluded that the significance of TTS on marine mammals exposed to seismic surveys is likely to be unimportant. Most cetaceans show some degree of avoidance of seismic vessels operating an airgun array. It is unlikely that these cetaceans would be exposed to airgun pulses at a sufficiently high level for a sufficiently long period to cause more than mild TTS, given the relative movement of the vessel and the marine mammal. TTS would be more likely in any odontocetes that bow- or wake-ride or otherwise linger near the airguns. However, while bow- or wake-riding, odontocetes would be near the surface where levels of sound pulses are reduced by pressure-release and Lloyd-mirror (interference) effects (see Appendix A). But if bow- or wake-riding animals were to dive intermittently near airguns, they would be exposed to strong sound pulses, possibly repeatedly. If some cetaceans did incur mild or moderate TTS through exposure to airgun sounds in this manner, this would very likely be a temporary and reversible phenomenon. However, it should be noted that even a temporary reduction in hearing sensitivity could be deleterious in the event that, during that period of reduced sensitivity, a marine mammal needed its full hearing sensitivity to detect approaching predators, or for some other reason.

Some pinnipeds show avoidance reactions to airguns, but their avoidance reactions are not as strong or consistent as those of cetaceans. Pinnipeds occasionally seem to be attracted to operating seismic vessels. There are no specific data on TTS thresholds of

subissent un TTS s'ils sont à la surface de l'eau, étant donné la détente de la pression dans l'air. Par ailleurs, les loutres de mer privilégient les habitats côtiers peu profonds, alors que les études sismiques s'effectuent généralement dans les zones plus profondes du large.

Probabilité d'un TTS provoqué par les impulsions d'un canon à air : Le MPO (2004a) a conclu que le degré d'importance des effets des levés sismiques sur le seuil d'audition des mammifères marins exposés serait probablement négligeable. La plupart des cétacés cherchent à éviter les navires sismiques qui font fonctionner une batterie de canons à air. Il est peu probable qu'ils soient exposés à des impulsions assez fortes sur une période assez longue pour leur occasionner davantage qu'un léger TTS, vu le déplacement des navires et des mammifères les uns par rapport aux autres. Le TTS serait plus probable chez les odontocètes qui nagent dans les vagues d'étrave ou le sillage des navires ou qui traînent autrement près des canons à air. Cependant, les odontocètes qui se laissent porter par la vague d'étrave ou nagent dans le sillage d'un navire se trouveraient près de la surface, où les impulsions sont réduites en raison des effets de détente et du miroir de Lloyd (interférences) (voir l'annexe A). Par contre, si ces animaux plongeaient par intermittence près des canons, ils seraient exposés à de fortes impulsions sonores, peut-être à répétition. S'il arrivait que certains cétacés subissent un TTS léger ou moyen suite à une exposition de ce genre aux tirs de canon à air, l'effet serait très probablement provisoire et réversible. Cela dit, il est à remarquer que même une réduction temporaire de la sensibilité auditive pourrait être néfaste si un mammifère marin avait besoin à ce moment-là de toute son acuité pour déceler l'approche de prédateurs ou pour une autre raison.

Certains pinnipèdes cherchent à éviter les canons à air, mais leurs réactions d'évitement ne sont pas aussi fortes ni aussi régulières que celles des cétacés. Les pinnipèdes semblent à l'occasion attirés par les navires sismiques en campagne. Il n'y a pas de données précises sur le niveau auquel

pinnipeds exposed to single or multiple low-frequency pulses. However, given the indications of a lower TTS threshold for the harbour seal than for odontocetes exposed to impulse sound (see above), it is possible that some pinnipeds close to a large airgun array could incur TTS.

apparaît le TTS chez les pinnipèdes exposés à des impulsions basse fréquence uniques ou multiples. Cependant, comme il semble que ce niveau soit plus faible chez le phoque commun que chez les odontocètes exposés à des impulsions sonores (voir plus haut), il est possible que certains pinnipèdes qui se trouvent à proximité d'une grosse batterie de canons à air subissent une perte d'audition temporaire.

NMFS (1995, 2000) concluded that cetaceans and pinnipeds should not be exposed to pulsed under-water noise at received levels exceeding, respectively, 180 and 190 dB re 1 μPa_{rms}. Those sound levels have not been considered to be the levels above which TTS might occur. Rather, they were the received levels above which, in the view of a panel of bioacoustics specialists convened by NMFS before TTS measurements for marine mammals started to become available, one could not be certain that there would be no injurious effects, auditory or otherwise, to marine mammals. As summarized above, data that are now available imply that TTS is unlikely to occur in various odontocetes (and probably mysticetes as well) unless they are exposed to a sequence of several airgun pulses stronger than 190 dB re 1 μPa_{rms}. On the other hand, for the harbour seal and any species with similarly low TTS thresholds (possibly including the harbour porpoise - Lucke et al. 2007), TTS may occur upon exposure to one or more airgun pulses whose received level equals the NMFS "do not exceed" value of 190 dB re 1 μPa_{rms}. That criterion corresponds to a single-pulse SEL of 175–180 dB re 1 $\mu Pa^2 \cdot s$ in typical conditions, whereas TTS is suspected to be possible (in harbour seals) with a cumulative SEL of ~171 dB re 1 $\mu Pa^2 \cdot s$.

Le NMFS (1995, 2000) a conclu que les cétacés et les pinnipèdes ne devraient pas être exposés à des impulsions sonores sous-marines dont le niveau perçu dépasserait, respectivement, 180 et 190 dB re 1 μPa_{rms}. Ces niveaux ***ne*** sont ***pas*** considérés comme les niveaux au-dessus desquels un TTS se produirait. Plutôt, il s'agissait des niveaux perçus au-dessus desquels on ne pouvait être certain qu'il n'y aurait pas d'atteintes, auditives ou autres, chez les mammifères marins, de l'avis d'un groupe de bioacousticiens réunis par le NMFS à l'époque où on ne disposait pas encore de mesures de TTS chez les mammifères marins. Comme nous le résumons plus haut, les données qui sont maintenant disponibles font croire que le TTS est peu probable chez divers odontocètes (et probablement chez les mysticètes aussi), à moins qu'ils soient exposés à une séquence de plusieurs impulsions de canon à air plus fortes que 190 dB re 1 $\mu Pa_{rms.}$ Par contre, le phoque commun et toute autre espèce chez qui le TTS apparaît à un niveau bas (y compris peut-être le marsouin commun – Lucke *et al.*, 2007), pourraient subir un TTS s'ils étaient exposés à une ou plusieurs impulsions de canon à air dont le niveau perçu égale la valeur « à ne pas dépasser » fixée par le NMFS de 190 dB re 1 $\mu Pa_{rms.}$ Ce critère correspond à un SEL d'impulsion unique de 175-180 dB re 1 $\mu Pa^2 \cdot s$ dans des conditions types, alors qu'on soupçonne que le TTS est possible (chez le phoque commun) à un SEL cumulatif de ~171 dB re 1 $\mu Pa^2 \cdot s$.

It has been shown that most large whales and many smaller odontocetes show at least localized avoidance of ships and associated seismic operations (see Displacement and Migratory Diversion section, below). Even when avoidance is

Il a été montré que la plupart des grandes baleines et bon nombre de petits odontocètes évitent, du moins de façon localisée, les navires et leurs signaux sismiques (voir plus loin la section « Déplacement et déviation des voies migratoires »). Même si l'animal se

limited to the area within a few hundred meters of an airgun array, that should usually be sufficient to avoid the possibility of TTS based on what is currently known about thresholds for TTS onset in cetaceans. In addition, ramping up airgun arrays, which is standard operational protocol for many seismic operators, should allow cetaceans near the airguns at the time of startup to move away from the seismic source and to avoid being exposed to the full acoustic output of the airgun array. Three species of baleen whales that have been exposed to the onset of pulses from single airguns showed avoidance, specifically gray whales [Malme et al. 1984, 1986, 1988]; bowhead whales [Richardson et al. 1986, Ljungblad et al. 1988] and humpback whales [Malme et al. 1985, McCauley et al. 1998, 2000a, b]. Since startup of a single airgun is equivalent to the start of a ramp-up (=soft-start), this strongly suggests that many baleen whales will begin to move away during the initial stages of a ramp-up. Thus, most baleen whales will likely not be exposed to high levels of airgun sounds provided the ramp-up procedure is applied. Likewise, many whales close to the trackline are likely to move away before the sounds from an approaching seismic vessel become sufficiently strong for there to be any potential for TTS or other hearing impairment. Therefore, there is little potential for baleen whales or odontocetes that show avoidance of ships or airguns to be close enough to an airgun array to experience TTS. The potential of a cetacean incurring TTS may be higher in confined areas (e.g., narrow coastal fjords) where options for avoiding a seismic vessel may be limited, or in animals (some odontocetes; many pinnipeds) that show little or no avoidance response. In the event that a few individual cetaceans did incur TTS through exposure to strong airgun sounds, this is a temporary and reversible phenomenon.

contente d'éviter le secteur dans un rayon de quelques centaines de mètres de la batterie de canons à air, cela devrait suffire à éviter un TTS, d'après ce qu'on sait maintenant du seuil de perte d'audition temporaire chez les cétacés. De plus, le démarrage progressif des tirs, qui fait partie du mode opératoire normalisé de beaucoup d'opérateurs sismiques, devrait permettre aux cétacés qui sont dans le voisinage au moment du démarrage de s'éloigner de la source sismique afin d'éviter d'être exposés à toute la puissance acoustique de la batterie. Trois espèces de baleines à fanons exposées aux premières impulsions d'un canon à air isolé ont montré un comportement d'évitement, précisément les *baleines grises* (Malme *et al.*, 1984, 1986, 1988), les *baleines boréales* (Richardson *et al.*, 1986; Ljungblad *et al.*, 1988) et les *rorquals à bosse* [Malme *et al.*, 1985; McCauley *et al.*, 1998, 2000a, b). Comme le démarrage d'un seul canon à air équivaut au démarrage progressif d'une batterie, ces résultats permettent bien de penser que de nombreuses baleines à fanons vont s'éloigner dans les premiers moments d'un démarrage progressif. Ainsi, la plupart des baleines à fanons ne seront vraisemblablement pas exposées aux sons puissants des tirs de canon à air, pour autant que le mode de démarrage progressif soit appliqué. De même, de nombreuses baleines se trouvant à proximité de la trajectoire s'éloigneront probablement avant que les signaux émis d'un navire sismique qui s'approche deviennent assez forts pour provoquer un TTS ou toute autre perturbation auditive. Par conséquent, il y a peu de risques que les baleines à fanons ou les odontocètes qui tendent à éviter les navires ou les canons à air s'en approchent assez près pour subir un TTS. Le risque qu'un cétacé subisse une perte d'audition temporaire est peut-être plus élevé en zone confinée (p. ex. dans les étroits fjords côtiers), où il est difficile d'éviter un navire sismique, ou chez les animaux (certains odontocètes et de nombreux pinnipèdes) qui ne montrent pas ou montrent peu de réactions d'évitement. S'il s'avérait que quelques individus chez les cétacés subissent un TTS par suite de l'exposition à de fortes détonations de canon à air, le phénomène serait provisoire et réversible.

Permanent Threshold Shift (PTS).— When PTS occurs, there is physical damage to the sound receptors in the ear. In severe cases, there can be total or partial deafness, whereas in other cases, the animal or human has an impaired ability to hear sounds in specific frequency ranges.

Déplacement permanent de seuil (PTS) – La perte d'audition permanente suppose qu'il y a lésion des organes de réception du son de l'oreille. Dans les cas graves, il survient une surdité partielle ou totale; autrement, l'animal, ou l'humain, a une capacité diminuée d'entendre les sons dans certaines plages de fréquence.

There is no specific evidence that exposure to pulses of airgun sound can cause PTS in any marine mammal, even with large arrays of airguns. However, given the possibility that some mammals close to an airgun array might incur TTS, there has been further speculation about the possibility that some individuals occurring very close to airguns might incur PTS. Single or occasional occurrences of mild TTS are not indicative of permanent auditory damage in terrestrial mammals. Relationships between TTS and PTS thresholds have not been studied in marine mammals, but are assumed to be similar to those in humans and other terrestrial mammals. PTS might occur at a received sound level at least several decibels above that inducing mild TTS if the animal were exposed to strong sound pulses with rapid rise time. The specific difference between the PTS and TTS thresholds has not been measured for marine mammals exposed to any sound type. However, some reasonable assumptions can be made based on TTS and PTS data from terrestrial mammals exposed to impulses (Southall et al. 2007).

Il n'y a pas de preuve particulière que l'exposition aux bruits impulsionnels de canon à air occasionne un PTS chez aucun mammifère marin, même lorsque les tirs proviennent de grosses batteries. Cela dit, étant donné la possibilité que certains mammifères à proximité d'une batterie puissent subir une perte temporaire d'audition, on s'est de nouveau intéressé à la possibilité que certains individus à proximité des canons à air subissent une perte permanente. L'apparition unique ou occasionnelle d'une légère perte d'audition temporaire n'est pas l'indication d'une lésion permanente chez les mammifères terrestres. Les relations entre les niveaux d'apparition des pertes temporaire et permanente n'ont pas été étudiées chez les mammifères marins, mais on suppose qu'ils sont analogues à ceux chez les humains et d'autres mammifères terrestres. Un PTS pourrait être provoquer par un niveau sonore perçu supérieur d'au moins plusieurs décibels au niveau provoquant un léger TTS si l'animal était exposé à de fortes impulsions sonores dont le front de montée est rapide. La différence précise entre la valeur limite du PTS et celle du TTS n'a pas été mesurée chez les mammifères marins exposés à quelque type de son que ce soit. Cependant, des hypothèses raisonnables peuvent être avancées d'après les données de TTS et de PTS chez les mammifères terrestres exposés à des impulsions (Southall *et al.*, 2007).

On an SEL basis, Southall et al. (2007:441-4) estimated that received levels would need to exceed the TTS threshold by at least 15 dB for there to be risk of PTS. Thus, for cetaceans they

D'après le niveau d'exposition sonore (SEL), Southall *et al.* (2007:441-4) ont estimé qu'il faudrait que les niveaux perçus dépassent la valeur limite d'un TTS d'au moins 15 dB pour qu'il y ait risque de PTS. Ainsi, ces auteurs

estimate[2] that the PTS threshold might be a cumulative SEL (for the sequence of received pulses) of ~198 dB re 1 $\mu Pa^2 \cdot s$[(2)]. Additional assumptions had to be made to derive a corresponding estimate for pinnipeds, as there are no specific published data concerning received levels of impulse sounds associated with TTS onset in pinnipeds. Southall et al. estimate that the PTS threshold could be a cumulative SEL of ~186 dB re 1 $\mu Pa^2 \cdot s$ in the harbour seal; for the California sea lion and northern elephant seal the PTS threshold would very likely be higher.

estiment[2] que la valeur limite de PTS chez les cétacés pourrait être un SEL cumulé (pour la séquence d'impulsions captées) de ~198 dB re 1 $\mu Pa^2 \cdot s$. Il a fallu formuler d'autres hypothèses pour effectuer une estimation correspondante à l'égard des pinnipèdes. En effet, aucune donnée précise n'a été publiée concernant les niveaux perçus d'impulsions sonores qui provoqueraient un TTS chez les pinnipèdes. Southall *et al.* estiment que le seuil de perte d'audition permanente pourrait s'établir à un SEL de ~186 dB re 1 $\mu Pa^2 \cdot s$ chez le phoque commun; dans le cas de l'otarie de Californie et de l'éléphant de mer boréal, cette valeur limite serait très probablement plus élevée.

Southall et al. (2007) also note that, regardless of the cumulative received energy (SEL), there is concern about the possibility of PTS if a cetacean or pinniped received one or more pulses with a very high peak pressure. Based on data from terrestrial mammals, a precautionary assumption is that impulse sounds might cause immediate PTS if the received peak pressure were 6 dB (or more) above than the TTS threshold as measured on a peak-pressure basis (Southall et al. 2007). They conclude that PTS might occur if cetaceans (as exemplified by belugas and bottlenose dolphins) and pinnipeds (as exemplified by the harbour seal) were exposed to peak pressures exceeding 230 or 218 dB re 1 µPa (peak), respectively. A peak pressure of 230 dB re 1 µPa (3.2 bar · m, 0-pk) would only be found within a few meters of the largest airguns used in most airgun arrays (Caldwell and Dragoset 2000). A peak pressure of 218 dB re 1

Southall *et al.* (2007) indiquent aussi que, quelle que soit l'énergie cumulée reçue (SEL), un PTS est à craindre si un cétacé ou un pinnipède devait subir une ou plusieurs impulsions avec une pression de crête très élevée. D'après les données sur les mammifères terrestres, on peut prudemment supposer que les impulsions sonores pourraient occasionner un PTS immédiat si la pression de crête perçue se situait 6 dB (ou plus) au-dessus du seuil de perte d'audition temporaire, mesuré d'après la pression de crête (Southall *et al.,* 2007). Ces auteurs concluent que le PTS pourrait se produire si les cétacés (par exemple les bélugas et les dauphins à gros nez) et les pinnipèdes (par exemple le phoque commun) étaient exposés à des pressions de crête dépassant 230 ou 218 dB re 1 µPa, respectivement. Une pression de crête de 230 dB re 1 $\mu Pa^2 \cdot s$ (3,2 barres · m, 0-crête) ne se ferait ressentir qu'à quelques mètres des plus gros canons à air utilisés dans la plupart des batteries (Caldwell et Dragoset, 2000). Une pression de crête de 218 dB re 1 µPa pourrait

[2] This is based on the evidence from Finneran et al. (2002) that the TTS threshold in a beluga exposed to a watergun pulse is about 186 dB re 1 $\mu Pa^2 \cdot s$ (flat weighted), or 183 dB re 1 $\mu Pa^2 \cdot s$ after discounting the low-frequency components that are not heard well by odontocetes; and on evidence that the PTS threshold, on an SEL basis, would be at least 15 dB higher than the TTS threshold (Southall et al. 2007).

[2] D'après les indications de Finneran et al. (2002), selon lesquelles le seuil de perte d'audition temporaire chez un béluga exposé à l'impulsion d'un canon à eau est d'environ 186 dB re 1 $\mu Pa^2 \cdot s$ (en pondération horizontale), ou 183 dB re 1 $\mu Pa^2 \cdot s$ déduction faite des éléments de basse fréquence que n'entendent pas bien les odontocètes. L'hypothèse se fonde aussi sur des indications que le seuil de perte d'audition permanente, d'après le SEL, serait supérieur d'au moins 15 dB au seuil de perte d'audition temporaire (Southall et al., 2007).

µPa could be received somewhat farther away; to estimate that specific distance, one would need to apply a model that accurately calculates peak pressures in the near-field around an array of airguns.

Although it is unlikely that airgun operations during most seismic surveys would cause PTS in cetaceans, caution is warranted given the limited knowledge about noise-induced hearing damage in marine mammals. Commonly applied monitoring and mitigation measures, including visual monitoring, ramp-ups, and power-downs/shutdowns of the airguns when mammals are seen within the "safety radii", are expected to minimize the already-low probability of exposure of cetaceans to sounds strong enough to potentially induce PTS.

Non-Auditory Physiological Effects

DFO (2004a) determined that exposure to seismic sound under field operating conditions is unlikely to result in damage to non-auditory body tissues of marine mammals but that other sound sources operating simultaneously with seismic operations should be evaluated.

Non-auditory physiological effects or injuries that theoretically might occur in marine mammals exposed to strong underwater sound include stress, neurological effects, bubble formation, resonance, and other types of organ or tissue damage (Cox et al. 2006; Southall et al. 2007). It is possible that some marine mammal species (i.e., beaked whales) may be susceptible to injury and/or stranding when exposed to some types of strong transient sounds. However, studies examining such effects are very limited. If any such effects do occur, they would probably be limited to unusual situations when animals might be exposed at close range for unusually long periods, when the sound is strongly channeled with less-than- normal

être perçue un peu plus loin; pour estimer la distance précise, il faudrait appliquer un modèle qui calcule avec exactitude les pressions de crête dans le champ proche autour d'une batterie de canons à air.

Bien qu'il soit peu probable que des tirs sismiques de canon à air occasionnent un PTS chez les cétacés, la prudence s'impose, puisqu'on connaît mal les dommages auditifs que peut causer le bruit chez les mammifères marins. Les mesures de surveillance et d'atténuation communément appliquées, y compris la surveillance visuelle, le démarrage progressif et la diminution de puissance ou l'arrêt des canons à air lorsque des mammifères sont découverts dans le « rayon de sécurité », devraient réduire au minimum la probabilité déjà faible d'exposition des cétacés à des bruits suffisamment forts pour provoquer un PTS.

Effets physiologiques extra-auditifs

Le MPO (2004a) considère qu'il est peu probable que l'exposition à des bruits sismiques dans des conditions de prospection en mer résulte en des dommages aux tissus autres que du système auditif chez les mammifères marins, mais qu'il convient d'évaluer la présence concomitante d'autres sources sonores.

Les lésions ou effets physiologiques extra-auditifs que pourraient théoriquement subir les mammifères marins exposés à des forts bruits sous l'eau englobent les effets du stress, les effets neurologiques, la formation de bulles gazeuses, la résonance et d'autres types d'atteintes aux organes ou aux tissus (Cox *et al.*, 2006; Southall *et al.*, 2007). Il est possible que certaines espèces de mammifères marins (baleines à bec) subissent des atteintes ou s'échouent lorsque exposées à certains types de sons transitoires puissants. Or, les études de ces effets sont rares. Pour autant qu'ils se produisent, ces effets se cantonneraient probablement à des situations inhabituelles – animaux exposés de près pour une période anormalement longue, son fortement canalisé avec une perte de propagation inférieure à la normale, ou dispersion des animaux

propagation loss, or when dispersal of the animals is constrained by shorelines, shallows, etc. Airgun pulses, because of their brevity and intermittence, are less likely to trigger resonance or bubble formation than are more prolonged sounds. DFO (2004a) concluded that exposure to seismic sound under field operating conditions is unlikely to result in non-auditory physiological effects.

Until recently, it was assumed that diving marine mammals are not subject to the bends or air embolism. Jepson et al. (2003) first suggested a possible link between mid-frequency sonar activity and acute and chronic tissue damage that results from the formation in vivo of gas bubbles, based on the beaked whale stranding in the Canary Islands in 2002 during naval exercises. Fernández et al. (2005a) showed those beaked whales did indeed have gas bubble-associated lesions as well as fat embolisms. Fernández et al. (2005b) also found evidence of fat embolism in three beaked whales that stranded 100 km north of the Canaries in 2004 during naval exercises. Examinations of several other stranded species have also revealed evidence of gas and fat embolisms (e.g., Arbelo et al. 2005; Jepson et al. 2005a; Méndez et al 2005). Most of the afflicted species were deep divers. There is speculation that gas and fat embolisms may occur if cetaceans ascend unusually quickly when exposed to aversive sounds, or if sound in the environment causes the destabilization of existing bubble nuclei (Potter 2004; Arbelo et al. 2005; Fernández et al. 2005a; Jepson et al. 2005b; Cox et al. 2006). Even if gas and fat embolisms can occur during exposure to mid-frequency sonar, there is no evidence that that type of effect occurs in response to airgun sounds.

contrainte par le rivage, les hauts-fonds, etc. Les impulsions de canon à air, en raison de leur brièveté et de leur intermittence, sont moins susceptibles de provoquer la résonance ou la formation de bulles gazeuses que les sons qui se prolongent. Le MPO (2004a) a conclu que l'exposition aux bruits de l'exploration sismique est peu susceptible d'avoir des effets physiologiques extra-auditifs.

Jusqu'à récemment, on supposait que les mammifères marins plongeurs ne risquaient pas d'atteintes ostéo-arthro-articulaires (ou *bends*) ni d'embolie gazeuse. Jepson *et al.* (2003) ont été les premiers à signaler un lien possible entre l'utilisation d'un sonar à moyenne fréquence et des atteintes aiguës et chroniques des tissus provoquées par la formation *in vivo* de bulles gazeuses. Cette hypothèse a été avancée après l'échouement de baleines à bec aux îles Canaries en 2002, au cours d'exercices navals. Fernández *et al.* (2005a) ont montré que ces baleines à bec avaient subi des lésions provoquées par des bulles gazeuses ainsi que des embolies graisseuses. Fernández *et al.* (2005b) ont aussi constaté des embolies graisseuses chez trois baleines à bec qui se sont échouées à 100 km au nord des Canaries en 2004, au cours d'exercices navals. L'examen de plusieurs autres espèces dont des spécimens se sont échoués a aussi révélé la présence d'embolies gazeuses et graisseuses (voir notamment Arbelo *et al.*, 2005; Jepson *et al.*, 2005a; Méndez *et al.*, 2005). La plupart des victimes appartenaient à des espèces à plongées profondes. On suppose que les embolies se produisent si les cétacés remontent avec une rapidité inhabituelle lorsqu'ils sont exposés à des bruits aversifs ou si le bruit ambiant déstabilise des noyaux gazeux présents (Potter 2004; Arbelo *et al.*, 2005; Fernández *et al.*, 2005a; Jepson *et al.*, 2005b; Cox *et al.*, 2006). Même si des embolies gazeuses ou graisseuses peuvent survenir à l'exposition à un sonar à moyenne fréquence, rien n'indique que ce genre d'effet se produit en réaction aux émissions de canon à air.

In general, little is known about the potential for seismic survey sounds to cause non-auditory physical effects in marine mammals. Available data suggest that such effects, if they occur at all, would be limited to short distances and probably to projects involving large arrays of airguns. The available data do not allow identification of a specific exposure level (if any) above which such effects can be expected (Southall et al. 2007), or any meaningful quantitative predictions of the numbers (if any) of marine mammals that might be affected in those ways. Marine mammals that show behavioural avoidance of seismic vessels, including most baleen whales, some odontocetes, and some pinnipeds, are especially unlikely to incur non-auditory physical effects. Also, mitigation measures typically employed during seismic programs, including shut-downs of the airguns (or power-downs in jurisdictions where such partial shut-downs are applied), will reduce any such effects that might otherwise occur.

En général, on connaît peu le risque que les bruits sismiques occasionnent des effets physiques extra-auditifs chez les mammifères marins. Selon les données dont on dispose, de tels effets, pour autant qu'ils se produisent, seraient limités à des courtes distances et supposeraient probablement l'utilisation de grosses batteries de canons à air. Les données ne permettent pas de déterminer un niveau d'exposition précis (s'il en est) auquel apparaîtraient les effets (Southall et al., 2007) ni de prévoir valablement le nombre de mammifères marins qui pourraient être affectés. Les mammifères marins qui montrent un comportement d'évitement des navires sismiques, y compris la plupart des baleines à fanons, certains odontocètes et certains pinnipèdes, sont particulièrement peu susceptibles de subir des effets physiques extra-auditifs. En outre, les mesures d'atténuation habituellement employées durant les campagnes sismiques, y compris l'arrêt des canons à air (ou la diminution de puissance, dans les territoires où de telles interruptions partielles sont prévues), réduiront tous les effets qui pourraient survenir.

Direct Behavioural Effects

Effets comportementaux directs

Displacement and Migratory Diversion[3]

DFO (2004a) concluded that "exposure to seismic sound can result in displacement and/or migratory diversion in some marine mammals, but this effect is species, individual, and contextually-related. The ecological significance of such effects is unknown, but there are conditions under which [the consequences of] the worst-case scenarios could be high."

Déplacement et déviation des voies migratoires[3]

Le MPO (2004a) conclut que « l'exposition à des bruits sismiques peut résulter en un déplacement et/ou une déviation des voies migratoires chez certains mammifères marins, mais ces effets dépendent de l'espèce, de l'individu et du contexte. Le degré d'importance écologique de ces effets est inconnu, mais il existe des conditions dans lesquelles les scénarios de la pire éventualité auraient de fortes incidences ».

Reactions to sound, if any, depend on species, state of maturity, experience, current activity, reproductive state, time of day, and many other factors (Wartzok et al. 2004; Southall et al. 2007). If a marine mammal does react briefly to an underwater sound by changing its

Les réactions au bruit dépendent de l'espèce, de la maturité, de l'expérience, de l'activité en cours, du stade reproducteur, du moment de la journée et de bien d'autres facteurs (Wartzok *et al.*, 2004; Southall *et al.*, 2007). Si un mammifère marin réagit brièvement à un son sous-marin en modifiant son comportement ou

[3] *This section also considers changes in feeding behaviour.*
[3] *Cette partie porte aussi sur la modification du comportement alimentaire.*

behaviour or moving a small distance, the impacts of the change are unlikely to be significant to the individual, let alone the stock or the species as a whole (NRC 2005). However, if a sound source displaces marine mammals from an important feeding or breeding area for a prolonged period, impacts on the animals could be significant. Given the many uncertainties in predicting the quantity and types of impacts of noise on marine mammals, it is common practice to estimate how many mammals were present within a particular distance of industrial activities, or exposed to a particular level of industrial sound. That likely overestimates the numbers of marine mammals that are affected in some biologically-important manner.

en s'éloignant un peu, les impacts du changement ont peu de chances d'être importants pour cet animal, encore moins pour la population ou pour l'espèce dans son ensemble (NRC 2005). Par contre, si une source sonore déplace des mammifères marins d'une importante zone d'alimentation ou de reproduction durant une longue période, les impacts sur ces animaux pourraient être importants. Vu les nombreuses incertitudes qui entachent la prévision de la quantité et du type d'impacts du bruit sur les mammifères marins, il est de pratique courante d'estimer combien de mammifères sont présents à une distance donnée d'activités industrielles ou qui sont exposés à un niveau donné de bruit industriel. Cette façon de faire surestime probablement le nombre de mammifères marins touchés d'une façon qui soit importante sur le plan biologique.

The sound criteria used to estimate how many marine mammals might be disturbed to some biologically important degree by a seismic program are based on behavioural observations during studies of several species. However, information is lacking for many species. Detailed studies of short-term responses (or lack thereof) have been done on humpback, gray, bowhead and sperm whales, and on ringed seals. Less detailed data are available for some other species of baleen whales, small toothed whales, and sea otters.

Les critères acoustiques utilisés pour estimer comment de nombreux mammifères marins pourraient être perturbés de façon importante sur le plan biologique par un programme sismique se fondent sur les comportements observés au cours d'études de plusieurs espèces. Cependant, les informations manquent pour de nombreuses espèces. Des études détaillées des réactions (ou de l'absence de réactions) à court terme ont été faites chez le rorqual à bosse, la baleine grise, la baleine boréale et le cachalot macrocéphale , ainsi que chez le phoque annelé. On dispose de données moins détaillées pour certaines autres espèces de baleines à fanons, de petites baleines à dents et de loutres de mer.

Mysticetes.—Mysticetes tend to avoid operating airguns, but avoidance radii are quite variable. Whales often reportedly show no overt reactions to airgun pulses at distances beyond a few kilometres, even though the airgun pulses remain well above ambient noise levels out to much longer distances. However, mysticetes exposed to strong noise pulses from airguns often react by deviating from their normal migration heading and/or interrupting their feeding and moving away. Recent studies and reviews on this topic include Gordon et al.

Mysticètes – Les mysticètes évitent généralement les tirs des canons à air, mais le rayon d'évitement est assez variable. Il semble que, souvent, les baleines ne montrent pas de réactions évidentes aux impulsions de canon à air lorsqu'elles se trouvent à plus de quelques kilomètres de distance, même si ces signaux impulsionnels sont beaucoup plus puissants que le bruit ambiant sur des distances beaucoup plus longues. Cela dit, les mysticètes exposés aux fortes impulsions sonores des canons à air réagissent souvent en s'écartant de leur voie de migration habituelle et/ou en arrêtant de s'alimenter pour s'éloigner. Les

(2004), Miller et al. (2005b), Moulton and Miller (2005), Stone and Tasker (2006), Gailey et al. (2007), Yazvenko et al. (2007a,b), and Weir (2008).

Recent Studies of Mysticete Reactions: It has been suggested that South Atlantic humpback whales wintering off Brazil may be displaced or even strand upon exposure to seismic surveys (Engel et al. 2004). The evidence for this was circumstantial, subject to alternative explanations (IAGC 2004), and not consistent with results from direct studies of humpbacks exposed to seismic surveys in other areas and seasons. After allowance for data from subsequent years, there was "no observable direct correlation" between strandings and seismic surveys (IWC 2007).

Results from bowhead whale studies show that responsiveness of a given species of mysticete to seismic surveys can be quite variable depending on the activity of the whales (e.g., migrating vs. feeding). Bowhead whales migrating west across the Alaskan Beaufort Sea in autumn, in particular, are unusually responsive, with substantial avoidance occurring out to distances of 20–30 km from a medium-sized airgun source, where received sound levels were on the order of 130 dB re 1 μPa_{rms} (Miller et al. 1999; Richardson et al. 1999). However, more recent studies of bowhead whales (Miller et al. 2005b; Harris et al. 2007) corroborate earlier evidence that, during the summer feeding season, bowheads are not as sensitive to seismic sources. In summer, bowheads typically begin to show avoidance reactions at a received level of about 160–170 dB re 1 μPa_{rms} (Richardson et al. 1986; Ljungblad et al. 1988; Miller et al. 2005a). Some individual bowheads on the feeding grounds apparently begin to react at distances a few kilometres away, beyond the distance at which observers on the

études et les analyses documentaires publiées récemment sur le sujet comprennent celles de Gordon *et al.* (2004), Miller *et al.* (2005b), Moulton et Miller (2005), Stone et Tasker (2006), Gailey *et al.* (2007), Yazvenko *et al.* (2007a,b), et Weir (2008).

Études récentes des réactions des mysticètes : Il a été avancé que les rorquals à bosse de l'Atlantique Sud hivernant au large du Brésil pourraient être déplacés ou même amenés à s'échouer par l'exposition à des tirs sismiques (Engel *et al.*, 2004). Les preuves de ce comportement étaient indirectes, et d'autres explications étaient possibles (IAGC, 2004). L'hypothèse ne s'accorde pas avec les résultats d'études directes de rorquals à bosse exposés à des tirs sismiques dans d'autres secteurs et à d'autres saisons. Une fois tenu compte des données des années ultérieures, il a été conclu qu'il n'y avait « aucune corrélation directe observable » entre les échouements et les levés sismiques (IWC, 2007).

Les résultats d'études chez la baleine boréale montre que la sensibilité d'une espèce donnée de mysticètes aux tirs sismiques peut être plutôt variable, selon l'activité des baleines (p. ex. migration ou alimentation). Les baleines boréales qui migrent vers l'Ouest et traversent la partie alaskienne de la mer de Beaufort à l'automne, en particulier, montrent une sensibilité inhabituelle : elles manifestent une réaction importante d'évitement à des distances d'entre 20 et 30 km d'un dispositif de canons à air de taille moyenne, quand elles reçoivent un niveau sonore de l'ordre de 130 dB re 1 μPa_{rms} (Miller *et al.*, 1999; Richardson *et al.*, 1999). Cela dit, des études plus récentes (Miller *et al.*, 2005b; Harris *et al.*, 2007) corroborent des données antérieures selon lesquelles, durant la période estivale d'alimentation, les baleines boréales ne sont pas aussi sensibles aux sources sismiques. À l'été, ces baleines commencent habituellement à manifester une réaction d'évitement à un niveau perçu d'environ 160-170 dB re 1 μPa_{rms} (Richardson *et al.*, 1986; Ljungblad *et al.*, 1988; Miller *et al.*, 2005a). Certains sujets dans les aires d'alimentation commencent apparemment à réagir à quelques kilomètres, mais trop loin pour que les observateurs à bord du navire

ship can readily observe bowheads (Richardson et al. 1986; Citta et al. 2007), but some others allow the seismic vessel to approach close enough for observers on the ship to see the whales (Harris et al. 2007). Although feeding bowheads often remain within a few kilometres of an active seismic vessel, statistical analysis showed evidence of subtle changes in surfacing, respiration and diving cycles when feeding bowheads were exposed to lower-level pulses from distant seismic operations (Richardson et al. 1986). Feeding whales may exhibit subtle changes in behaviour in response to the sounds, but the need to feed apparently reduces the tendency to move away.

puissent les observer (Richardson *et al.*, 1986; Citta *et al.*, 2007), mais d'autres baleines boréales laissent le navire sismique s'approcher suffisamment pour que les observateurs à bord puissent les voir (Harris *et al.*, 2007). Même si les baleines boréales en quête de nourriture demeurent souvent à quelques kilomètres d'un navire qui procède à des tirs sismiques, l'analyse statistique révèle de petites modifications dans les cycles de remontée, de respiration et de plongée quand elles étaient exposées à de faibles impulsions provenant de tirs sismiques lointains (Richardson *et al.*, 1986). Les baleines qui s'alimentent modifient parfois légèrement leur comportement en réaction aux bruits, mais le besoin de se nourrir réduit apparemment la tendance à s'éloigner.

Recently published data on the responses of western Pacific gray whales to 3D seismic exploration on their feeding grounds off Russia's Sakhalin Island have considerably augmented earlier data on effects of seismic surveys on feeding gray whales. One part of this Sakhalin study involved intensive daily aerial surveys to document the distribution and abundance of the whales, and their bottom feeding activity as evident through observation of mud plumes on the water surface (Yazvenko et al. 2007a, b). The aerial surveys did not find a statistically significant effect of the seismic survey on the frequency of occurrence of mud plumes of gray whales and concluded that the 2001 seismic survey had no measurable effect on bottom feeding activity (Yazvenko et al. 2007a). Analyses revealed a localized redistribution of some gray whales within the feeding area when the seismic survey was fully operational, but the total number of gray whales observed remained stable during the seismic survey (Yazvenko et al. 2007b). Simultaneous shore-based observations determined that the relative number of western gray whales and pods recorded did not significantly differ during periods when seismic surveys were occurring compared to periods without seismic surveys and to post-seismic periods

Des données ont récemment été publiées sur les réactions de baleines grises du Pacifique occidental à une exploration sismique tridimensionnelle menée dans leurs aires d'alimentation au large de l'île russe de Sakhaline. Ces données ont considérablement enrichi les informations antérieures sur les effets des levés sismiques sur les baleines grises en quête de nourriture. L'étude de Sakhaline a compris une intense campagne de reconnaissances aériennes quotidiennes pour documenter la répartition et l'abondance des baleines ainsi que leur activité d'alimentation sur le fond par l'observation des panaches de boue à la surface de l'eau (Yazvenko *et al.*, 2007a, b). Les reconnaissances aériennes n'ont pas montré un effet statistiquement significatif des tirs sismiques sur la fréquence d'observation des panaches de boue soulevés par les baleines grises. Il en a été conclu que les levés sismiques de 2001 n'avaient pas eu d'effet mesurable sur l'activité d'alimentation sur le fond (Yazvenko *et al.*, 2007a). Les analyses ont révélé une redistribution localisée de certains individus dans l'aire d'alimentation lorsque la campagne sismique battait son plein, mais le nombre total de baleines grises observées est demeuré stable durant la campagne (Yazvenko *et al.*, 2007b). Des observations simultanées à partir du rivage ont déterminé que le nombre relatif d'individus et de groupes de baleines grises occidentales n'était pas tellement différent

(Gailey et al. 2007). However, exposure to seismic sounds did have statistically significant effects on some measures of movement behaviour. Studies of the effectiveness of monitoring and mitigation measures determined that the techniques used were successful in reducing exposure of feeding gray whales to seismic sound to levels that did not result in serious disturbance effects (Johnson et al. 2007). Acoustic measurements at the start of the seismic survey determined that reduction of the originally-planned air gun array to 14 airguns and 1,640 in^3 (Rutenko et al. 2007), combined with establishment of a 4–5 km buffer zone, were effective in ensuring that western gray whales were not exposed to received levels exceeding a pre-selected "do not exceed" level of 163 dB re 1 μPa_{rms} (Johnson et al. 2007).

durant les tirs qu'entre les périodes de tir ou après la campagne sismique (Gailey *et al.*, 2007). Cependant, l'exposition à des bruits sismiques avait des effets statistiquement significatifs sur certains aspects mesurés du comportement de déplacement. Des études sur l'efficacité des mesures de surveillance et d'atténuation ont déterminé que les techniques utilisées réussissaient à réduire l'exposition des baleines grises en quête de nourriture au bruit sismique pour ramener l'exposition à des niveaux ne provoquant pas de perturbations importantes (Johnson *et al.*, 2007). Les mesures acoustiques prises au début des levés sismiques ont montré que la réduction de la taille de la batterie prévue à l'origine, qui a été ramenée à un dispositif de 14 canons à air d'un volume de 1 640 po^3 (Rutenko *et al.*, 2007), conjuguée à l'établissement d'une zone tampon de 4 ou 5 km, a réussi à empêcher l'exposition des baleines grises occidentales à des niveaux sonores perçus dépassant un seuil fixé de 163 dB re 1 μPa_{rms} (Johnson *et al.*, 2007).

Gray whales in British Columbia exposed to seismic survey sounds with received levels up to about 170 dB re 1 µPa $_{P-P}$ did not appear to be disturbed (Bain and Williams 2006). However, the small sample size (four sightings) and complex topography of the study area prevent any meaningful conclusions from being drawn.

En Colombie-Britannique, les baleines grises exposées à des bruits sismiques dont les niveaux perçus allaient jusqu'à environ 170 dB re 1 µPa crête à crête n'ont pas paru perturbées (Bain et Williams, 2006). Toutefois, la petitesse de l'échantillon (quatre observations) et la topographie complexe de la zone d'étude empêchent de tirer des conclusions sérieuses.

Among wintering humpback whales off Angola (n = 52 useable groups), there were no significant differences in encounter rates (sightings/hr) when a 24-airgun array (3147 in^3 or 5085 in^3) was operating vs. silent (Weir 2008). There was also no significant difference in the mean CPA (closest observed point of approach) distance of the humpback sightings when airguns were on vs. off (3050 m vs. 2700 m, respectively).

Parmi des rorquals à bosse hivernant au large de l'Angola (*n* = 52 groupes utilisables), l'utilisation d'une batterie de 24 canons à air (3 147 po^3 ou 5 085 po^3) n'a pas provoqué de différence importante dans le taux de rencontre (n^{bre} d'observations par heure) par rapport à lorsqu'il n'y avait pas de tirs (Weir, 2008). Il n'y a pas eu non plus de différence appréciable du point de rapprochement maximal (PRM) moyen observé des rorquals au moment où les canons tiraient et au moment où ils ne tiraient pas (3 050 m contre 2 700 m).

Various species of Balaenoptera (blue, sei, fin, and minke whales) have quite regularly been reported in areas of the North Atlantic ensonified by airgun pulses.

Diverses espèces de la famille des balénoptéridés (rorquals bleus, rorquals boréals, rorquals communs et petits rorquals) ont été signalées assez

Sightings by observers on seismic vessels (201 surveys) off the United Kingdom from 1997 to 2000 suggest that, at times of good sightability, numbers of rorquals seen are similar when airguns are active and inactive (Stone and Tasker 2006). Although the available data for individual species did not show significant displacement in relation to seismic surveys, when data from all baleen whales were combined, median distances (CPA) from the airguns were found to be significantly larger (~1600 m vs. 1000 m; see Figure 4 in Stone and Tasker 2006) and whales tended to head away from the vessel during seismic vs. non-seismic periods (Stone and Tasker 2006).

Similarly, in a study on the Scotian Slope, near the Gully submarine canyon (now a Marine Protected Area), Moulton and Miller (2005) found little difference in sighting rates (after accounting for water depth) and initial average sighting distances of balaenopterid whales when airguns were operating (mean = 1324 m) vs. silent (mean = 1303 m). However, there were indications that these whales were more likely to be moving away when seen during airgun operations. Baleen whales at the average sighting distance during airgun operations would have been exposed to sound levels (via direct path) of about 169 dB re 1 μPa_{rms} (Moulton and Miller 2005).

Ship-based monitoring studies of baleen whales (blue, fin, sei and minke whales) offshore Newfoundland (Orphan Basin and Laurentian Sub-basin) found no more than small differences in sighting rates and swim directions during seismic vs. non-seismic periods (Moulton et al. 2005, 2006a,b). Analyses of CPA data yielded variable results. The CPA of baleen whales sighted from the seismic vessels was, on average, significantly closer during non-seismic periods vs. seismic

régulièrement dans les zones de l'Atlantique Nord insonifiées par les impulsions de canon à air. Des observateurs à bord de navires sismiques (201 levés) au large du Royaume-Uni entre 1997 et 2000 ont signalé que, en périodes de bonne visibilité, le nombre de rorquals aperçus était analogue quand les canons à air tiraient que quand ils ne tiraient pas (Stone et Tasker, 2006). Les données disponibles pour chaque espèce n'ont pas montré que les tirs provoquaient un déplacement significatif, mais une fois réunies les données sur toutes les baleines à fanons, la distance moyenne (PRM) des canons à air s'est avérée beaucoup plus grande (~1 600 m contre 1 000 m; voir la figure 4 dans Stone et Tasker, 2006), et les baleines tendaient à s'éloigner du navire quand ses canons tiraient plutôt que quand ils étaient silencieux (Stone et Tasker, 2006).

Pareillement, dans une étude menée sur le talus Scotian, près du canyon sous-marin du Goulet (lequel est maintenant une aire marine protégée), Moulton et Miller (2005) ont trouvé peu de différence dans les taux d'observation (compte tenu de la profondeur de l'eau) et les distances moyennes initiales d'observation des balénoptéridés entre les moments où les canons à air tiraient (moyenne = 1 324 m) et les moments où ils étaient silencieux (moyenne = 1 303 m). Cela dit, il semble que les baleines aperçues au moment des tirs étaient plus susceptibles de s'éloigner. À la distance moyenne d'observation durant les tirs, les baleines à fanons auraient été exposées à des niveaux sonores (sur une trajectoire directe) d'environ 169 dB re 1 μPa_{rms} (Moulton et Miller, 2005).

Des études de surveillance des baleines à fanons (rorquals bleus, rorquals communs, rorquals boréals et petits rorquals) effectuées à partir de navires au large de Terre-Neuve (bassin Orphan et sous-bassin Laurentien) n'ont trouvé que de légères différences dans les taux d'observation et les directions où nageaient les baleines durant les tirs sismiques et durant les périodes sans tir (Moulton *et al.*, 2005, 2006a, b). Les analyses des données du point de rapprochement maximal ont livré des résultats variables. En

periods in 2004 in the Orphan Basin (means 1526 m vs. 2316 m, respectively; Moulton et al. 2005), but did not differ significantly (and were farther away during non-seismic periods) in 2005 in the Orphan Basin (973 m vs. 832 m, respectively; Moulton et al. 2006a) or in the Laurentian Sub-basin (means 1928 m vs. 1650 m; Moulton et al. 2006b). The authors of these reports, concluded that, based on observations from the seismic vessel, some mysticetes exhibited localized avoidance of seismic operations (Moulton et al. 2005,2006a).

2004, le PRM des baleines à fanons aperçues à partir des navires sismiques était, en moyenne, beaucoup plus près durant les périodes de levés sismiques qu'autrement dans le bassin Orphan (moyenne de 1 526 m contre 2 316 m; Moulton *et al.*, 2005). Par contre, aucune différence significative n'a été relevée en 2005 (et le PRM était plus éloigné durant les périodes où il n'y avait pas de levés) dans le bassin Orphan (973 m c. 832 m; Moulton *et al.*, 2006a) et dans le sous-bassin Laurentien (moyenne de 1 928 m c. 1 650 m; Moulton *et al.*, 2006b). Les auteurs des rapports ont conclu que, d'après les observations à partir du navire sismique, certains mysticètes montraient une réaction d'évitement localisé face aux tirs (Moulton *et al.*, 2005, 2006a).

Synthesis: Mysticetes tend to avoid operating airguns, but avoidance radii are quite variable. Whales are often reported to show no overt reactions to airgun pulses at distances beyond a few kilometres, even though the airgun pulses remain well above ambient noise levels out to much longer distances. However, studies done since the late 1990s of humpback and especially migrating bowhead whales show that reactions, including avoidance, sometimes extend to greater distances than documented earlier. Avoidance distances often exceed the distances at which boat-based observers can see whales, so observations from the source vessel may be biased. Studies indicate monitoring over broader areas may be needed to determine the range of potential effects of some larger seismic surveys (Miller et al. 1999; Bain and Williams 2006; Moore and Angliss 2006).

Synthèse : Les mysticètes tendent à éviter les tirs de canon à air, mais les rayons d'évitement varient pas mal. On signale souvent que les baleines ne montrent pas de réactions manifestes aux impulsions des canons à air à plus de quelques kilomètres, même si ces impulsions demeurent bien supérieures au bruit ambiant sur des distances beaucoup plus longues. Cela dit, des études réalisées depuis la fin des années 1990 chez le rorqual à bosse et surtout chez les baleines boréales migratrices révèlent que les réactions, y compris d'évitement, surviennent parfois à des distances beaucoup plus grandes que celles qui avaient été documentées auparavant. Comme les distances d'évitement dépassent souvent les distances auxquelles les observateurs à bord de bateaux peuvent apercevoir les baleines, les observations à partir du navire source peuvent être biaisées. Des études indiquent que la surveillance sur des zones plus vastes sera peut-être nécessaire pour déterminer l'éventail des effets possibles de campagnes sismiques d'envergure (Miller *et al.*, 1999; Bain et Williams, 2006; Moore et Angliss, 2006).

Some mysticetes show considerable tolerance of seismic pulses. However, when the pulses are strong enough, avoidance or other behavioural changes become evident. Because the responses

Certains mysticètes montrent une tolérance considérable à l'égard des impulsions sismiques. Toutefois, quand les impulsions sont assez fortes, une réaction d'évitement ou une autre modification du comportement se

become less obvious with diminishing received sound level, it has been difficult to determine the maximum distance (or minimum received sound level) at which reactions to seismic become evident and, hence, how many whales are affected.

manifestent. Comme les réactions deviennent moins évidentes à mesure que le niveau sonore perçu diminue, il a été difficile de déterminer la distance maximale (ou le niveau sonore perçu minimal) à laquelle les réactions aux tirs sismiques se manifestent et, donc, de déterminer combien de baleines sont touchées.

Studies of gray, bowhead, and humpback whales have determined that received levels of pulses in the 160–170 dB re 1 μPa_{rms} range seem to cause obvious avoidance behaviour in a substantial fraction of the animals exposed. In the case of migrating bowhead whales, avoidance extends to lower received sound levels and larger distances. However, in other situations, various mysticetes tolerate exposure to full-scale airgun arrays operating at closer distances, with only localized avoidance and minor changes in activities.

Des études chez la baleine grise, la baleine boréale et le rorqual à bosse ont déterminé que des niveaux perçus d'impulsions dans la plage de 160-170 dB re 1 μPa_{rms} semble occasionner un comportement d'évitement manifeste chez une bonne proportion des animaux exposés. Dans le cas des baleines boréales en migration, l'évitement se manifeste à des niveaux sonores perçus moins élevés et sur des distances plus longues. Par contre, dans d'autres situations, divers mysticètes tolèrent l'exposition à des batteries complètes de canons à air tirant à distance rapprochée, ne manifestant qu'un évitement localisé et ne modifiant que légèrement leurs activités.

Data on short-term reactions (or lack of reactions) of cetaceans to impulsive noises do not necessarily provide information about long-term effects. It is not known whether impulsive noises affect reproductive rate or distribution and habitat use in subsequent days or years. Furthermore, effects likely vary among species, locations, and times of year, and depending on past exposure to seismic sounds. In general, among mammals, mysticetes are relatively long-lived, mature late, have relatively low reproductive rates, and require high maternal investment in young. This is particularly true for bowhead and right whales. Thus, the female's ability to provide adequate care to her offspring during a prolonged period of dependency is critical to the continued recovery and long-term viability of these populations. These life history traits support the need to avoid disturbance in certain seasons or locations (Wilson et al. 2006). It has been suggested that migrating bowheads may warrant special consideration among mysticetes in terms of documented

Les données sur les réactions (ou sur l'absence de réactions) à court terme des cétacés à des bruits impulsionnels ne fournissent pas nécessairement d'informations sur les effets à long terme. On ne sait pas si les bruits impulsionnels modifient le taux de reproduction ou la répartition et l'utilisation de l'habitat dans les jours ou les années qui suivent. De plus, les effets varient probablement entre les espèces, entre les lieux et entre les moments de l'année, et dépendent de l'exposition passée à des bruits sismiques. En général, par comparaison aux autres mammifères, les mysticètes vivent assez longtemps, atteignent la maturité tard et ont un taux de reproduction relativement faible, et les jeunes exigent un grand investissement maternel. C'est particulièrement vrai chez la baleine boréale et la baleine noire de l'Atlantique Nord. Ainsi, la capacité de la femelle de prendre un soin adéquat de sa progéniture durant la longue période de dépendance de celle-ci est cruciale pour que les populations continuent de se rétablir et soient viables à long terme. Ces particularités du cycle biologique confirment le besoin d'éviter de perturber ces

deflection impacts of seismic operations, particularly during the spring when ice may constrain migration pathways (Wilson et al. 2006). However, given the remarkable abilities of bowheads to travel through heavy ice, and the impossibility of conducting conventional seismic surveys in heavy ice, this does not seem likely to be an issue.

Odontocetes.—Few studies similar to the more extensive baleen whale/seismic pulse work have been reported for odontocetes, and none similar in size and scope to the studies of humpback, bowhead, and gray whales. However, a systematic study on sperm whales has been done (see Jochens et al. 2006; Miller et al. 2006), and there is an increasing amount of information about responses of various odontocetes to seismic surveys based on monitoring studies (e.g., Smultea et al. 2004; Moulton and Miller 2005; Bain and Williams 2006; Holst et al. 2006; Stone and Tasker 2006; Weir 2008).

Seismic operators and marine mammal observers regularly see dolphins and other small odontocetes near operating airgun arrays, but in general there seems to be a tendency for most delphinids to show some limited avoidance of operating seismic vessels, on the order of 1 km or less (e.g., Moulton and Miller 2005; Holst et al. 2006; Weir 2008). Some dolphins (and Dall's porpoises) seem to be attracted to the seismic vessel and floats, and some ride the bow wave of the seismic vessel even when large arrays of airguns are active (e.g., MacLean and Koski 2005; Moulton and Miller 2005). Nonetheless, small toothed whales often tend to head away, or to maintain a somewhat greater distance from the

animaux à certaines saisons ou dans certains lieux (Wilson *et al.*, 2006). On a laissé entendre que les baleines boréales migratrices mériteraient peut-être une attention particulière parmi les mysticètes pour ce qui est de documenter l'effet de déport qu'auraient sur elles les tirs sismiques, surtout au printemps, lorsque la glace contraint le parcours migratoire (Wilson *et al.*, 2006). Cela dit, vu la capacité remarquable des baleines boréales de se déplacer dans un encombrement de glaces et vu l'impossibilité d'effectuer des levés sismiques conventionnels dans de la glace épaisse, il ne semble pas justifier de s'attarder à cet aspect.

Odontocètes – Peu d'études semblables aux vastes travaux effectués sur l'effet des impulsions sismiques sur les baleines à fanons ont été recensées à l'égard des odontocètes, et aucune de l'envergure des études effectuées chez les rorquals à bosse, les baleines boréales et les baleines grises. Cependant, une étude systématique a été réalisée chez les cachalots macrocéphales (voir Jochens *et al.*, 2006; Miller *et al.*, 2006), et il y a une quantité croissante d'informations sur les réactions de divers odontocètes aux levés sismiques d'après les études de surveillance (voir notamment Smultea *et al.*, 2004; Moulton et Miller, 2005; Bain et Williams, 2006; Holst *et al.*, 2006; Stone et Tasker, 2006; Weir, 2008).

Les opérateurs sismiques et les observateurs de mammifères marins voient régulièrement des dauphins et d'autres petits odontocètes près de batteries qui déchargent leurs canons à air, mais, en général, il semble que la plupart des delphinidés montrent une réaction restreinte d'évitement des navires sismiques en activité, dans un rayon de l'ordre de 1 km ou moins (voir notamment Moulton et Miller, 2005; Holst *et al.*, 2006; Weir, 2008). Certains dauphins (et le marsouin de Dall) paraissent attirés par les navires et les flotteurs sismiques, et certains se laissent porter dans les vagues d'étrave du navire même lorsque de grosses batteries de canons à air fonctionnent (voir notamment MacLean et Koski, 2005; Moulton et Miller, 2005). Cela dit, les petites baleines à dents

vessel, when a large array of airguns is operating than when it is silent (see Stone and Tasker 2006; Weir 2008). The beluga may be a species that (at least at times) shows long-distance avoidance of seismic vessels. Aerial surveys during seismic operations in the southeastern Beaufort Sea recorded much lower sighting rates of beluga whales within 10–20 km of an active seismic vessel. These results were consistent with the low number of beluga sightings reported by observers aboard the seismic vessel, suggesting that some belugas might be avoiding the seismic operations at distances of 10–20 km (Miller et al. 2005a). Similarly, very few belugas were observed during a recent seismic monitoring program in the southeastern Beaufort Sea (Harris et al. 2007).

s'éloignent souvent d'un navire qui décharge sa grosse batterie ou se tiennent à plus grande distance que lorsqu'il ne tire pas (voir Stone et Tasker, 2006; Weir, 2008). Le béluga est peut-être une espèce qui (du moins parfois) montre une réaction d'évitement à grande distance des navires sismiques. La reconnaissance aérienne au cours de levés sismiques dans le sud-est de la mer de Beaufort a donné des taux d'observation du béluga beaucoup plus faibles dans un rayon de 10 à 20 km d'un navire sismique en activité. Ces résultats s'accordent avec le peu d'individus aperçus par les observateurs à bord du navire, ce qui fait supposer que certains bélugas pourraient éviter les tirs sismiques à des distances de 10-20 km (Miller *et al.*, 2005a). De même, très peu de bélugas ont été observés au cours d'un récent programme de surveillance sismique dans la partie sud-est de la mer de Beaufort (Harris *et al.*, 2007).

During two National Science Foundation (NSF)-funded L-DEO seismic surveys in which a large 20-airgun array (~7,000 in3) was used, sighting rates of delphinids were lower and initial sighting distances were farther away from the vessel during seismic than non-seismic periods (Smultea et al. 2004; Holst et al. 2005a, 2006). The mean CPA for delphinids for both cruises was significantly farther during seismic (1043 m) than during non-seismic (151 m) periods. Surprisingly, during one of these cruises in the southeastern Caribbean, nearly all acoustic detections of odontocetes (including delphinids and sperm whales) were made during airgun operations (Smultea et al. 2004). In contrast, during the second survey (off the Yucatán Peninsula, Mexico), acoustic detection rates of odontocetes were nearly five times higher during non-seismic vs. seismic periods (Holst et al. 2005a).

Au cours de deux campagnes sismiques de l'observatoire terrestre Lamont-Doherty financées par la Fondation nationale des sciences des États-Unis, le fonctionnement d'une grosse batterie de 20 canons à air (~7 000 po^3) a fait baisser le taux d'observation de delphinidés et augmenter la distance d'observation initiale par rapport au navire par comparaison à lorsqu'il n'y avait pas de tirs sismiques (Smultea *et al.*, 2004; Holst *et al.*, 2005a, 2006). Le point de rapprochement maximal moyen des delphinidés au cours des deux campagnes était sensiblement plus éloigné durant les tirs sismiques (1 043 m) que durant les périodes silencieuses (151 m). Étonnamment, au cours d'une de ces campagnes dans le sud-est de la mer des Caraïbes, presque toutes les détections acoustiques d'odontocètes (y compris de delphinidés et de cachalots macrocéphales) ont été faites durant les tirs de canon à air (Smultea *et al.*, 2004). Par contre, au cours de la seconde campagne (au large de la péninsule du Yucatán, au Mexique), le taux de détection acoustique d'odontocètes a été presque cinq fois plus élevé durant les périodes silencieuses que durant les périodes de tirs (Holst *et al.*, 2005a).

An analysis of observations taken during 201 seismic surveys in UK and adjacent waters indicated that small odontocetes showed a greater range of responses to seismic surveys than did mysticetes or larger odontocetes, including significant declines in sighting rates during periods of seismic surveys (Stone and Tasker 2006). On the other hand, larger odontocetes (long-finned pilot whales, killer whales and sperm whales) showed little response to airgun activities and no reduction in sighting rates during periods of seismic surveys. Stone and Tasker (2006) suggested that avoidance behaviours exhibited by small odontocetes, and to a lesser extent by other cetaceans, appeared to be temporary.

Two seismic surveys were completed in the Orphan Basin, off Newfoundland and Labrador, in 2004 and 2005 (Moulton et al. 2005, 2006a). During both surveys, dolphin sighting rates, taking temporal variation into consideration, were higher during non-seismic periods than during seismic periods, although this difference was only statistically significant in 2004. The mean CPA of dolphins was significantly closer during non-seismic periods (652 m) vs. seismic periods (807 m) in 2005, but the difference was not statistically significant in 2004 (705 m vs. 665 m, respectively). The sighting rates of large odontocetes, primarily sperm whales, (taking temporal variation into consideration) and CPAs did not differ statistically between seismic periods vs. non-seismic periods in 2004 or 2005 in the Orphan Basin. The authors concluded that based on observations from the seismic vessel some odontocetes exhibited localized avoidance of seismic operations (Moulton et al. 2005, 2006a). Similar results for odontocetes were observed during a marine mammal monitoring program in the Laurentian Sub-basin (Moulton et al. 2006b). A major study of sperm whales in the Gulf of Mexico found that they did not show any large-scale avoidance reactions to operating airguns (Jochens et al. 2006).

L'analyse des observations faites au cours de 201 levés sismiques dans les eaux du Royaume-Uni et dans les eaux avoisinantes montre que les petits odontocètes ont eu un éventail plus large de réactions aux tirs sismiques que n'en ont eu les mysticètes ou les grands odontocètes. Notamment, le taux d'observation des petits odontocètes chutait durant les périodes de tirs (Stone et Tasker, 2006). Au contraire, les grands odontocètes (globicéphales noirs, épaulards et cachalots macrocéphales) ont peu réagi aux tirs des canons à air, et le taux d'observation n'a pas diminué en période de tirs. Stone et Tasker (2006) ont indiqué que le comportement d'évitement manifesté par les petits odontocètes, et dans une moindre mesure par d'autres cétacés, semblait temporaire.

Deux campagnes sismiques ont été réalisées dans le bassin Orphan, au large de Terre-Neuve-et-Labrador, en 2004 et en 2005 (Moulton *et al.*, 2005, 2006a). Au cours des deux campagnes, le taux d'observation des dauphins, compte tenu de la variation temporelle, a été plus élevé en périodes silencieuses qu'en périodes de tirs, bien que la différence n'ait été statistiquement significative qu'en 2004. Le PRM moyen des dauphins était sensiblement plus près en périodes silencieuses (652 m) qu'en périodes de tirs (807 m) en 2005, mais la différence n'a été statistiquement significative qu'en 2004 (705 m contre 665 m). Les taux d'observation des grands odontocètes, principalement les cachalots macrocéphales (compte tenu de la variation temporelle) et les PRM n'ont pas montré de différence statistiquement significative entre les périodes de tirs et les périodes silencieuses en 2004 ou en 2005 dans le bassin Orphan. Les auteurs concluent, d'après les observations à partir du navire sismique, que certains odontocètes ont manifesté un évitement localisé des tirs (Moulton *et al.*, 2005, 2006a). On a obtenu des résultats analogues chez les odontocètes dans le contexte d'un programme de surveillance des mammifères marins dans le sous-bassin Laurentien (Moulton *et al.*, 2006b). Une vaste étude des cachalots macrocéphales dans le golfe du Mexique a montré qu'ils ne manifestaient pas de réactions à grande

Similarly, a recent study off Angola found no significant effect of a prolonged seismic operation on sperm whale sighting rates or distances (Weir 2008).

échelle d'évitement des tirs de canon à air (Jochens *et al.*, 2006). De même, une étude récente au large de l'Angola n'a pas révélé qu'une campagne sismique prolongée avait eu d'effet important sur le taux d'observation ou la distance des cachalots macrocéphales (Weir, 2008).

Reactions of odontocetes to a single airgun or other small airgun source are not well documented, but do not seem to be very substantial (e.g., Stone 2003). Results from three NSF-funded L-DEO seismic surveys using small arrays (up to three GI guns totalling up to 315 in^3) were inconclusive. During surveys in the Eastern Tropical Pacific (Holst et al. 2005b) and in the Northwest Atlantic (Haley and Koski 2004), detection rates were slightly lower during seismic operations compared to non-seismic periods. However, mean CPAs were closer during seismic operations during one cruise (Holst et al. 2005b), and greater during the other cruise (Haley and Koski 2004). Interpretation of the data was confounded by the fact that survey effort and/or number of sightings during non-seismic periods during both surveys was small.

Les réactions d'odontocètes à un seul canon à air ou à un autre petit dispositif de tirs à air comprimé ne sont pas bien documentées, mais elles semblent considérables (voir notamment Stone, 2003). Les résultats de trois levés sismiques de l'observatoire terrestre Lamont-Doherty financés par la Fondation nationale des sciences n'ont pas été concluants; on utilisait de petites batteries (jusqu'à trois canons GI pour un volume total d'au plus 315 po^3). Au cours de levés dans la partie est de l'océan Pacifique tropical (Holst *et al.*, 2005b) et dans le nord-ouest de l'Atlantique (Haley et Koski, 2004), les taux de détection étaient légèrement inférieurs durant les tirs sismiques que durant les périodes silencieuses. Toutefois, les PRM moyens ont été plus près durant les tirs au cours d'une campagne (Holst *et al.*, 2005b), et plus éloignés durant l'autre campagne (Haley et Koski, 2004). Le fait qu'il s'agissait de petites campagnes et que le nombre d'observations en périodes silencieuses a été faible dans les deux cas a constitué un facteur de confusion dans l'interprétation des données.

Porpoises, like delphinids, show variable reactions to seismic operations, and reactions apparently depend on species. The limited available data suggest that harbour porpoises show stronger avoidance of seismic operations than Dall's porpoises (Stone 2003; MacLean and Koski 2005; Bain and Williams 2006). In Washington State waters, the harbour porpoise - despite being considered a high-frequency specialist - appeared to be the species affected by the lowest received level of sound (<145 dB re 1 μPa_{rms} at a distance > 70 km) (Bain and Williams 2006). In contrast, Dall's porpoises seem relatively tolerant of airgun operations (MacLean and Koski 2005; Bain and Williams 2006). This

Les marsouins, comme les delphinidés, manifestent face aux tirs sismiques des réactions variées, qui dépendent apparemment de l'espèce. D'après le peu de données disponibles, il semble que le marsouin commun montrent une réaction d'évitement plus forte que celle du marsouin de Dall (Stone, 2003; MacLean et Koski, 2005; Bain et Williams, 2006). Dans les eaux de l'État de Washington, le marsouin commun – pourtant considéré comme un amateur de hautes fréquences – semble être une espèce touchée par le niveau sonore perçu le plus bas (< 145 dB re 1 μPa_{rms} à une distance de > 70 km) (Bain et Williams, 2006). Par contre, le marsouin de Dall paraît plutôt tolérant aux tirs des canons à air (MacLean et Koski, 2005; Bain et Williams, 2006). Cette différence

apparent difference in responsiveness of these two porpoise species is consistent with their relative responsiveness to boat traffic and some other acoustic sources (Richardson et al. 1995; Southall et al. 2007).

apparente de sensibilité entre les deux espèces de marsouin s'accorde avec leur sensibilité relative à la circulation des navires et à d'autres sources sonores (Richardson *et al.*, 1995; Southall *et al.*, 2007).

There are no specific data on the behavioural reactions of beaked whales to seismic surveys. Most beaked whales tend to avoid approaching vessels of other types (e.g., Würsig et al. 1998; see also Sorensen et al. 1984). They may also dive for an extended period when approached by a vessel (e.g., Kasuya 1986). It is likely that these beaked whales would normally show strong avoidance of an approaching seismic vessel, but this has not been documented explicitly. However, northern bottlenose whales sometimes are quite tolerant of slow-moving vessels (see Reeves et al. 1993; Hooker et al. 2001). However, those vessels were not emitting airgun pulses. Northern bottlenose whales have been observed from seismic vessels during periods of airgun operations (Moulton et al. 2006a,b).

Il n'y a pas de données précises sur le comportement des baleines à bec en réaction à des levés sismiques. La plupart des baleines à bec tendent à éviter tout navire qui s'approche (voir notamment Würsig *et al.*, 1998; Sorensen *et al.*, 1984). Elles peuvent aussi plonger pour un long moment lorsqu'un navire s'approche (voir notamment Kasuya, 1986). Il est probable que ces baleines manifesteraient normalement une forte réaction d'évitement à un navire sismique s'approchant, mais le fait n'a pas été explicitement documenté. Cela dit, les baleines à bec communes sont parfois très tolérantes des navires qui avancent lentement (voir Reeves *et al.*, 1993; Hooker *et al.*, 2001). Dans les cas relevés, cependant, les navires n'émettaient pas d'impulsions de canon à air. Les baleines à bec communes ont été observées à partir de navires sismiques durant des tirs (Moulton *et al.*, 2006a,b).

Conclusion: Dolphins and porpoises are often seen by observers on active seismic vessels, occasionally at close distances. However, some studies show localized avoidance. Belugas summering in the Beaufort Sea tended to avoid waters out to 10–20 km from an operating seismic vessel (Miller et al. 2005b). Recent studies show little evidence of avoidance reactions by sperm whales to airgun pulses, contrary to earlier indications.

Conclusion : Des dauphins et des marsouins sont souvent aperçus par des observateurs à bord de navires sismiques en activité, à l'occasion de près. Toutefois, certaines études révèlent un évitement localisé. Les bélugas passant l'été dans la mer de Beaufort tendent à éviter les parages (10-20 km) d'un navire sismique en activité (Miller *et al.*, 2005b). Des études récentes ont trouvé peu d'indications d'une réaction d'évitement chez les cachalots macrocéphales face aux impulsions de canon à air, contrairement à ce qui avait été indiqué antérieurement.

Odontocete reactions to large arrays of airguns are variable. For delphinids and Dall's porpoises,significant disturbance seems to be confined to a smaller radius than has been observed for the more responsive of the mysticetes, belugas, and harbour porpoises. For delphinids and Dall's porpoises (and also pinnipeds), strong reactions seem to be largely

Les réactions des odontocètes à de grosses batteries de canons à air varient. Chez les delphinidés et le marsouin de Dall, les perturbations importantes semblent confinées à un rayon plus court que celui observé chez les mysticètes, bélugas et marsouins communs parmi les plus sensibles. Chez les delphinidés et le marsouin de Dall (ainsi que chez les pinnipèdes), les réactions fortes se limitent

limited to the area within 1 or 2 km of airgun arrays. Given the available data on typical received levels of airgun array sound at those distances, a ≥170 dB re 1 μPa_{rms} disturbance criterion is probably more appropriate for delphinids, Dall's porpoises (and pinnipeds) than the ≥160 dB criterion that is often used. The 160 dB criterion originated from studies of gray, bowhead and humpback whales, and its blanket application to odontocetes is not well justified.

Pinnipeds.—Monitoring results from the Canadian Beaufort Sea during 2001-2002 were variable (Miller et al. 2005b). During 2001, sighting rates of seals (mostly ringed seals) were similar during all seismic states, including periods without airgun operations. However, seals were seen closer to the vessel (on average) during non-seismic than during seismic periods. In contrast, during 2002, sighting rates of seals were higher during non-seismic periods than seismic operations, and seals tended to be seen farther from the vessel during non-seismic compared to seismic activity (a marginally significant result). The combined data for both years showed that sighting rates were higher during non-seismic periods compared to seismic periods, and that sighting distances were similar during both seismic states. Miller et al. (2005b) concluded that seals showed very limited avoidance to the operating airgun array. That conclusion was consistent with results from six seasons of seismic monitoring in the Alaskan Beaufort Sea (Harris et al. 2001; Moulton and Lawson 2002).

In summary, visual monitoring from seismic vessels has shown only slight (if any) avoidance of airguns by pinnipeds, and only slight (if any) changes in behaviour. This, and other studies, indicate that pinnipeds frequently do not avoid the area within a few hundred meters of an operating airgun array. This indicates that most pinnipeds are

largement à une distance de 1 à 2 km des batteries. Selon les données disponibles sur les niveaux sonores habituellement perçus des canons à air à ces distances, un critère de perturbation de ≥ 170 dB re 1 μPa_{rms} convient probablement mieux à l'égard des delphinidés et du marsouin de Dall (ainsi que des pinnipèdes) que le critère de ≥ 160 dB qui est souvent utilisé. Le critère de 160 dB provient d'études chez la baleine grise, la baleine boréale et le rorqual à bosse, et son application généralisée à tous les odontocètes se justifie mal.

Pinnipèdes – Les résultats de surveillance dans la partie canadienne de la mer de Beaufort en 2001-2002 ont varié (Miller *et al.*, 2005b). En 2001, les taux d'observation des phoques (surtout du phoque annelé) ont été similaires à toutes les étapes de la campagne sismique, même en périodes silencieuses. Cependant, les phoques s'approchaient davantage du navire, en moyenne, durant les périodes silencieuses que durant les périodes de tirs. En revanche, en 2002, les taux d'observation des phoques ont été plus élevés durant les périodes silencieuses que durant les tirs, et les phoques étaient vus en général plus loin du navire quand il n'y avait pas de tirs (résultat marginalement significatif). La combinaison des données des deux années a montré que les taux d'observation étaient plus élevés en périodes silencieuses, et que les distances d'observation étaient analogues, avec ou sans tir. Miller *et al.* (2005b) ont conclu que les phoques manifestaient une réaction très restreinte d'évitement à l'égard des batteries de canons à air en activité. Cette conclusion s'accordait avec les résultats de six saisons de surveillance sismique dans la partie alaskienne de la mer de Beaufort (Harris *et al.*, 2001; Moulton et Lawson, 2002).

En résumé, la surveillance visuelle à partir de navires sismiques a montré une réaction d'évitement légère (ou nulle) des canons à air de la part des pinnipèdes et seulement une modification légère (ou aucune modification) du comportement. Ce résultat, et ceux d'autres études, indiquent que les pinnipèdes souvent n'évitent pas la zone de quelques centaines de mètres autour d'une batterie de canons à air qui

apparently not much disturbed even by the rather close approach of an operating seismic vessel. On the other hand, this lack of avoidance is a concern because it suggests that one cannot rely on pinnipeds to move away before received levels of airgun sound approach those that may cause TTS (and perhaps even PTS in certain cases).

Fissipeds.—No information on sea otter and polar response to seismic sounds has become available since 2004. From past studies, it appears that sea otters may be less responsive to marine seismic pulses than other marine mammals (Riedman 1983, 1984). Also, sea otters spend a great deal of time at the surface feeding and grooming. While at the surface, the potential noise exposure of sea otters would be much reduced by the pressure release effect at the surface.

Airgun effects on polar bears have not been studied. However, polar bears on the ice would be unaffected by underwater sound. Sound levels received by polar bears in the water would be attenuated because polar bears generally do not dive much below the surface and received levels of airgun sounds are reduced near the surface because of the pressure release effect at the water's surface (Greene and Richardson 1988; Richardson et al. 1995).

Changes in Dive and Respiratory Patterns

DFO (2004a) concluded that "exposure to seismic sound can result in changes in dive and respiratory patterns of some marine mammals, but this effect is expected to vary with species, individual, and context. The ecological significance of such effects is unknown, but there are conditions under which [the consequences of] the worst-case scenarios could be high."

tire. La plupart des pinnipèdes ne sembleraient donc pas très perturbés même par la présence plutôt rapprochée d'un navire sismique en activité. Cette absence de réaction d'évitement est préoccupante, car elle signifie qu'on ne peut compter que les pinnipèdes s'éloigneront avant que le niveau perçu de bruit sismique approche le niveau qui pourrait occasionner un TTS (voir dans certains cas un PTS).

Fissipèdes – On ne dispose d'aucune information sur la réaction à des bruits sismiques de la loutre de mer et de l'ours polaire depuis 2004. D'après les études passées, il semble que la loutre de mer soit moins sensible aux impulsions de la sismique marine que d'autres mammifères marins (Riedman, 1983, 1984). De plus, la loutre de mer passe beaucoup de temps à la surface pour s'alimenter et faire sa toilette. Lorsqu'elle se trouve à la surface, l'exposition éventuelle est très réduite en raison de la détente de pression.

L'effet des canons à air sur l'ours blanc n'a pas été étudié. Toutefois, quand il se trouve sur la glace, l'ours ne serait pas affecté par le bruit sous-marin. Le niveau sonore perçu dans l'eau serait atténué, parce que l'ours blanc, en général, ne plonge pas très loin de la surface, et les niveaux perçus des sons provenant des canons à air sont réduits près de la surface, en raison de la détente de pression à la surface de l'eau (Greene et Richardson, 1988; Richardson *et al.*, 1995).

Changements dans les régimes de plongée et de respiration

Le MPO (2004a) conclut que « l'exposition à des bruits sismiques peut résulter en des changements dans les régimes de plongée et de respiration chez certains mammifères marins, mais on s'attend à ce que ces effets varient selon l'espèce, l'individu et le contexte. Le degré d'importance écologique de ces effets est inconnu, mais il existe des conditions dans lesquelles le pire des scénarios pourrait avoir de fortes incidences ».

Recent results from the sperm whale tagging studies in the northern Gulf of Mexico have shown that, among eight tagged sperm whales exposed to airgun sounds, neither gross diving behaviour nor direction of movement changed for any of the individuals exposed to onset of seismic airgun sounds. These observations were obtained at the onset of gradual ramp-up at ranges of 7–13 km or during full-power exposures 1.5–12.8 km from the airguns (Jochens et al. 2006). However, some changes in foraging behaviour were observed that suggested avoidance of deep dives near operating airguns. Foraging behaviour was disrupted by airguns at exposure levels ranging from <130 to 162 dB re 1 μPa_{P-P} at distances of roughly 1–12 km from the sound source. The sample size was small. These results raise questions about the efficacy of ramp-up as a mitigation strategy for sperm whales, i.e., whether they swim away from oncoming seismic vessels. However, the observations may not be relevant to sperm whales in habitats where there has been less seismic exploration than the Gulf of Mexico (Jochens et al. 2006). Sperm whales in the Gulf of Mexico may be habituated to airgun pulses.

Les résultats récents d'une étude par marquage menée dans le nord du golfe du Mexique et portant sur le cachalot macrocéphale montrent que, sur huit cachalots macrocéphales marqués qui ont été exposés aux impulsions de canon à air, aucun des individus exposés aux impulsions de départ n'a modifié son comportement général de plongée ou la direction dans laquelle il se mouvait. Ces observations ont été faites au début du démarrage progressif des canons à des distances de 7 à 13 km, ou pendant l'exposition à la pleine puissance des canons, à des distances de 1,5 à 12,8 km (Jochens *et al*., 2006). On a toutefois observé certains changements dans leur quête de nourriture, les cachalots semblant éviter de plonger en profondeur à proximité des canons à air en activité. La quête de nourriture a été perturbée à des niveaux d'exposition allant de moins de 130 à 162 dB re 1 µPa crête à crête, à des distances d'environ 1 à 12 km de la source sonore. La taille de l'échantillon était petite. Ces résultats mettent en question l'efficacité de la méthode du démarrage progressif (élévation graduelle du niveau de bruit) comme mesure d'atténuation pour les cachalots macrocéphales, c'est-à-dire qu'on ne sait pas si ces cachalots s'éloignent à l'approche des navires sismiques. Toutefois, les observations qui précèdent pourraient ne pas s'appliquer aux cachalots macrocéphales dont l'habitat fait moins souvent l'objet de prospection sismique que le golfe du Mexique (Jochens *et al*., 2006). Il est possible que les cachalots macrocéphales du golfe se soient habitués aux impulsions des canons à air.

Shore-based observations of western gray whales on their feeding grounds indicated that most measures of surfacing, respiration and diving behaviour were not significantly correlated with seismic survey variables (Gailey et al. 2007). After accounting for effects of temporal and environmental covariates, they found no correlation between seismic variables and the mean number of whale exhalations per minute at the surface, mean time at the surface, and mean number of exhalations per minute during a

Des observations, à partir de l'île Sakhaline, de baleines grises dans leur aire d'alimentation ont révélé qu'il n'y avait pas de corrélation significative de la plupart des mesures concernant leurs comportements de nage à la surface, de respiration et de plongée avec les variables des levés sismiques (Gailey *et al*., 2007). Après avoir considéré les effets des covariables temporelles et environnementales, aucune corrélation n'a été observée entre les variables sismiques et le nombre moyen d'expirations par minute à la surface, la durée moyenne où les baleines demeuraient à la

whales' surface-to-dive cycle. In contrast, at higher received sound energy exposure levels, whales were observed to stay under water longer between respirations (a result contrary to some previous data from gray and bowhead whales).

surface et le nombre moyen d'expirations par minute pendant leur cycle surface-plongée. Par contre, lorsqu'elles étaient exposées à des niveaux d'énergie acoustique plus élevés, on a observé que les baleines restaient plus longtemps sous l'eau entre les respirations (un résultat contraire à certaines données antérieures sur les baleines grises et sur les baleines boréales).

Changes in Social Behaviour

DFO (2004a) concluded that *"it is unknown if exposure to seismic sound can result in changes in marine mammal social behaviour but if it were to occur there are conditions under which the worst-case consequences of such changes could be highly significant."*

Changements dans le comportement social

Le MPO (2004a) conclut que *« on ne sait pas si l'exposition à des bruits sismiques peut résulter en des changements dans le comportement social des mammifères marins, mais s'ils se produisaient, il existe des conditions dans lesquelles le pire des scénarios pourrait avoir des conséquences très importantes ».*

Previous studies described in this review and past reviews mainly relate to the effects of seismic surveys on marine mammal distribution, movements, and avoidance (or lack thereof) during feeding, migration, and (in some cases) unspecified activities. There are no published studies aimed at examining the specific impacts of seismic surveys on social behaviours such as mating, cooperative feeding, or aggressive interactions.

Les études décrites dans notre évaluation et dans des évaluations antérieures concernent surtout les effets des levés sismiques sur la répartition des mammifères marins, leurs mouvements et leur réaction ou absence de réaction d'évitement au cours de la recherche de nourriture, la migration et, dans certains cas, d'autres activités non précisées. Aucune étude n'a été publiée qui cible les effets précis des levés sismiques sur les comportements sociaux des mammifères marins, comme l'accouplement, l'alimentation en coopération ou les interactions agressives.

Changes in Vocalization Patterns

DFO (2004a) concluded that "*it is known that exposure to seismic sound can result in changes in marine mammal vocal behaviour, and when it occurs, there are conditions under which the worst-case consequences could be highly significant."*

Changements des vocalisations

Le MPO (2004a) conclut que *« on sait que l'exposition à des bruits sismiques peut résulter en des changements dans le comportement de vocalisation chez les mammifères marins et, lorsque cela se produit, il existe des conditions dans lesquelles le pire des scénarios pourrait avoir des conséquences très importantes ».*

Several studies demonstrate that various marine mammals adapt the source levels or frequencies of their calls in response to the levels and frequencies of background sounds (reviewed in Tyack 2008). However, the available information pertains mainly to continuous or prolonged sounds, not to low-duty-cycle

Plusieurs études montrent que divers mammifères marins adaptent le niveau d'émission ou la fréquence de leurs appels en fonction des niveaux et des fréquences des sons ambiants (analyse de Tyack, 2008). Toutefois, les renseignements disponibles à ce sujet touchent principalement les sons continus ou prolongés et non les sons à petit facteur de

sounds such as seismic pulses.

Some baleen and toothed whales are known to continue calling in the presence of seismic operations and often can be heard between the seismic pulses (e.g., Richardson et al. 1986; McDonald et al. 1995; Greene et al. 1999a,b; Nieukirk et al. 2004; Smultea et al. 2004). Although there has been one report that sperm whales ceased calling when exposed to pulses from a very distant seismic ship (Bowles et al. 1994), a more recent study reports that sperm whales off northern Norway continued calling in the presence of seismic pulses (Madsen et al. 2002). That has also been shown during recent work in the Gulf of Mexico (Tyack et al. 2003; Smultea et al. 2004; Jochens et al. 2006). Dolphins and porpoises commonly are heard calling while airguns are operating (e.g., Gordon et al. 2004; Smultea et al. 2004; Holst et al. 2005a,b). There is one recent summary report indicating that calling fin whales distributed in one part of the North Atlantic went silent for an extended period starting soon after the onset of a seismic survey in the area (Clark and Gagnon 2006). It is not clear from that preliminary paper whether the whales ceased calling as a behavioural response to seismic noise or because of masking (see below).

An early study in the Canadian Beaufort Sea showed that bowhead whales continue to call in the presence of airgun sounds, with the types of calls being unchanged (Richardson et al. 1986). A subsequent study in the Alaskan Beaufort Sea provided evidence of a reduction in bowhead calling (or at least call detection rate) when airgun sounds were present (Greene et al. 1999a,b). However, it is uncertain whether that change was a function of altered calling rate upon receipt of airgun sounds, or altered

forme, comme les impulsions sismiques.

On sait que certaines espèces de baleines à fanons et de baleines à dents continuent leurs appels au cours d'opérations sismiques et elles se font souvent entendre entre deux impulsions sismiques (voir notamment, Richardson *et al*., 1986; McDonald *et al*., 1995; Greene *et al*., 1999a, b; Nieukirk *et al*., 2004; Smultea *et al*., 2004). Bien qu'on ait signalé une fois que des cachalots macrocéphales avaient cessé leurs appels alors qu'ils étaient exposés à des impulsions provenant d'un navire sismique très éloigné (Bowles *et al*., 1994), une étude plus récente indique que des cachalots macrocéphales observés au nord de la Norvège ont continué à émettre leurs appels malgré des impulsions sismiques (Madsen *et al*., 2002). Cette observation a aussi été faite lors d'études récentes menées dans le golfe du Mexique (Tyack *et al*., 2003; Smultea *et al*., 2004; Jochens *et al*., 2006). Des dauphins et des marsouins sont fréquemment entendus pendant que des canons à air sont déchargés (voir notamment, Gordon *et al*., 2004; Smultea *et al*., 2004; Holst *et al*., 2005a, b). Un rapport sommaire récent indique que les appels de rorquals communs répartis dans une partie de l'Atlantique Nord ont cessé pendant une longue période, peu après le début d'un levé sismique dans ce secteur (Clark et Gagnon, 2006). Ce rapport préliminaire ne permet pas d'établir clairement si le silence des rorquals constitue une réponse comportementale aux bruits sismiques ou si leurs appels ont été masqués (voir plus bas).

Une étude ancienne dans la partie canadienne de la mer de Beaufort a montré que les baleines boréales continuent leurs appels en présence des sons produits par les canons à air, sans changer les types d'appel (Richardson *et al*., 1986). Une étude ultérieure dans la partie alaskienne de la mer de Beaufort a permis de prouver la diminution du nombre d'appels des baleines boréales (du moins la diminution du taux de détection des appels) en présence des signaux émis par les canons à air (Greene *et al*., 1999a,b). Toutefois, il n'est pas certain que le changement ait été lié à une modification

distribution of the whales (which was independently demonstrated to occur - Miller et al. 1999; Richardson et al. 1999).

A series of seismic surveys in the Chukchi and Beaufort seas from July to November 2006 examined the distribution and relative levels of vocal activity of bowhead and beluga whales as determined via passive acoustic detection (Funk et al. 2007). (Similar follow-on work, not yet widely reported, was done in 2007.) The results from 2006 indicated that there was insufficient evidence to evaluate whether or not the distribution and relative levels of vocal activity of bowhead and beluga whales were affected by the airgun sounds. The authors warn that until much more is known about the variations in the acoustic behaviours of bowhead whales and the natural factors influencing calling behaviour, relationships between bowhead acoustic behaviour and airgun activity will remain anecdotal and speculative. There are indications that various features of bowhead calling behaviour are correlated with a variety of natural environmental variables, and possibly with variable levels of industrial sound (Blackwell et al. 2008).

Functional Consequences of Physical and Behavioural Effects

Reduced Communication and Echolocation Efficiency

DFO (2004a) concluded that "*it is unknown if exposure to seismic sound can result in reduced communication or echolocation efficiency in marine mammals.*"

du taux d'appel causée par le captage des sons produits par les canons à air ou à une modification dans la répartition des baleines (modification qui a été constatée par ailleurs [Miller *et al*., 1999; Richardson *et al*., 1999]).

Un ensemble de levés sismiques effectués de juillet à novembre 2006 dans la mer des Tchouktches et dans la mer de Beaufort ont permis d'étudier la répartition de même que les niveaux relatifs d'activité vocale des baleines boréales et des bélugas par détection acoustique passive (Funk *et al*., 2007). Une étude ultérieure similaire, dont les résultats ne sont pas encore tous connus, a été menée en 2007. Les résultats de l'étude de 2006 indiquent que les preuves étaient insuffisantes pour évaluer si les émissions des canons à air jouaient ou non sur les niveaux relatifs d'activité vocale et sur la répartition des baleines boréales et des bélugas. Les auteurs ont précisé que, tant qu'une quantité beaucoup plus importante de renseignements n'aura pas été recueillie sur les variations du comportement acoustique des baleines boréales et sur les facteurs naturels qui influent sur les vocalisations, les liens entre le comportement d'appel des baleines boréales et les émissions des canons à air demeureront anecdotiques et basés sur des suppositions. Certains indices donnent à penser que diverses caractéristiques du comportement d'appel des baleines boréales sont corrélées avec un éventail de variables environnementales naturelles et, possiblement, avec des niveaux variables de sons d'origine industrielle (Blackwell *et al*., 2008).

Conséquences fonctionnelles des effets physiques et comportementaux

Efficacité réduite de la communication et de l'écholocation

Le MPO (2004a) conclut que *« on ne sait pas si l'exposition à des bruits sismiques peut résulter en une réduction de l'efficacité d'écholocation chez les mammifères marins ».*

Masking effects of pulsed sounds on marine mammal calls and other natural sounds are expected to be limited, although there are very few specific data on this. Because of the intermittent nature and low duty cycle of seismic pulses, animals can emit and receive sounds in the relatively quiet intervals between pulses. Most studies that have examined the potential adverse effects of masking caused by anthropogenic underwater sounds have involved exposure of marine mammals to sounds that are often continuous or nearly continuous, and are not airgun pulses. This section deals only with airgun and similar pulsed sounds.

On présume que les effets de masquage des impulsions sonores sur les appels des mammifères marins et sur les autres sons naturels sont limités, bien qu'il y ait très peu de données précises à ce sujet. La nature intermittente et le petit facteur de forme des impulsions sismiques font que les animaux peuvent émettre et recevoir des sons pendant l'intervalle de silence relatif entre les impulsions. La plupart des études qui ont porté sur les effets potentiellement néfastes du masquage causé par les bruits sous-marins d'origine humaine traitaient aussi de l'exposition des mammifères marins aux sons qui sont souvent continus, ou presque, et qui ne sont pas des impulsions produites par des canons à air. Cette section ne traitera que des sons qui proviennent des canons à air et des sons impulsionnels semblables.

An anthropogenic sound source will mask (i.e., reduce) the effective communication or echolocation distance of a marine mammal only if overlaps the sound signal in time and frequency. If little or no overlap occurs between the sound and the frequencies used, communication and echolocation are not expected to be disrupted or masked. As reviewed in Appendix A, most energy in sound pulses emitted by seismic airgun arrays is at low frequencies, with strongest spectrum levels below 200 Hz,considerably lower spectrum levels above 1,000 Hz, and smaller amounts of energy emitted up to ~150kHz. These low frequencies are mainly used by mysticetes, but generally not by odontocetes, pinnipeds, or fissipeds (see Appendix B). Strong anthropogenic sounds are presumed not to interfere with signalling of marine mammals that are using frequencies outside the range of the anthropogenic sounds. Furthermore, the discontinuous nature of seismic pulses makes significant masking effects unlikely even for mysticetes.[4] Studies demonstrating that cetacean species continue to call in the

Une source sonore d'origine humaine aura un effet de masque, c'est-à-dire réduira la distance effective de communication ou d'écholocation d'un mammifère marin seulement si les sons émis chevauchent le signal vocal de l'animal en durée et en fréquence. Si le chevauchement est très léger ou nul, la communication et l'écholocation ne devraient pas être perturbées ou masquées. Comme le montre l'analyse présentée à l'annexe A, la majeure partie de l'énergie produite par les impulsions sonores des batteries de canons à air sismiques est de basse fréquence; les niveaux spectraux étant pour l'essentiel sous les 200 Hz, une part considérablement moindre au-dessus de 1 000 Hz, et de petites quantités de l'énergie émises jusqu'à ~ 150 kHz. Ces basses fréquences sont principalement utilisées par les mysticètes, et généralement pas par les odontocètes, les pinnipèdes et les fissipèdes (voir l'annexe B). On présume que les sons forts d'origine humaine ne devraient pas gêner les signaux des mammifères marins qui utilisent des fréquences qui se situent hors de la gamme de fréquence des sons d'origine humaine. De plus, les impulsions sismiques étant intermittentes, il est peu probable qu'elles produisent un effet de masquage significatif,

presence of seismic operations are described in the previous section, Changes in Vocalization Patterns.

même pour les mysticètes.[4] Les études qui montrent que les cétacés continuent leurs appels au cours d'opérations de prospection sismique sont présentées plus haut à la section « Changements des vocalisations ».

There is no information on masking of pinniped calls by pulsed sounds like airgun signals, but any such masking is expected to be minimal due mainly to the low duty cycle of airgun pulses.

Aucune donnée n'existe sur le masquage des appels des pinnipèdes par les impulsions sonores telles que les signaux sismiques, mais on présume que ce masquage devrait être minime, principalement à cause du petit facteur de forme des impulsions des canons à air.

Masking effects of seismic pulses are expected to be negligible in the case of polar bears and sea otters due to their use of in-air rather than underwater calls.

Les effets de masquage des impulsions sismiques devraient être négligeables pour les ours blancs et les loutres de mer, puisque leurs appels se font hors de l'eau.

Hampered Passive Acoustic Detection of Prey and Predators

Capacité diminuée de détection acoustique passive des proies et des prédateurs

DFO (2004a) concluded that "*it is unknown whether exposure to seismic sound can hamper the passive acoustic detection of prey by marine mammals. DFO also concluded that it is unknown whether exposure to seismic sound could increase the vulnerability of marine mammals to predators."*

Le MPO (2004a) conclut que *« on ne sait pas si l'exposition à des bruits sismiques pourrait diminuer la capacité de détection acoustique passive de proies chez les mammifères marins ». Le MPO conclut aussi que « on ne sait pas si l'exposition à des bruits sismiques pourrait accroître la vulnérabilité des mammifères marins à leurs prédateurs ».*

No studies, either recent or older, have specifically examined the potential effects of seismic sound on the abilities of marine mammals to detect prey and/or predators. It is also unknown which, if any, species of marine mammals would use passive acoustic detection of prey as an important feeding strategy, with perhaps the exception of transient killer whales (e.g., Barrett-Lenard et al. 1996; Deecke et al. 2005). In general, masking by airgun signals is unlikely to have much effect on passive acoustic detection of prey. The

Aucune étude, récente ou non, n'a analysé de façon précise les effets potentiels des bruits sismiques sur la capacité des mammifères marins de détecter les proies et les prédateurs. On ignore aussi quelles espèces de mammifères marins, s'il en existe, auraient recours à la détection acoustique passive des proies comme grande stratégie d'alimentation, à l'exception, peut-être, des épaulards migrateurs (voir notamment Barrett-Lenard *et al*., 1996; Deecke *et al*., 2005). De manière générale, le masquage produit par les impulsions des canons à air risque peu d'avoir

[4]Near the source, the predominant part of a seismic pulse is about 10–20 ms in duration and the interpulse interval is typically 10-12 s, resulting in a low duty cycle (<5%). Other sounds are audible in the gaps except perhaps in the unusual situation where there is strong reverberation of sound that persists for much of the gap between received pulses.

[4] Près de la source sonore, la majeure partie d'une impulsion sismique dure environ 10 à 20 ms, et l'intervalle entre les impulsions dure habituellement de 10 à 12 s, ce qui se traduit par un petit facteur de forme (< 5 %). D'autres sons sont audibles pendant les intervalles, sauf, peut-être, dans des cas exceptionnels où une forte réverbération du son persiste pendant presque tout l'intervalle entre les impulsions captées.

low duty cycle of the pulses means that audibility of other sounds will be little affected during the intervals between pulses.

beaucoup d'effets sur la détection acoustique passive des proies. Le petit facteur de forme des impulsions signifie que l'audibilité des autres sons est peu touchée pendant les intervalles entre les impulsions.

For similar reasons, vulnerability to predators is unlikely to be much affected through masking by airgun signals. However, ability to detect predators could, at least in theory, be impaired if a marine mammal's auditory sensitivity was reduced either temporarily or - more importantly - permanently (TTS or PTS, respectively).

Pour des raisons analogues, la vulnérabilité aux prédateurs est peu susceptible d'être accrue par l'effet de masquage produit par les impulsions des canons à air. Toutefois, la capacité des animaux de détecter les prédateurs pourrait, du moins en théorie, être réduite si le seuil d'audition d'un mammifère marin est déplacé de façon temporaire (TTS) ou, dans des cas plus graves, de façon permanente (PTS).

Hampered Avoidance of Anthropogenic Threats (such as ship strikes, net entanglement)

Capacité diminuée d'évitement des menaces anthropiques (collision avec des navires, enchevêtrement dans les filets)

DFO (2004a) concluded that *"it is a concern that exposure to seismic sound could reduce the ability of marine mammals to avoid anthropogenic threats, but the risk has not been demonstrated."*

Le MPO (2004a) conclut que *« le fait que l'exposition à des bruits sismiques pourrait réduire la capacité des mammifères marins d'éviter des menaces anthropiques est préoccupant, mais le risque n'a pas été prouvé. »*

While nearly all species of large whale have been victims of collisions with ships (Laist et al. 2001; Jensen and Silber 2003; Vanderlaan and Taggart 2007), right whales are especially vulnerable, likely in large part because of certain characteristic behaviours during which they may be less aware of their surroundings. Controlled exposure experiments in the right whale summer feeding area in the Bay of Fundy showed that right whales did not respond to the playback of the sound made by a 120-m container ship passing within 100 m in spite of the fact that they were apparently able to hear it (Nowacek et al. 2004). When exposed to alert signals, right whales responded by swimming strongly to the surface, a response likely to increase rather than decrease the risk of collision (Nowacek et al. 2004).

Bien que presque toutes les espèces de baleines de grande taille soient victimes de collisions avec des navires (Laist *et al*., 2001; Jensen et Silber, 2003; Vanderlaan et Taggart, 2007), les baleines noires sont particulièrement vulnérables, probablement surtout à cause de certains comportements caractéristiques où elles sont moins à l'affût de ce qui les entoure. Des expériences en milieu contrôlé dans l'aire d'alimentation estivale de la baleine noire, dans la baie de Fundy, ont montré que les baleines noires ne réagissaient pas lorsqu'on leur faisait entendre la reproduction du bruit produit par un navire porte-conteneurs de 120 mètres, à une distance d'environ 100 mètres, malgré le fait qu'elles étaient, selon toute vraisemblance, capables de l'entendre (Nowacek *et al*., 2004). Lorsqu'elles étaient exposées à des signaux d'alerte, les baleines noires réagissaient en nageant vigoureusement vers la surface, réaction susceptible de faire augmenter plutôt que d'atténuer les risques de collision (Nowacek *et al*., 2004).

Evidence suggests that a greater rate of mortality and serious injury correlates with a greater vessel speed at the time of a ship strike (Laist et al. 2001; Vanderlaan and Taggart 2007). Most lethal and severe injuries to large whales resulting from documented ship strikes have occurred when vessels were travelling at 14 knots or greater (Laist et al. 2001). Vanderlaan and Taggart (2007), using a logistic regression modelling approach based upon vessel strike records, found that for vessel speeds greater than 15 knots, the probability that a collision will result in a lethal injury (mortality or severely injured) approaches 1. The probability that a collision will result in lethal injury declined to approximately 20 % at speeds of 8.6 knots and to less than 5 % at of 4 knots (Vanderlaan and Taggart 2007). Considering the reduced speed at which seismic survey vessels travel during periods of active seismic surveying (typically 4.5 to 5 knots), plus the extra noise that they emit relative to routine vessel traffic, the risk of lethal injury from a vessel strike, would be limited. However, if exposure to seismic pulses causes TTS or (worse) PTS in marine mammals, this could lead to a reduction in their ability to detect and avoid approaching vessels.

Les données disponibles donnent à penser qu'à des taux plus élevés de mortalité et de blessures graves correspond une plus grande vitesse des navires au moment des collisions (Laist *et al*., 2001; Vanderlaan et Taggart, 2007). Selon les données disponibles, la plupart des blessures graves ou mortelles chez les baleines de grande taille qui ont été victimes de collisions avec des navires se sont produites alors que les navires allaient à 14 nœuds ou plus (Laist *et al*., 2001). À l'aide de modèles de régression logistique fondés sur les registres de collisions des navires, Vanderlaan et Taggart (2007) ont découvert que, pour les navires dont la vitesse était supérieure à 15 nœuds, la probabilité qu'une collision entraîne des blessures mortelles (blessures graves ou décès) était près de 1. La probabilité qu'une collision entraîne des blessures mortelles baisse à environ 20 % à une vitesse de 8,6 nœuds et à moins de 5 % à une vitesse de 4 nœuds (Vanderlaan et Taggart, 2007). Compte tenu de la vitesse à laquelle les navires sismiques se déplacent pendant les périodes de prospection (généralement entre 4,5 et 5 nœuds) et le bruit supplémentaire qu'ils produisent en circulant, les risques de blessures mortelles découlant d'une collision devraient être limités. Toutefois, si l'exposition à des impulsions sismiques entraîne un TTS, ou pire, un PTS chez des mammifères marins, la capacité des ces derniers de détecter et d'éviter les navires qui s'approchent pourrait être réduite.

Hampered Parental Care or Bonding

DFO (2004a) concluded that *"it is unknown if exposure to seismic sound can hamper parental care or bonding in marine mammals."*

No studies had, or have since, examined this potential effect.

Capacité diminuée de soigner les petits ou de former des liens parentaux

Le MPO (2004a) conclut que *« on ne sait pas si l'exposition à des bruits sismiques peut réduire la capacité de soin des petits ou de formation de liens parentaux chez les mammifères marins ».*

Aucune étude n'a porté sur ces effets éventuels.

Chronic Effects (e.g., stress-related physiological changes, reduced fecundity)

DFO (2004a) concluded that *"it is unknown if exposure to seismic sound can result in chronic effects, such as immuno-supression or reduced fecundity, on marine mammals."*

Romano et al. (2004) examined the effects of single underwater impulse sounds from a seismic water gun (up to 228 dB re 1 µPa peak-to-peak pressure) and single pure tones (SPL up to 201 dB re 1 µPa) on the nervous and immune systems of a beluga whale and a bottlenose dolphin. They found that neural-immune changes to noise exposure were minimal. Although levels of some stress-released substances (e.g., catecholamines) changed significantly with exposure to sound, levels returned to baseline after 24 hours. Further information about the occurrence of noise-induced stress in marine mammals is not available at this time. Tyack (2008) summarizes evidence from other animals concerning the importance of physiological stress in affecting resilience and fitness, and discusses the potential relevance to marine mammals.

Effets chroniques (changements physiologiques causés par le stress, fécondité réduite)

Le MPO (2004a) conclut que *« on ne sait pas si l'exposition à des bruits sismiques peut résulter en de tels effets chroniques [immunosuppresion ou diminution de la fécondité] chez les mammifères marins ».*

Romano *et al*. (2004) ont examiné les effets des impulsions sonores sous-marines isolées provenant d'un canon à air (pression crête à crête allant jusqu'à 228 dB re 1 µPa) de même que des sons purs isolés (niveau de pression acoustique allant jusqu'à 201 dB re 1 µPa) sur les systèmes nerveux et immunitaire d'un béluga et d'un dauphin à gros nez. Les chercheurs ont noté que les changements d'ordre neuro-immunitaire liés à l'exposition aux bruits étaient minimes. Bien qu'on ait observé un changement significatif de la concentration des substances sécrétées en situation de stress (p. ex. catécholamines) lorsque les animaux étaient exposés aux sons, les concentrations sont revenues à la normale au bout de 24 heures. D'autres renseignements sur l'occurrence du stress causé par le bruit chez les mammifères marins ne sont pas disponibles pour le moment. Tyack (2008) résume les résultats portant sur d'autres animaux et sur l'importance du rôle que joue le stress physiologique sur la résilience et sur la condition physique, et explique en quoi ces résultats sont pertinents pour les mammifères marins.

Indirect Effects (e.g., reduced prey availability)

DFO (2004a) concluded that *it is unknown if exposure to seismic sound can result in indirect effects, such as reduced prey availability (through displacement or reduced catchability) on marine mammals.*

No studies had, or have since, examined this potential indirect effect. Studies of fish responses to airgun pulses often show temporary changes in fish behaviour (e.g., McCauley et al. 2000a,b; Wardle et al.

***Effets indirects* (p. ex. disponibilité réduite de proies)**

Le MPO (2004a) conclut *qu'on ne sait pas si l'exposition à des bruits sismiques peut résulter en de effets indirects sur les mammifères marins, par exemple réduire la disponibilité des proies, soit par déplacement de celles-ci soit par la réduction de leur capturabilité.*

Aucune étude ciblée n'existe concernant cet effet indirect possible. Les études qui portent sur la réponse des poissons aux émissions des canons à air montrent souvent des changements temporaires de comportement

2001; Hassel et al. 2003; Slotte et al. 2004), which in some situations might have short-term consequences for availability of prey to fish-eating marine mammals.

(voir notamment McCauley *et al*., 2000a, b; Wardle *et al*., 2001; Hassel *et al*., 2003; Slotte *et al*., 2004) qui, dans certaines situations, pourraient avoir des conséquences à court terme sur la disponibilité des proies pour les mammifères marins qui se nourrissent de poissons.

APPENDIX A: CHARACTERISTICS OF AIRGUN PULSES

Airguns function by venting high-pressure air into the water. The pressure signature of an individual airgun consists of a sharp rise and then fall in pressure, followed by several positive and negative pressure excursions caused by oscillation of the resulting air bubble. The sizes, arrangement,and firing times of the individual airguns in an array are designed and synchronized to suppress the pressure oscillations subsequent to the first cycle. The resulting downward-directed pulse lasts only 10 to 20 ms, with only one strong positive and one strong negative peak pressure (Caldwell and Dragoset 2000).

The predominant energy emitted from airguns is at relatively low frequencies. For example, typical high-energy airgun arrays emit most energy at 10–120 Hz. However, the pulses contain some energy up to 500–1,000 Hz and above (Goold and Fish 1998; Potter et al. 2007). Substantial high-frequency energy output of up to 150 kHz was found during tests of 60 in^3 and 250 in^3 airguns (Goold and Coates 2006). In fact, the output of these airguns covered the entire frequency range known to be used by marine mammals. This output included substantial energy levels as to be clearly audible to most, if not all, cetacean species (Goold and Coates 2006). Other recent studies—including controlled studies of sperm whales in the Gulf of Mexico (Tyack et al. 2006)—have also found that airgun arrays exposed animals to significant sound energy above 500 Hz (Goold and Fish 1998; Sodal 1999). These data increase concerns about the potential impacts of seismic sounds on odontocetes with poor low-frequency hearing but good higher-frequency hearing.

Levels of anthropogenic underwater sounds, including those produced by seismic surveys, have been increasing worldwide. Concurrently, there is growing concern by the general public, researchers, government entities, and others regarding exposure of marine mammals to these sounds (e.g., Hildebrand 2004; Marine Technology Society 2004; Simmonds et al. 2006). In a comparison of anthropogenic underwater sound sources, airgun arrays worldwide were estimated to introduce 3.9 x 1013 Joules of energy into the ocean, second only to the potential release of energy from underwater nuclear explosions and ranking above military sonars (Moore and Angliss 2006). As a result, there has been increasing interest in and studies on methods to estimate the numbers of animals exposed to various sound levels and to mitigate exposure to these sounds (e.g., Hollingshead and Harrison 2005).

Recent attention has focused on developing sound exposure criteria appropriate to the acoustic sensitivities of various marine mammal groups and species (e.g., Hollingshead and Harrison 2005; Miller et al. 2005; Southall et al. 2007). These exposure criteria have important implications for identifying appropriate “safety radii” and sound exposure limits, including balancing mitigation with goals of geophysical seismic studies conducted by industry, universities and others (e.g., Barton et al. 2006). Various empirical data are being collected, and modeling and predictions of the propagation and received levels of airgun sounds are being developed and applied (e.g., Breitzke et al. 2006; Diebold et al. 2006; Frankel et al. 2006; Miller et al. 2006; Racca et al. 2006; Turner et al. 2006; Tyack et al. 2006). These recent studies are affecting the way underwater sound is modeled. For example, DeRuiter et al. (2005) reported that on-axis source levels and spherical spreading assumptions alone insufficiently describe airgun pulse propagation and the extent of exposure zones.

Several important mitigating factors need to be kept in mind regarding the characteristics of seismic airgun arrays compared to other types of underwater anthropogenic sounds. (1) Airgun arrays produce intermittent sounds involving emission of a strong sound pulse for a small fraction of a second followed by several seconds of near silence. In contrast, some other sources produce sounds with lower peak levels that are continuous or discontinuous, but persist

for much longer durations than seismic pulses. (2) Airgun arrays are designed to transmit strong sounds downward through the seafloor, and the amount of sound transmitted in near-horizontal directions is considerably reduced. Nonetheless, they also emit sounds that travel horizontally toward non-target areas. (3) An airgun array is a distributed source, not a point source. The nominal source level is an estimate of the sound that would be measured from a theoretical point source emitting the same total energy as the airgun array. That figure is useful in calculating the expected received levels in the far field (i.e., at moderate and long distances). However, because the airgun array is not a single point source, there is no one location within the near field (or anywhere else) where the received level is as high as the nominal source level.

The strengths of airgun pulses can be measured in different ways, and it is important to know which method is being used when interpreting quoted source or received levels. Geophysicists usually quote peak-to-peak levels, in bar-meters or (less often) dB re 1 µPa-1 m. The peak (= 0-to-peak) level for the same pulse is typically about 6 dB less. In the biological literature, levels of received airgun pulses are often described based on the "average" or "root-mean-square" (rms) level, where the average is calculated over the time interval encompassing 90% of the total acoustic energy from a single pulse. The rms value for a given airgun pulse is typically about 10 dB lower than the peak level, and 16 dB lower than the peak-to-peak value (Greene 1997; McCauley et al. 1998, 2000). A fourth measure that is increasingly being used is the energy, or sound exposure level (SEL), in dB re 1 $\mu Pa^2 \cdot s$. Because the pulses are <1 s in duration, the numerical value of the SEL energy value is lower than the rms pressure level but the units are different. Because the level of a given pulse will differ substantially depending on which of these measures is being applied, it is important to be aware which measure is in use when interpreting any quoted pulse level. In the past, NMFS has commonly referred to rms levels when discussing levels of pulsed sounds that might "harass" marine mammals, but SEL values are coming into wider use for this purpose.

Seismic sound received at any given point will arrive in several ways. These include sound arriving via a direct path through the water, indirect paths that include reflection from the sea surface and bottom, and other indirect paths including transmission through the bottom sediments. Sounds propagating via indirect paths travel longer distances and often arrive later than sounds arriving via a direct path. (However, sound traveling in the bottom may travel faster than that in the water, and thus may, in some situations, arrive slightly earlier than sound traveling along the direct path despite traveling a greater distance.) These variations in travel time effectively lengthen the duration of the received pulse, or may cause two or more received pulses from a single emitted pulse. Near the source, the predominant part of a seismic pulse is about 10–20 ms in duration. In comparison, the pulse duration as received at long horizontal distances can be much greater. For example, for one airgun array operating in the Beaufort Sea, pulse duration was about 300 ms at a distance of 8 km, 500 ms at 20 km, and 850 ms at 73 km (Greene and Richardson 1988).

An important aspect of sound propagation is that received levels of low-frequency underwater sounds diminish close to the water's surface because of pressure-release and interference phenomena that occur at and near the surface (Urick 1983; Richardson et al. 1995). Paired measurements of received airgun sounds at depths of 3 m vs. 9 m or 18 m have shown that received levels are typically several decibels lower at 3 m (Greene and Richardson 1988). For a marine mammal at the surface, whose auditory organs are within 0.5–1 m of the surface, the received level of the predominant low-frequency components of the airgun pulses would be further reduced. Conversely, in deep water, the received levels at deep depths can be considerably higher than those at relatively shallow (e.g., 18 m) depths and the same horizontal distance from the airguns (Tolstoy et al. 2004a, b).

In addition, research conducted in shallow-water environments has recently shown that when the seafloor is within the near field of the source array, the associated partitioning of energy can cause uncharacteristically rapid loss of energy with distance (Diebold et al. 2006). These data suggest that, in some shallow water environments, recent mitigation measures may be more conservative than necessary. Empirical site-specific data collected in situ may facilitate identification of the most appropriate safety radii in these shallow-water and other environments (Turner et al. 2006).

Recent reports suggest that monitoring seismic airgun sound over broad areas may be needed to determine the scale of potential effects of seismic surveys (e.g., Bain and Williams 2006). Pulses of underwater sound from open-water seismic exploration are often detected 50–100 km from the source location, even during operations in nearshore waters (Greene and Richardson 1988; Burgess and Greene 1999). At those distances, the received levels are low: <120 dB re 1 μPa_{rms}. However, faint seismic pulses are sometimes detectable at even greater ranges (e.g., Bowles et al. 1994; Fox et al. 2002). In fact, recent data show that, in deep water areas, low-frequency airgun signals can sometimes be detected thousands of kilometres from their source. For example, sound from seismic surveys conducted offshore of Nova Scotia, the coast of western Africa, and northeast of Brazil were reported as a dominant feature of the underwater noise field recorded along the mid-Atlantic ridge (Nieukirk et al. 2004). In addition, considerably higher levels can occur at distances out to several kilometres from an operating airgun array. A further consideration is that, with depending on propagation conditions, received levels are not necessarily a simple declining function of distance. For example, Madsen et al. (2006) reported that received levels of the first arrivals of seismic pulses at 12 km were as high as received levels 2 km from the seismic array. In some situations, secondary sound arrivals can have higher received levels at 5–12.6 km from the source than they do at ranges closer to (Madsen et al. 2006).

APPENDIX B: HEARING ABILITIES OF MARINE MAMMALS

The hearing abilities of marine mammals are functions of the following (Richardson et al. 1995; Au et al. 2000):

1. Absolute hearing threshold (the level of sound barely audible in the presence of significant ambient noise) at the frequency in question. The “best frequency” is the frequency with the lowest absolute threshold.

2. Critical ratio (the signal-to-noise ratio required to detect a sound at a specific frequency in the presence of background noise around that frequency).

3. The ability to localize sound direction at the frequencies under consideration.

4. The ability to discriminate among sounds of different frequencies and intensities.

Marine mammals rely on the use of underwater sounds to communicate and gain information about their surroundings. Experiments also show that they hear and may react to many anthropogenic sounds including sounds made during seismic exploration. Seismic surveys often use sonar systems simultaneously with airguns; however, the majority of studies that have examined the potential impacts of seismic surveys on marine mammals have focused on the impacts of airguns rather than sonar.

Baleen Whales (Mysticetes)

The hearing abilities of mysticetes have not been studied directly. However, the anatomy of the baleen whale inner ear seems to be well adapted for detection of low-frequency sounds (Ketten 1991, 1992, 1994, 2000). Behavioural evidence also indicates that they hear well at low frequencies <1 kHz (see Richardson et al. 1995). The sound levels that they can detect below 1 kHz are probably limited by increasing levels of natural ambient noise at decreasing frequencies; at frequencies below 1 kHz, natural ambient levels tend to increase (see Richardson et al. 1995; Clark and Ellison 2004).

The hearing systems of mysticetes are thought to be more sensitive to low-frequency sounds than are the ears of the small odontocetes that have been studied directly. Thus, mysticetes are likely to hear airgun pulses farther away than can small odontocetes and, at closer distances, airgun sounds may seem more prominent to mysticetes than to odontocetes. However, mysticetes have commonly been seen well within the distances where seismic sounds would be detectable and yet often show no overt reaction to those sounds. Behavioural responses by mysticetes to seismic pulses have been documented, but received levels of pulsed sounds necessary to elicit behavioural reactions are typically well above the assumed minimum detectable levels (Malme et al. 1984, 1988; Richardson et al. 1986, 1995; McCauley et al. 2000; Johnson et al. 2007).

However, some studies do suggest that mysticetes may also be able to hear and respond to much higher frequency sounds. Mysticetes produce sounds at frequencies up to 8 kHz and, for humpback whales, to >24 kHz (Au et al. 2001, 2006). Watkins (1986) noted that some mysticetes reacted to pinger sounds up to 28 kHz, but not to pingers or sonars emitting sounds at >36 kHz. Todd et al. (1992) reported that mysticetes reacted to sonar sounds at 3.5 kHz when received levels were 80–90 dB re 1 µPa. Migrating gray whales reacted to a 21–25 kHz whale-finding sonar with a source level of 215 dB re 1 µPa-m (Frankel 2005). Southall et al.

(2007) concluded that the functional hearing range for ysticetes as a group is from about 7 Hz to 22 kHz.

Toothed Whales (Odontocetes)

Hearing abilities of some odontocetes have been studied in detail (reviewed by Richardson et al. 1995; Au et al. 2000; Southall et al. 2007). Hearing sensitivities as a function of frequency have been determined for several species. The small- to moderate-sized odontocetes that have been the subject of audiology studies have relatively poor hearing sensitivity at frequencies below 1 kHz, but extremely good sensitivity at and above several kHz. There are very few data on the absolute hearing thresholds of most of the larger, deep-diving odontocetes, such as the sperm and beaked whales. However, Mann et al. (2005) and Cook et al. (2006) both report that a Gervais' beaked whale showed evoked potentials from 5–80 kHz, with the best sensitivity at 40–80 kHz. Southall et al. (2007) concluded that the functional hearing range for "mid-frequency" and "high-frequency" cetaceans as groups are from about 150 Hz to 160 kHz and from about 200 Hz to 180 kHz, respectively.

Despite the relatively poor sensitivity of small odontocetes at the low frequencies that contribute most of the energy in pulses of sound from airgun arrays, the sounds are sufficiently strong that their received levels sometimes remain above the hearing thresholds of odontocetes at distances out to several tens of kilometres (Richardson and Würsig 1997). However, there is no evidence that small odontocetes react to airgun pulses at such long distances, or even (with the exception of belugas.Miller et al. 2005) at intermediate distances where sound levels are well above the ambient noise level.

Seals and Sea Lions (Pinnipeds)

Behavioural measures of hearing are available for five species of earless seals (phocids), two species of eared seals (otariids), and the walrus (reviewed in Richardson et al. 1995:211ff.; Kastak and Schusterman 1998, 1999; Kastelein et al. 2002; Southall et al. 2007). In comparison with odontocetes, pinnipeds tend to have lower best frequencies, lower high-frequency cutoffs, better auditory sensitivity at low frequencies, and poorer sensitivity at the best frequency. In particular phocid seals have better sensitivity at low frequencies (1 kHz) than do odontocetes.

Below 30–50 kHz, the hearing thresholds of most tested pinniped species are essentially flat down to about 1 kHz, and range from 60–85 dB re 1 µPa. Measurements for a harbour seal indicate that, below 1 kHz, its thresholds deteriorate (increase) gradually to ~97 dB re 1 µPa at 100 Hz (Kastak and
Schusterman 1998). The northern elephant seal appears to have better underwater sensitivity than does the harbour seal, at least at low frequencies (Kastak and Schusterman 1998, 1999). For the otariids, the high frequency cutoff is lower, and the sensitivity at low frequencies (e.g., 100 Hz) is poorer than for phocids, at least for harbour and elephant seals.

The underwater hearing of a walrus has been measured at frequencies from 125 Hz to 15 kHz (Kastelein et al. 2002). The range of best hearing was 1–12 kHz, with maximum sensitivity (67 dB re 1µPa) occurring at 12 kHz.

Southall et al. (2007) concluded that the functional hearing range for pinnipeds in water as a group is from about 75 Hz to 75 kHz. This range is primarily based on data for phocids, and as such, would be lower for otariids.

Sea Otter and Polar Bear (Fissipeds)

No data are available on the hearing abilities of sea otters (Ketten 1998), although the in-air vocalizations of sea otters have most of their energy concentrated at 3 to 5 kHz (McShane et al. 1995; Thomson and Richardson 1995). Sea otter vocalizations are considered to be most suitable for short-range communication among individuals (McShane et al. 1995).

Data on the specific hearing capabilities of polar bears are also largely lacking. A recent study of in-air hearing of polar bears involved use of the auditory evoked potential method while tone pips were played to anesthetized bears (Nachtigall et al. 2007). Hearing was tested in ½ octave steps from 1 to 22.5 kHz and best hearing sensitivity was found between 11.2 and 22.5 kHz. These data suggest that polar bears have sensitive hearing over a wide frequency range.

Polar bear behaviour (e.g., remaining on the ice, at the water surface, or on land) reduces or avoids their exposure to underwater sounds. Similarly, the tendency of sea otters to be at the water surface (or on land) much of the time would reduce their exposure to underwater sounds.

A risk assessment of the sustainability of the harvest of beluga (*Delphinapterus leucas* (Pallas 1776)) in West Greenland

Carlos M. Alvarez-Flores and Mads Peter Heide-Jørgensen

Alvarez-Flores, C. M. and Heide-Jørgensen, M. P. 2004. A risk assessment of the sustainability of the harvest of beluga (*Delphinapterus leucas* (Pallas 1776)) in West Greenland. – ICES Journal of Marine Science, 61: 274–286.

Risk assessments to assess the efficiency of management procedures to regulate removals of marine mammals have rarely been conducted. Using Bayesian methods, we conducted a risk assessment on a harvested beluga population off West Greenland. The population size in recent years was estimated to be 22% of the size in 1954. Results indicate that current catches are unsustainable and that continuation of this situation represents a 90% probability that the population will become extinct in 20 years. The analyses suggest that the harvest should be reduced to no more than 130 animals. Constant catch quotas represent a greater risk of depletion compared with catch limits that are a function of harvest rate and population size. An alternative gradual reduction schedule is proposed as a viable strategy, reducing the harvest in 5 years and adjusting the subsequent quota using a harvest rate of 0.5 of R_{max}, with updates in the abundance. This analysis is presented as an alternative for cases where an immediate catch reduction is desirable but not feasible for marine mammal populations that appear vulnerable or in danger and where catch and abundance data are available.

Introduction

Management of marine species is not limited to the evaluation of the biological characteristics of the resource, as social and political considerations also play an important role in the final decisions. Therefore, management alternatives should be evaluated in terms of their ability to meet some specific management goals. If a biologically desirable strategy cannot be implemented immediately, the manager should know the risk of departing from the optimum (Hilborn, 1997). Methods for evaluating harvesting strategies for marine mammal populations have incorporated means of accounting for the associated uncertainties but usually offer a single estimate of the maximum allowable removal. These methods include the Potential Biological Removals (PBR; Wade, 1998) used mainly by the US government, and the Revised Management Procedure (RMP; Cooke, 1995) of the International Whaling Commission (IWC). Such methods work efficiently under specific, institutionally dictated management goals.

The beluga (*Delphinapterus leucas*) has long been part of the Inuit hunting culture, providing meat for humans and dogs, and the nutritious skin and blubber called "mattak" in Greenland or "muktuk" in North America. However, in several areas where large-scale harvesting has taken place (e.g. Svalbard, Cook Inlet, Saint Lawrence river, Ungava Bay, East Hudson Bay, and Cumberland Sound), the beluga stocks have apparently been reduced in numbers and/or there has been a contraction in the spatial distribution (Gjertz and Wiig, 1994; O'Corry-Crowe and Lowry, 1997; Kingsley, 2002). In West Greenland, the introduction of new hunting methods and the subsequent large catches is assumed to have resulted in the disappearance of belugas from most of the area south of 65°N (Heide-Jørgensen, 1994). Apparently, the beluga either abandoned some fjords where they were previously found in large numbers or the fraction of the population with affinity for these fjords were eliminated through overharvesting. Indeed, belugas are no longer found in many areas where they were harvested during their seasonal migrations.

The main winter distribution in West Greenland has recently been monitored as a proxy for indications of changes in population size (Heide-Jørgensen *et al.*, 1993; Heide-Jørgensen and Reeves, 1996). Survey results indicate that the relative abundance of belugas wintering off West Greenland has declined considerably since 1981. The population estimate for 1998–1999 is 7941 individuals (95% CI: 4264–14 789; Heide-Jørgensen and Acquarone, 2002).

We examine the current harvest in West Greenland, assuming that all belugas in the area belong to a single stock. Alternative management strategies are evaluated for their ability to ensure that the declining trend is stopped, if possible, allowing for some harvest. Although a risk assessment approach is not unknown in the fishery literature (e.g. Punt and Walker, 1998), it has rarely been applied to marine mammals (e.g. Maunder *et al.*, 2000). We present this assessment as a case where management alternatives are weighted by the amount of risk of not meeting pre-determined goals. Options are offered to administrators, providing time and opportunity to develop economic alternatives for the people affected by drastic reductions in a catch that represents an important source of income. This requires an estimate of the sustainability of different catch levels over the next 5–10 years.

Simultaneous with our study, two independent assessments were conducted on the same stock. One used the IWC HITTER-FITTER model (Butterworth *et al.*, 2002), while the other used Bayesian methods and included belugas from Canadian waters (Innes and Stewart, 2002). These studies were restricted to the estimation of population parameters and of potential yields to be recommended as catch limits. In contrast, after estimating population parameters, we considered a range of alternative catch scenarios and evaluated the risk of not achieving a specific management goal. The underlying philosophy of this approach is discussed.

Methods

Harvest statistics

The catch statistics span a time-series from 1954 to 1999. The difficulty in collecting accurate catch data along the entire coastline of West Greenland prohibits conventional estimates of the uncertainty associated with the data. Instead, the available information has been corrected for potential levels of underreporting and for animals struck and lost to provide three sets (low, medium, and high) based on different assumptions (Heide-Jørgensen and Rosing-Asvid, 2002). We selected the average between the high and medium values as an appropriate balance between potential overestimates and underestimates of the true number of kills. The average was assumed to be an accurate observation of the kill with no associated uncertainty (Table 1). The same approach was applied by Butterworth *et al.* (2002). An alternative approach would be to incorporate a model parameter that accounts for negative bias in the catch as suggested by Innes and Stewart (2002). Their estimate of the correction parameter increased the average catch by 40%, whereas the mean of medium and high catches increased the catch by approximately 30%. Noting that the distribution of the correction parameter was skewed towards smaller values, the two approaches appear to give roughly comparable estimates of the numbers killed.

The catch in 1954 was noticeably higher than in all other years. This was caused by the occurrence of a phenomenon known as "ice entrapment", during which Arctic cetaceans

Table 1. Annual catch of belugas in West Greenland (average between the maximum and medium values reported by Heide-Jørgensen and Rosing-Asvid, 2002). NB: data for 1999 were not available at the time of analysis (presumed catch was 600).

may get trapped in ice that forms rapidly and prevents access to open water. An ice entrapment in 1954 included about 3000 belugas (Golodnoff, 1956). When an ice entrapment of this magnitude occurs in Disko Bay, it is unlikely to go unnoticed, and hunters take advantage of the situation. Ice entrapments have occurred in other years (Heide-Jørgensen *et al.*, 2002), but none of the recent events was as large as the one in 1954.

Abundance

Population trends have been monitored through aerial surveys in selected years between 1981 and 1999 (Figure 1) that provide indices of relative abundance (Table 2). The surveys in 1981 and 1982 differed from later surveys in the type of aircraft used, survey design, methods for extrapolation, and personnel involved (Heide-Jørgensen *et al.*, 1993; Heide-Jørgensen and Acquarone, 2002).

An estimate of absolute abundance is only available for 1998 and 1999, when the correction factor (and its variance) for missed and submerged animals could be estimated. The estimated absolute abundance for 1998/1999 (combining data for the 2 years) is 7941 animals (CV: 0.32; Heide-Jørgensen and Acquarone, 2002). This value was assumed to apply to 1998 in our calculations.

Using the entire series of indices of relative abundance (1981−1999), a first attempt to derive an estimate of the intrinsic rate of population increase (R_{max}) yielded a value

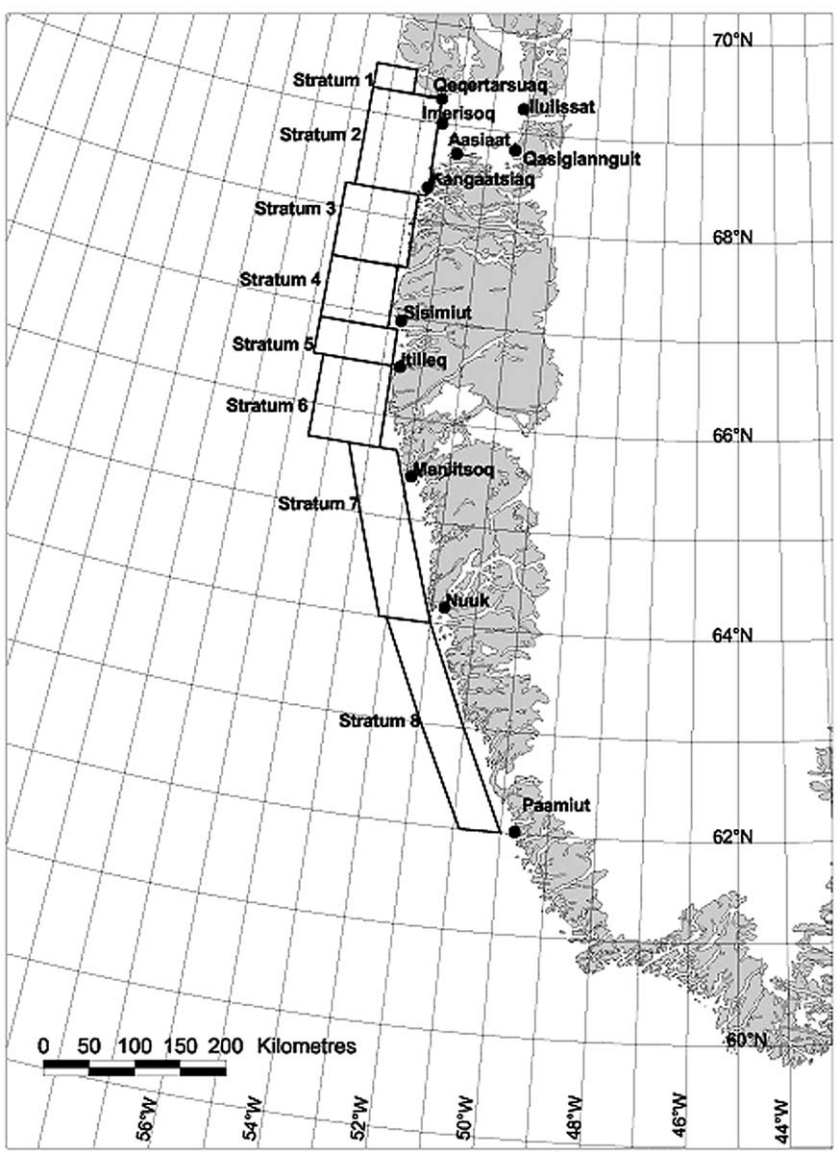

Figure 1. The West Greenland coastline and the strata used in the aerial survey design.

Table 2. Indices (standard error) of relative abundance of belugas in West Greenland (estimates for 1981, 1982, and 1991 from Heide-Jørgensen *et al.*, 1993; others from Heide-Jørgensen and Acquarone, 2002).

Year	Index (s.e.)
1981	3 776 (1 008)
1982	2 192 (400)
1991	1 471 (356)
1993	899 (192)
1994	1 196 (188)
1998	929 (221)
1999	735 (201)

close to zero, which was considered inconsistent with the available information on beluga biology. This effect could be traced back to the indices for 1981 and 1982. Because survey design and methods were different, data for these years were removed from the analysis initially. However, to make these data usable, separate re-scaling parameters of relative abundance were estimated for 1981, 1982, and 1990–1999.

Model structure

A simple discrete generalized logistic model was used to represent the dynamics of the population. The particular form used was a difference equation variant of the Pella and Tomlinson (1969) model:

$$N_{t+1} = N_t + N_t R_{max}(1 - (N_t/K)^z) - C_t, \quad (1)$$

where N is the abundance, in numbers, at time t or t + 1 (in years), R_{max} is the discrete intrinsic rate of increase, K is the pre-exploited population size (here assumed to be equal to the population in 1954), z is a parameter that determines the population size where productivity is maximum (also known as the "shape parameter"; for simplicity, z was arbitrarily fixed to a value of 3, which sets the Maximum Sustainable Yield at 63% of K), and C_t is the number of animals removed by the fishery in year t, including killed but lost whales. It is assumed that all animals recruit to the exploitable population and that there is no selection for specific age groups or sex in the hunt.

Parameter estimation

Population parameters were estimated in two different ways, by maximum likelihood (MLE; Punt and Hilborn, 1996; Hilborn and Mangel, 1997) and by Bayesian integration (Gelman *et al.*, 1995; Punt and Hilborn, 1997). MLE was based on non-linear fitting of the model to both the relative and the absolute abundance estimates, assuming that their residuals are normally distributed. This choice is arbitrary because the number of strata in the aerial surveys (n = 8) is not large enough to approximate normality, but being an estimate obtained by pooling, a lognormal is even more unlikely. Anyway, the predicted trends obtained based on one assumption about error distribution or the other should not differ by much. Likelihood profiles (Punt and Hilborn, 1996; Hilborn and Mangel, 1997) were also generated. Parameter estimates were obtained by minimization of the negative log likelihood of the objective function:

$$-\ln L(\text{data}\,|\,\text{parameters}) = \sum_y -\ln L(\text{data}_y\,|\,\text{parameters}), \quad (2)$$

where the year-specific likelihood for any estimate of absolute abundance is given (ignoring constants) by

$$-\ln L(\hat{A}_y|\theta) = \ln(\sigma_{Ay}) + (\hat{A}_y - A_y)^2/2\sigma^2_{Ay}, \quad (3)$$

where $\hat{A}_y$ is any observed estimate of absolute abundance, A_y is the model-predicted abundance, θ is the vector of parameters in the model (Equation (1)), σ_{Ay} is the standard error associated with each estimate of absolute abundance, and subscript y refers to year.

The year-specific likelihood for any estimate of relative abundance is given by:

$$-\ln L(\hat{I}_y|\theta) = \ln(\sigma_{Iy}) + (\hat{I}_y - (q_i \times N_y))^2/2\sigma^2_{Iy}, \quad (4)$$

where $\hat{I}_y$ is the observed index of abundance, N_y is the expected absolute abundance, σ_{Iy} is the standard error associated with each estimate of relative abundance, q_i is the re-scaling parameter for periods i = 1 to 3 (1981, 1982, 1991–1999), and $q_i \times N_y$ is the associated expected index of relative abundance at year y.

Posterior probability distributions for population parameters were calculated by means of Bayesian integration using the Markov Chain Monte Carlo (MCMC) method (Gelman *et al.*, 1995). Prior probability distributions were uniform, bounded between 0.01 and 0.08 for R_{max} and between 14 000 and 120 000 for K. An additional parameter q was estimated that re-scales the relative abundance in relation to the absolute estimate. The prior distribution for q was completely uninformative (uniform and unbounded). Two approaches were followed to estimate q. One single q is estimated if the 1981 and 1982 indices of abundance are removed from the series. In the other option, q values are estimated separately for 1981 and 1982 and for the period 1990–1999.

A Bayesian posterior distribution was also obtained for a derived parameter specified to evaluate the actual state of depletion of the population as a consequence of the harvest: the ratio of the population size in the last year with catch data to the estimated abundance in 1954 (K_{1954}).

MLE, likelihood profile calculation and MCMC simulation for Bayesian estimation of parameters were conducted using AD Model Builder (© Otter Research).

Risk assessment

Derived parameters (V_p), which represent the ratios of the population size after p years of harvest against the population size at the time when the catch limits were introduced, were calculated to evaluate the consequences of

Downloaded from http://icesjms.oxfordjournals.org/ by guest on August 13, 2013

future catch restrictions. These parameters are obtained by first saving a sample of the sets of individual model parameters obtained during the MCMC process. When a large number of simulations are run and convergence in the Markovian chain is achieved (a large sample is also desirable), the sample closely resembles the joint posterior distribution of the parameters. The population is then projected without process error (natural variability is not considered) using all the sampled sets of parameters. This assumption could lead to underestimation of the risk, particularly if no feedback is obtained through future surveys. During the projections, a proposed catch scheme is subtracted from each population trajectory (one for each set of parameters sampled from the Markovian chain), resulting in the posterior distribution of future population size after a number of years. For a future trend scenario presented by each set of parameters, the final population is compared to what it was right before a policy is implemented, evaluating in this way the effect of future harvests. The total risk of not meeting a management goal (e.g. stop population decline) is calculated by constructing the cumulative probability of population change. This procedure incorporates the uncertainty around the parameters into the process of calculating the future status of a population. This is a useful way to propose that the specific outcome for the application of a policy is not absolute, and that the real situation can differ from the prediction.

Three different trials (A, B, and C) were conducted to evaluate the risk of not meeting a management goal (Table 3). The management goal in the trials A and B was to stop the population decline (reference point: $V_p = 1$). In trial C, the goal was to avoid extinction (reference point: $V_p = 0$).

Table 3. Trials conducted for the risk assessment of the hunt for belugas in West Greenland (CC: constant catch quota; HR: harvest rate; PBR: potential biological removal; F_r: recovery factor; V_p: N_{t+p}/N_t; R_{max}: intrinsic rate of increase; for options in the reduction plan see Table 5).

Trial A: comparison of management strategies ($V_p = 1$; ref.:1999)	
HR	CC
1999–2004; 1999–2009	1999–2004; 1999–2009
PBR F_r-1	150
PBR F_r-0.5	200
$0.75R_{max}$	300
$0.5R_{max}$	500

Trial B: reduction plan ($V_p = 1$; ref.: 2001)		
CC	CC first 5 yr, followed by HR	
2001–2010	2001–2010	2001–2030
All options	All options	Options 3 and 5; HR = PBR F_r-1

Trial C: probability of extinction ($V_p = 0$; ref.: 2001)

CC: 100, 300, 500, 700, and 1 000 individuals
Projections: 10, 20, 30, 40, and 50 yr

Trial A compared the performance of two choices for setting catch limits: (1) constant annual catch quota or (2) quota set as a function of population size and a constant harvest rate, applied over both a 5-year and a 10-year period. This evaluation was conducted before information on the catch for 1998 was available and therefore parameter estimates used in the simulations (Bayesian means: $K = 30\,610$ and $R_{max} = 0.035$) differ slightly from the final estimates shown in Table 5. Given that differences were small, we decided not to redo these trials, because the comparison of the performances of the two approaches, our main purpose, remains valid.

Constant catch limits were set to 150, 200, 300, and 500 removals per year. Catches based on harvest rates were specified as for PBR:

$$PBR = 0.5 \times N_{min} \times R_{max} \times F_r, \quad (5)$$

where F_r is a "recovery factor" that can be incorporated into the PBR calculation as 1 if the stock is above the level of maximum net productivity (MNPL, also known as N_{msy}) or <1 if the population is below MNPL (we used 0.5), and

$$N_{min} = \hat{N} \times e^{-\nu\sqrt{\ln(1+CV(\hat{N})^2)}}. \quad (6)$$

N_{min} is a conservative estimate of the population size with a negative bias, estimated as a lower (20th in this case) percentile of the confidence interval of a survey-based point estimate $\hat{N}_t$ considered the "best" available estimate; ν is a constant that determines the percentile of the lognormal distribution represented by N_{min}, fixed to 0.842 for the 20th percentile.

Additional harvest rates were set to correspond to $0.5R_{max}$ and $0.75R_{max}$,coinciding with MSY rates if the shape parameter z equals 1 and 3 (default), respectively. If a harvest rate is applied, the estimate of abundance for 1998 is used to calculate the catch for the following 5 years ($HR \times \hat{N}_{1998}$). If the trial projects the population for 10 years, then in year 2004, an estimate of abundance (e.g. from a survey) is simulated by sampling from a lognormal distribution with a mean equal to the predicted value for the year and a CV of 0.2. This simulated estimate of abundance is multiplied by the harvest rate to obtain the new catch level.

In a first approach, catch options were calculated using harvest rates by direct utilization of the Bayesian means of R_{max} calculated without the 1981–1982 abundance data but with catch data up to 1999 (because catch data for 1999 were incomplete, we assumed a kill of 600 animals). As an alternative management scheme to mitigate the effects of a drastic reduction in the catch and to give managers and hunters time to develop economic alternatives, trial B involved gradual catch reductions and an evaluation of the outcome after 10 years. Because the priority at this point is to prevent further depletion of the population, the reference point for evaluation is the probability that the population

Downloaded from http://icesjms.oxfordjournals.org/ by guest on August 13, 2013

after 10 years is smaller than in 2001. Because management policies in our scenario will be applied from 2001 onwards, catches had to be assumed for 1999 (600) and 2000 (700). The situation under a constant removal of 700 animals (option 1) is compared to five alternative scenarios (Table 4).

The same analysis was conducted again under the same catch options as those applied for the first 5 years, but adjusting catches for the remaining 5 years to a new "observation" of abundance obtained in 2005 (see above). The use of new estimates of abundance represents the common feedback mechanism in situations where new catch limits (based on harvest rates) are estimated based on updated knowledge about the managed stock. The same four (constant) harvest rate alternatives tested in trial A were used in this case. In addition, this experiment was repeated projecting 30 years ahead for: (1) the scenario that is proposed as the "best" alternative (option 3, see Results) and (2) for the scenario where such action is delayed for 2 years (option 5). In both cases, catches after year 2005 are calculated using harvest rates applying PBR with $F_r = 1$. Population "estimates" are again obtained every 5 years by simulation to adjust the catch.

In trial C, the probability that the population will become extinct was calculated projecting the population forward during 10, 20, 30, 40, and 50 years. In each case, catches were kept constant at 100, 300, 500, 700, and 1000 animals.

Results

Parameter estimates and current status of the stock

Figure 2 shows the likelihood profiles and posterior probability distributions for the estimated parameters. The posterior probability of R_{max} was very similar to the prior within the interval 0.01–0.08. To better demonstrate the degree of uncertainty associated with this parameter, another estimation was conducted, expanding the upper bound to 0.15, and the resulting profile and posterior distribution are shown in Figure 2A. The posterior probabilities and profiles for the other parameters are better defined than those for R_{max}.

Table 5 provides a summary of the point estimates of population parameters obtained with the complete data set

catches) to estimate the replacement yield of the population $(N_t R_{max}(1 - N_t/K))$, a plot of the replacement yield and catch, both standardized by dividing by K, shows that the kill consistently has exceeded the sustainable catch (Figure 3). The conclusion must be that the stock historically has been overexploited and that the actual kill is still too high. This result is in agreement with the point estimate (Bayesian mean) of the level of depletion that, despite differences in parameter estimates, consistently shows a population size that is near 20% of the original size (Table 5). Under the assumptions of the model, there is a 95% probability that the population is currently $\leq$38% of the size in 1954.

Probability of extinction

If 1000 animals are caught per year, there is a 99% probability that the population will be extinct in 20 years (Figure 4). At the actual catch level (around 700 animals), the estimated probability of extinction is 90% after 20 years, and 99% after 50 years. A catch of 100 animals shows a small probability (3%) of extinction after 50 years.

Alternative management strategies and allowable catch

Figure 5 summarizes the population response under the uncertainty associated with the knowledge that can be extracted from the data about the parameters. The figure compares the cumulative posterior probability distributions of population status after 5 and 10 years of implementing different quota regimes under the two management strategies (fixed quota and fixed harvest rates). In these figures, a V_p value of 1 corresponds to the management objective of "stop decline". Larger V values imply that the population is increasing and thus the management objective has been met; lower values indicate a decline.

A fixed catch of 500 animals will cause the population to continue to decline with high probability (Figure 5A, B). When this strategy is used, there is no feedback mechanism to adjust the catch to changes in population size. Under these conditions and given the uncertainty, the longer the time an overharvesting policy is applied, the greater the probability that the population will decline. Even a small constant catch of 150 animals implies a total risk of about 20% that the population will not grow.

In contrast, if future catch limits are based on a constant harvest rate and an updated estimate of absolute abundance, the risk of continued population decline is of concern only when harvest rate is set at $0.75R_{max}$ (Figure 5C, D). Use of any of the lower harvest rates implies, at the most, a small risk of population decline. Because the catch is adjusted in time with the acquisition of new information on the population response, the probability of a decline in population size becomes smaller as time progresses.

Table 6 compares the catch levels that result by applying alternative harvest rates directly to the actual stock size estimated for 1999 (7941). The most aggressive policy under the most optimistic scenario suggests a sustainable

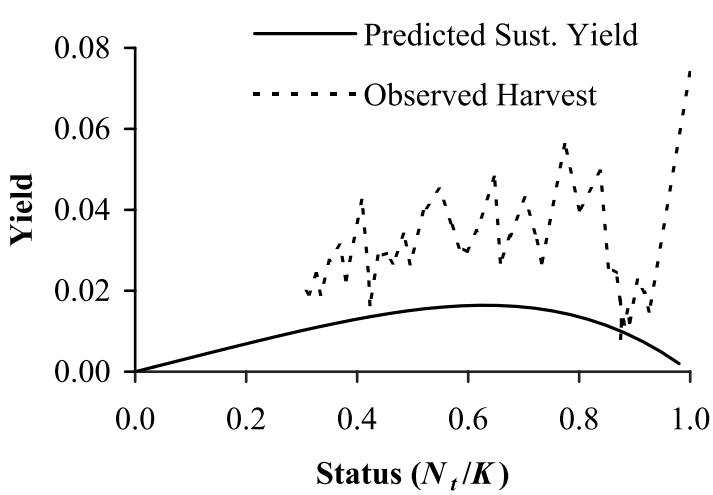

Figure 3. Trajectory of the observed harvest of beluga in West Greenland compared with the sustainable yield as predicted using the Bayesian mean of logistic parameters (both standardized by dividing by pre-exploitation size).

Downloaded from http://icesjms.oxfordjournals.org/ by guest on August 13, 2013

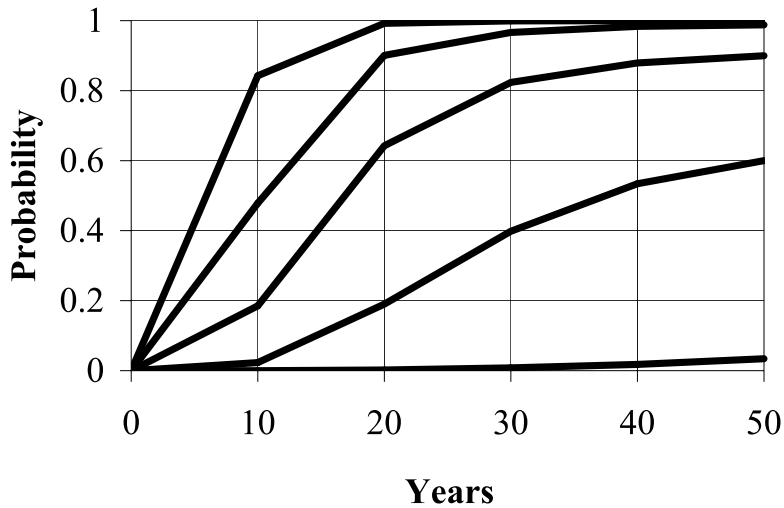

Figure 4. Probability of extinction at different times based on different constant catch levels (from top to bottom: 1000, 700, 500, 300, and 100 animals).

catch of about 200 animals given the current population size, while a more conservative approach under less optimistic scenarios suggests a sustainable catch of <100 animals per year. A moderate approach using a harvest rate of half the Bayesian mean of R_{max} defines a sustainable catch of about 130 animals.

The maximum probabilities of population decline under different strategies considered are presented in Table 7. These probabilities must be interpreted as the upper bound of an open interval such that the actual probability of decline is smaller than the bound and indicate that if the management goal is to prevent decline in 10 years, the only way to be 100% sure that the population will not have declined after 10 years is by either banning any catch or immediately reducing the catch to the PBR value obtained with an F_r of 0.5. The next lowest probabilities are achieved if the annual catch is reduced to 100 animals for the first 5 years and harvest rates are used for the following 5 years (option 4) or by exclusively using harvest rates. However, if the management goal is expanded to prevent population decline after 30 years, the feedback effect of the application of harvest rates during the following 25 years reduces the uncertainty, and the probability of a decline under the combination of catch option 3 and PBR with F_r of 0.5 is reduced from 37% to 17%.

Discussion

Estimates of population parameters are in general consistent with each other, except the Bayesian means for R_{max} and K using the entire data set (Table 5). We have not examined these differences and cannot explain them formally, but they may be related to the added uncertainty of two extra parameters (q_1, q_2, and q_3 instead of a single q) for estimation. The estimate of R_{max} with the complete data set but only one q estimated was close to zero, a situation that could occur only if the production was extremely low or if natural mortality was very high. To our knowledge, there is no evidence of either one except the observed ice entrapment events that do not occur very often. Whatever the causes, these results indicate that the indices of relative abundance obtained in the past are not strictly comparable, which is probably related to recorded changes in survey design and methods.

The uncertainty around R_{max} is very large (Figure 2), resulting in a poorly defined posterior distribution (and likelihood profile) within the original bounds of the prior (0.01−0.08). This is an indication of the limitations of the information contained in the available data (i.e. poor contrast in the abundance data). However, the point estimates between 0.03 and 0.04 (Table 5) are in accordance with the expectations based on information for a long-lived species with similar life history characteristics (Reilly and Barlow, 1986). Also, simulation studies using beluga life history parameters derived from field data predicted that populations could potentially grow at 2−3% (Beland *et al.*, 1988).

From the management point of view, the resulting narrow posterior distribution of the level of depletion of the population (N_{1999}/N_{1954}) is more important. This result is consistent with earlier simulations suggesting that the estimate of this depletion parameter is usually robust and reliable (Alvarez-Flores, 2002). Most of the probability density in the posterior distribution of depletion level is observed in population sizes much lower than the MNPL ($\sim$0.6K; cf Figure 2D). This is consistent with the permanent state of overexploitation since 1954 (Figure 3). Continuation of this trend represents a serious threat for the beluga population.

Three alternative ways to manage the hunt for belugas in West Greenland may be considered. Although decisions

on management alternatives are a political rather than a scientific issue, we comment on them because of the strong biological implications of each one and their potential socio-economic effects. In the first scenario that no action is taken at all, belugas most likely will go extinct in West Greenland and with them all future economic, cultural, and nutritional benefits from this resource. If this alternative is selected, hunters should be advised to take measures to find alternative sources of future income to compensate for the loss of profit of a restricted catch. Even if hunters do so, it is unlikely that this alternative would provide an acceptable long-term solution given the biological, cultural, and economic loss.

The second alternative is to immediately impose a sharp reduction of harvest level. This may be the more desirable solution from the conservation point of view. If the catch is drastically reduced or even eliminated, the stock should start to recover immediately. Unfortunately, the recovery of a marine mammal stock is slow and it will take decades before the hunters may enjoy the benefits of the recovery. The decision here revolves around the question of whether the hunters can and must give up the current levels of benefit to ensure that future generations can use the resource sustainably at a safe maximum potential.

The third alternative provides an intermediate solution that combines a gradual catch reduction plan, thereby allowing managers and hunters to develop economic alternatives to buffer the transition from a high-catch regime to a low-catch regime, with the primary objective of at least having a low risk of further decline of the stock.

Given the uncertainty associated with parameter estimates, we analysed the relevant question of what level of catch may be recommended from different perspectives. Depending on which harvest rate and estimation method was used, catch options at the present stock size ranged between 74 and 202 animals (Table 6), suggesting a median value around 130. Because of the inertia involved in updating appropriate catch limits for the following years, situations where 100 animals or more were annually removed were tested and compared to catch quota based on harvest rates that were adjusted with new survey data of abundance after 5 years. The results indicate that complete ignorance of parameter values and abundance propagates any positive or negative effects on future population size: the longer the constant catch policy is applied, the larger the uncertainty about the future population. On the contrary, use of a harvest rate strategy reduces the uncertainty because of the feedback provided by new estimates of population size. Even if the population is projected 5 years forward with a fixed-catch policy, predictions of future population sizes are better if they are followed by a harvest rate strategy than those obtained when continuing the fixed-quota policy. The reason for this is that the uncertainty in parameter values is being incorporated in the update. Therefore, each trial results in a different catch limit. For the same reasons, and contrary to the results using fixed quota, applying harvest rates enhances our certainty about the potential outcomes in time. This characteristic has been previously suggested in the context of a description of ways to ensure that management procedures are robust to associated uncertainties (Butterworth *et al.*, 1997).

Based on the current status of the population, the analyses favour a drastic reduction in the catch and use of a harvest rate to set future catches. The required reduction is so large that opponents could argue that the estimate of R_{max} is negatively biased (e.g. through severe underestimation of abundance) and that this error would disproportionately affect the hunters. Therefore, it is useful to consider the consequences of underestimating R_{max}. Assuming that the West Greenland population could maintain life history characteristics that are distinct from other populations, R_{max} values >0.07 (upper bound for the prior set at 0.08) would require either a calving interval of <3 years (which is unlikely; Hazard, 1988), or unrealistically high survivorship values relative to a longevity of 30 years. Assuming $R_{max} = 0.07$ and applying a harvest rate of 0.5 of R_{max} with the current estimate of population size, the catch limit would be 277 animals, less than half of the current harvest. Clearly, the population cannot sustain the present harvest pressure and if the trend continues, the population will soon become extinct.

Downloaded from http://icesjms.oxfordjournals.org/ by guest on August 13, 2013

Proceeding with a catch reduction for a resource with great social and cultural value is a difficult matter. Imposing an immediate severe catch limit is likely only to be eventually exceeded, given the limitations in monitoring the cumulative catch during a hunting season, but a biologically acceptable limit implies a severe and sharp reduction from the current kill levels. The controversy about how much the catch must be reduced increases because alternative scenarios (defined by the ranges in the posterior probabilities of the parameters) suggest that the catch could be greater than the suggested 130. Although overoptimistic scenarios are associated with high risk and their use requires extreme caution, the catch for the next years even under the most optimistic scenario should not exceed 200 animals.

A gradual reduction program combined with quota based on harvest rates and a feedback every so often has good chances of succeeding in achieving the goal of recovery (Table 7). If ultimate recovery is the primary goal, the time that this may take will have to be established in terms of a combination of socio-economic and biological factors. If the management goal is to prevent any further decline in 10 years (NAMMCO, 2000), the probability that this goal will not be met may be relatively high (taking, for example, option 3 and PBR F_r-0.5: 37%; Table 7) even if the most likely event is no decline. However, this is to some extent an artificial perspective. When using a feedback control, the probability of not meeting the management goal becomes smaller as the policy is applied longer. For instance, the probability of population decline after 30 years for option 3 is reduced to 17%.

We stress that the alternative of a gradual reduction plan differs from an immediate severe reduction in that the transition time may make the effects less difficult to cope with for the hunters. Of course, the population will be reduced even further and recovery to maximum sustainable levels will take longer. On the other hand, the development of an economic alternative should be an essential element of management. If the beluga catch would be completely banned, the hunting effort may be redirected to other species without planning. Then, the problem would simply be relocated, not eliminated.

Previous attempts to determine the allowable catch of monodontid populations have been restricted to the calculation of limits on numbers taken as fixed proportions of population size (Sergeant, 1981; Kingsley, 1989).

The relevant parameter estimates presented are similar to those reported by Innes and Stewart (2002) and Butterworth *et al.* (2002). For example, the Bayesian mean of the level of depletion is here estimated to be near 20%, with relatively small variations depending on model structure, which is in the upper range of values estimated by Butterworth *et al.* (2002). However, these authors made each estimate of depletion dependent on a specific assumption about a parameter used as a proxy for the maximum growth rate, while we estimated the posterior probability distribution for the intrinsic rate of increase from the data, avoiding any assumptions about population growth rates. Innes and Stewart (2002), also using Bayesian methods, estimated that the mean of the posterior distribution of the maximum rate of population change was 1.037. This value is approximately equivalent to 0.037 if expressed as intrinsic growth rate, which is close to our own Bayesian mean estimate (0.034). Both Innes and Stewart (2002) and Butterworth *et al.* (2002) offer estimates of sustainable yield and use these as limits to be considered "to secure against possible further reduction of the population over the immediate future" (Butterworth *et al.*, 2002). Despite this assertion, they did not consider specific management goals.

Even though the three papers assessed the current status of the beluga population off West Greenland and results were similar overall, our work differs fundamentally. Although we agree that the population is overexploited and that catches must be substantially reduced, we considered it unrealistic to suggest that such course of action could be implemented immediately. Therefore, we formally evaluated a wide range of alternative scenarios, ranging from no action to a complete ban.

To our knowledge, the only evaluation of alternative management options in a formal risk assessment in relation to marine mammals refers to the by-catch of Hooker sea lions in the squid fishery of New Zealand (Maunder *et al.*, 2000). These authors evaluated the ability of alternative decisions to reach a goal of population recovery simultaneously with economic losses associated with these decisions.

A stepwise approach has been applied to gradually reduce the by-catch mortality of dolphins in the tuna fishery (IATTC, 1997). The management action was not evaluated in terms of its ability to reach a specific population size of dolphins, because the ultimate goal was a by-catch close to zero. What is relevant here is that the parties involved recognized the impossibility of reducing the by-catch in the immediate short term and realized that the only way to reach an agreement was to propose a gradual reduction programme.

Although the simplicity of our population model may be subject to debate, the principles proposed can also be applied if a model of higher complexity is required. The most important lesson is that a formal risk evaluation of the full range of alternative management options, with incorporation of different sources of uncertainty, is possible. This range should cover the entire array of views of all parties involved so that the consequences of reaching the conservation goal can be weighed against the consequences for the people using the resource.

We acknowledge that there are sources of uncertainty other than those incorporated in the analysis. (1) Kills by hunters during ice entrapment events (Siegstad and Heide-Jørgensen, 1994; Heide-Jørgensen *et al.*, 2002) may be considered as part of the natural mortality if the animals would not survive anyway. To what extent the effects of "natural" mass mortality are represented in the estimated intrinsic rate of increase remains unknown and additional

Downloaded from http://icesjms.oxfordjournals.org/ by guest on August 13, 2013

modelling may be required. (2) The population has been exploited for centuries and the population in 1954 is undoubtedly a biased estimate of pre-exploitation population size. Although catch data for earlier years are available, they require a substantial review (Heide-Jørgensen and Rosing-Asvid, 2002) before they could be used. An alternative approach would be to account for bias in K, but this would require the estimation of a large number of additional parameters. (3) The possible existence of sub-stocks (cf. Palsbøll *et al.*, 2002) has been ignored because of insufficient knowledge. (4) Intrinsic model performance in relation to particular characteristics of the data used (Punt, 1995) has not been addressed. (5) Trying to quantify the overall uncertainty associated with the bias in the catch data would be in line with the intention of our analysis. The problem with incorporating formal bias parameters is that their sheer number may prohibit estimation. (6) The decision about an appropriate value of the shape parameter (z; associated with the relative population size at which the Maximum Sustainable Yield may be taken: MNPL/K) is a difficult one. A sensitivity analysis indicated that MNPL/K values <0.5 or >0.8 are unlikely for marine mammals (Taylor and DeMaster, 1993). These authors also showed that multiple factors affect the value of z, that their individual effect is not easily inferred, and that empirical data are scarce. From the perspective of incorporating all possible sources of uncertainty, it would have been more appropriate to release the assumption and to use a semi-informative prior. We opted to assume a shape parameter resulting in a MNPL/K value of 0.63, within the range of 0.6–0.7 applied in sensitivity analyses testing the performance of methods to calculate allowable catches of marine mammals (IWC, 1992; Wade, 1998).

Habitat Use of Ringed Seals (*Phoca hispida*) in the North Water Area (North Baffin Bay)

ERIK W. BORN,[1] JONAS TEILMANN,[2] MARIO ACQUARONE[2] and FRANK F. RIGET[2]

(*Received 24 February 2003; accepted in revised form 16 October 2003*)

ABSTRACT. In conjunction with the International North Water Polynya Study in Smith Sound (northern Baffin Bay) in 1997–99, we examined the area use and diving activity of 23 ringed seals (*Phoca hispida*) that had been equipped with satellite transmitters on the Greenland side of the North Water (NOW) area. The study covered the period 12 August 1996–30 June 1999. Contact with the seals was maintained for an average of 108 days (range: 8–332 days). Four seals emigrated from the NOW area. During all seasons, the seals that remained in the area spent about 90% of the time in coastal (< 100 m deep) waters in the eastern parts of the NOW area. The total area visited by the seals during the open-water season ranged between 10 300 km^2 (1996) and 18 500 km^2 (1998), corresponding to about 15% to 25% of the entire NOW area. In winter, the total area visited by the seals varied between 2500 km^2 (1996–97) and 7000 km^2 (1998–99), and in spring, between 800 km^2 (1999) and 2100 km^2 (1997). Individual movement was significantly greater during the open-water season than during winter and spring. Maximum dive depths recorded were over 500 m (maximum for the instrument) outside and 376 m inside the NOW, for a 96 kg male seal. Non-adult seals spent about 99% of the time in waters less than 100 m deep, and more than 92% of the time in the upper 50 m. In contrast, adults tended to spend more time at greater depths. The study indicated that (1) the ringed seals took advantage of the generally lighter ice conditions in the eastern NOW, and (2) that non-adults likely exploited ice-associated amphipods and young polar cod (*Boreogadus saida*), and adults, mainly older polar cod and cephalopods taken at greater depths.

Key words: ringed seal, *Phoca hispida*, North Water, polynya, satellite telemetry, habitat use, diving behaviour

RÉSUMÉ. Conjointement avec l'étude internationale sur la polynie de l'Eau du Nord dans le détroit de Smith (partie nord de la baie de Baffin) menée de 1997 à 1999, on a examiné l'utilisation de cette zone et l'activité de plongée de 23 phoques annelés (*Phoca hispida*) munis d'émetteurs-satellite du côté groenlandais de la région de l'Eau du Nord («NOW»). L'étude a couvert la période allant du 12 août 1996 au 30 juin 1999. Le contact avec les phoques a été maintenu pendant une moyenne de 108 jours (étendue: 8–332 jours). Quatre phoques ont émigré de la zone NOW. Durant toutes les saisons, les phoques qui restaient dans la zone passaient environ 90% du temps dans des eaux côtières (profondeur < 100 m) dans les secteurs orientaux de NOW. La superficie totale visitée par les phoques durant la saison d'eau libre allait de 10 300 km^2 (1996) à 18 500 km^2 (1998), correspondant à environ 15 à 25% de toute la zone NOW. En hiver, l'étendue totale fréquentée par les phoques allait de 2500 km^2 (1996–1997) à 7000 km^2 (1998–1999), et au printemps, de 800 km^2 (1999) à 2100 km^2 (1997). Les déplacements individuels étaient de beaucoup plus grands durant la saison d'eau libre qu'au cours de l'hiver et du printemps. Les profondeurs maximales de plongée enregistrées dépassaient 500 m (limite de l'instrument) à l'extérieur de la zone NOW et 376 m à l'intérieur, pour un phoque mâle de 96 kg. Les phoques non adultes passaient environ 99% du temps dans des eaux à une profondeur ne dépassant pas 100 m, et plus de 92% du temps dans les 50 m supérieurs. En revanche, les adultes avaient tendance à passer plus de temps à de plus grandes profondeurs. L'étude révèle 1) que les phoques annelés tiraient parti du fait qu'il y avait moins de glace dans la partie orientale de NOW, et 2) que, selon toute vraisemblance, les non-adultes exploitaient amphipodes et jeune morue polaire (*Boreogadus saida*) associés à la glace, les adultes se nourrissant surtout de morue polaire plus âgée et de céphalopodes prélevés à de plus grandes profondeurs.

Mots clés: phoque annelé, *Phoca hispida,* Eau du Nord, polynie, télémesure par satellite, utilisation de l'habitat, plongée

INTRODUCTION

The North Water (NOW) of the Smith Sound–northern Baffin Bay region between Greenland and Ellesmere Island (Canada) is one of the largest recurrent polynyas (70 000 – 80 000 km^2) in the Arctic (e.g., Lewis et al., 1996; Barber et al., 2001a; Mundy and Barber, 2001). Polynyas remain open in winter and become ice-free early in spring; thus, they are areas of relatively high biological productivity, which begins earlier there than in ice-covered areas at the same latitudes (e.g., Stirling et al., 1981; Klein et al., 2002; Ringuette et al., 2002). Birds and marine mammals use polynyas for feeding and mating, and marine mammals use them as overwintering grounds as well (e.g., Vibe, 1950; Brown and Nettleship, 1981; Stirling et al., 1981; Stirling, 1997). Large colonies of dovekies (*Alle alle*) and thick-billed murres (*Uria lomvia*) in the North Water (e.g., Kampp, 1990; Boertmann and Mosbech, 1998; Kampp et al., 2000; Pedersen and Falk, 2001) testify to the area's great productivity, particularly on its eastern side. Vibe (1950) suggested that animal life was richer on the eastern versus the western side of the polynya due to earlier ice breakup and inflow of a nutrient rich and relatively warm current from southern Greenland (Kiilerich, 1933; Grøntved and Seidenfaden, 1938).

The International North Water Polynya Study was conducted from 1997 through 1999, with emphasis in 1998, to document physical and biological processes (Barber et al., 2001b; Deming et al., 2002). We examined the use of the NOW area by ringed seals (*Phoca hispida*) as one component of that international study.

Ringed Seal Ecology

Ringed seals are abundant year-round residents at both eastern and western margins of the NOW (Vibe, 1950; Born and Knutsen, 1989), as evidenced by large annual harvests by the Inuit living in Jones Sound, Canada (Reeves et al., 1998), and the Thule area, NW Greenland (Teilmann and Kapel, 1998).

Ringed seals prefer annual landfast ice with good snow cover in fjords and bays with complex coastlines (e.g., McLaren, 1958a, b), but they also range widely in offshore pack ice (e.g., Finley et al., 1983). Adult ringed seals tend to winter under stable nearshore ice, whereas subadults are often found at the edges of the landfast ice (e.g., McLaren 1958a). In winter, ringed seals spend most of their time in the water or in subnivean lairs on the stable ice, but after the breeding season (March–early May), they haul out on the ice to molt until ice breakup (Vibe, 1950; McLaren, 1958a, b; Smith, 1973, 1987; Smith and Hammill, 1981). Ice breakup usually occurs in late July in the eastern areas of the NOW (Vibe, 1950; Born et al., 2002). Although the ringed seals feed relatively little (e.g., Smith, 1973, 1987) during the molt, they feed intensively during the open-water period (from late July until late October) in pelagic and demersal habitats (e.g., Smith, 1987; Weslawski et al., 1994). They are euryphagous, eating a variety of crustaceans, mainly the hyperiid amphipod *Themisto* (*Parathemisto*) *libellula*, and fish, mainly polar cod, *Boreogadus saida*, and arctic cod, *Arctogadus glacialis* (e.g., McLaren, 1958a; Weslawski et al., 1994; Siegstad et al., 1998; Wathne et al., 2000; Holst et al., 2001). Some evidence suggests that juveniles and adults forage in different habitats (Holst et al., 2001).

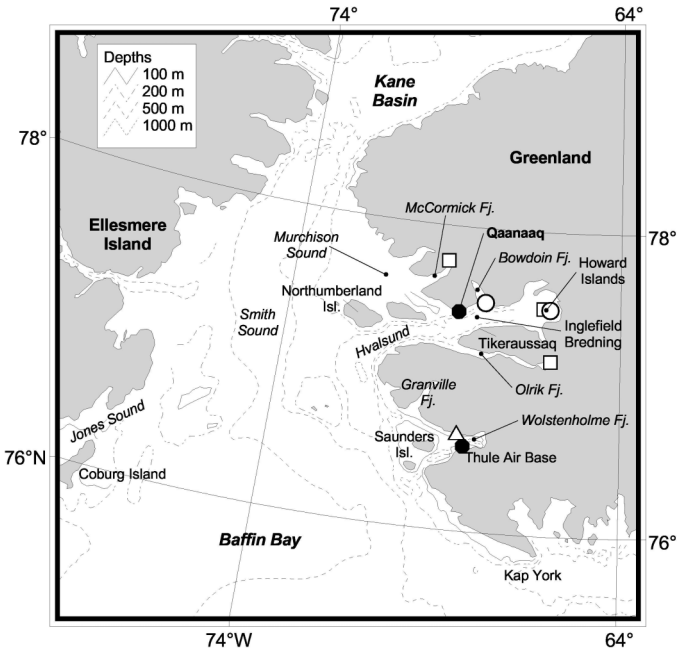

FIG. 1. Map with bathymetry of the North Water study area, indicating sites where 23 ringed seals were caught and equipped with satellite-linked radio transmitters in 1996 (squares), 1997 (open circles), and 1998 (triangle).

Studies of Ringed Seal Movement and Distribution in the NOW

Previous studies of ringed seal movement in the NOW area included information on gross movement of some seals that were tagged between 1988 and 1997 (Kapel et al., 1998) and studies of movement, mainly during summer and fall, that used satellite transmitters (Heide-Jørgensen et al., 1992; Teilmann et al., 1999). To present an overall picture of habitat use by ringed seals in the NOW area, the seals tracked by Teilmann et al. (1999) are included in the present study. Holst and Stirling (2001) presented preliminary information, based on shipboard censuses, on the distribution and abundance of ringed seals in the NOW area during August 1997, April to July 1998, and September 1999.

Ringed seals have relatively great "ecological flexibility" (i.e., high mobility, ability to survive the winter in ice-covered waters, broad spectrum of food taken in all strata of the water column). Consequently, we assumed that ringed seals fitted with satellite transmitters could help identify geographical areas and water-column strata of

[1] Suffix indicates year of tagging.

[2] Age class (see Methods): S = Subadult; P = Pubescent; A = Adult.

[3] Types of satellite-linked radio transmitter: A = ST-6, continuous transmission; B = ST-10, transmission suspended after four hours of haul-out; C = same as "B" but with continuous transmission; D = SSC3, transmission suspended after four hours of haul-out. The units used in 1996 recorded dives only down to 250 m, whereas those deployed in 1997 and 1998 all recorded depths down to 500 m.

[4] Shot or netted by Inuit from the Thule area. Data not included in summary of system performance.

biological productivity. We studied the seasonal distribution of ringed seals and their diving behavior in the NOW area (i.e., the North Water polynya sensu stricto and adjacent fjords) by outfitting 23 seals with satellite transmitters in the Thule region from 1996 through 1998.

METHODS

Field Activities and Study Animals

We caught 23 ringed seals using modified drift gill nets (cf. Kapel et al., 1998; Teilmann et al., 1999) at different locations in the Thule region (76° to 78°30'N, 66° to 73° W; Fig. 1), and then attached a satellite-linked radio transmitter to each seal (Table 1). All seals were handled and treated according to Greenland regulations and law concerning animal care.

The overall activity of subadult seals may differ from that of adult seals because the two groups usually occupy different coastal ice habitats, behave differently during the mating season, and may have different diving capability and diet (McLaren, 1958a; Teilmann et al., 1999; Holst et al., 2001). Therefore, the study animals were categorized at capture, on the basis of body length and mass, as subadults, pubescents, or adults (Born et al., 2002, and references therein; Table 1).

The Satellite Transmitters

Different types of satellite transmitters were used (Table 1), but the configuration, battery capacity, and mass of the transmitters were similar to those described in Teilmann et al. (1999). All transmitters were manufactured by Wildlife Computers (Seattle, U.S.A.). The sampling protocol of the transmitters was described in Teilmann et al. (1999) and Born et al. (2002). On all seals except three, the unit was positioned with the antenna pointing backward. On seals 1859-98, 3984-98, and 1856-98 (Table 1), the antenna pointed forward.

Sampling of Dive Activity

The transmitters sampled "time" and "pressure" (depth) every 10 seconds. These data were stored in six-hour blocks and then relayed to the satellite during the following 24 hours. Three types of dive data were used to describe the vertical use of the NOW area by the seals: (1) Daily maximum dive depth (MDD), (2) number of dives per day, and (3) time spent in each depth interval (Time At Depth, or TAD). Dive data were stored in 10 user-defined intervals that were organized as follows for analysis: 0–50 m, 51–100 m, 101–200 m, ≥ 201 m. Haul-out periods (Born et al., 2002) were extracted from the activity data before analyses and presentation of diving activity.

Organization of Data and Statistical Analyses

Data on movements and dive behavior were collected via the Argos Location Service Plus system (Toulouse, France; cf. Harris et al., 1990; www.cls.fr). The software program Satpak 3.14 (Wildlife Computers, 1997) was used to validate locations and dive data received.

In analyzing the activity of the study animals, we defined three "ecological seasons" based on ice and light conditions and the basic life history of ringed seals: (1) "Summer" or the "open-water season" (1 August–31 October), the time between breakup of the landfast ice and its formation in the fall; (2) "Winter" (1 November–31 March), when the fjords are covered with fast ice and darkness prevails for most of the time; and (3) "Spring" (1 April–31 July), when the seals are breeding and spend progressively more time hauling out. The spring season ends with the breakup of the fast ice.

Information on ice formation, ice coverage, and ice type was determined from ice charts provided by the Canadian Ice Services (Environment Canada) and from National Oceanic and Atmospheric Administration (NOAA) infrared satellite images. In addition, information on ice formation and ice breakup was obtained from people living in the Thule area. In 1996, a dense layer of fast ice formed in the Inglefield Bredning by 1 November (Teilmann et al., 1999). Fast ice formed in the fjords of the Thule area by 10 November in 1997 and by 9 November in 1998 (Born et al., 2002). Local residents reported that in 1998, breakup of the landfast ice occurred on 17 July in Wolstenholme Fjord and around 28 July in Inglefield Bredning.

At 77° N, there is 24-hour daylight between 22 April and 21 August, and darkness prevails from 1 November until 12 February.

We produced digital maps of the North Water area, with the permission of the Canadian Hydrographic Service, from Bathymetric Map 817-A (scale 1:2 000 000; Canadian Hydrographic Service). In some cases, the existing bathymetric contours were refined and corrected on the basis of soundings made during the NOW cruises (courtesy: L. Fortier, Département de Biologie, Université Laval, Québec, Canada).

The extension of the North Water polynya varies annually and seasonally (e.g., Barber et al., 2001a). However, in the present paper, the NOW area was defined as the waters (including adjacent fjords) between ca. 75°45' N (southern entrance to Jones Sound, Ellesmere Island) and ca. 79° N (position in some years of the "ice bridge" between Canada and Greenland in northern Smith Sound and southern Kane Basin).

We used ArcView 3.0a to map seal movement and calculate distances and rates of movement. Except for one seal, we used only location classes 1, 2, and 3, for which theoretical radial precision has been specified by Argos as less than 1000 m (cf. Harris et al., 1990; Anon., 1996). Because of a general lack of good-quality locations from an adult male (11271-97), class 0 locations (for which accuracy is not specified by Argos) were included in the analyses.

The areas visited by the seals ("ranges") were mapped using the locations from all seals that transmitted during the season in question. A daily location for each seal was selected using the highest quality class available. Total seasonal ranges for all seals combined were calculated using the fixed-kernel method (Seaman and Powell, 1996) using the ArcView extension "Animal Movement v. 2.04" (Hooge et al., 1999) and "ArcGIS Spatial Analyst 1.1" (ESRI, http://www.esri.com/software/arcgis/arcgisxtensions/ spatialanalyst/index.html). The 95% probability contours of the seasonal ranges were depicted (Figs. 2 and 3).

Monthly gross movement of a seal was determined by summing all linear distances (km) between consecutive locations received for an individual during a month. Monthly net movement, or shift in geographic position, of each animal was defined as the linear distance (km) between first and last locations recorded each month. Following Amstrup et al. (2001), these estimators of movement or displacement were calculated only if 20 or more days had elapsed between the first and last locations recorded during a month.

To minimize uncertainty in determining swimming speed from distance between locations and time, we included only cases for which (1) the combined theoretical uncertainty was less than 10% of the "point" distance between the two positions, (2) time elapsed between the two locations was between 0.5 and 6 hours (Teilmann et al., 1999), and (3) at least five estimates of speed were available per season.

We used analysis of variance (ANOVA) to test the influence of four factors—sex, age class, season of deployment, and position of the transmitter (i.e., antenna pointing backward or forward)—on the performance of the transmitters (i.e., number of days of contact with the transmitters). The data on duration were $\log_{10}$-transformed to obtain normality and homoscedasticity.

Movement data were ln-transformed and ANOVA (factors: sex, age, season, and the interaction between sex and season) was applied to test for differences in gross movement, net movement, and swimming speed during the three seasons. Seasonal differences in range size were tested with ANOVA (and Tukey post hoc test) weighted with number of seals.

ANOVA was also used to test differences in diving behavior. For analyses of MDD, ANOVA and Tukey-Kramer post hoc tests were made, whereas Wilcoxon Signed Rank analyses were used to test for differences among age groups in time spent at various depths (TAD).

Pearson's correlations were used to analyze the relationships between MDD and the deepest map depth in areas visited by a seal during the same day. This analysis included only seals that remained in the NOW area and were equipped with transmitters able to record depths down to 500 m (Table 1) and for which at least 45 pairs of MDD and map readings were available.

TABLE 2. The number of ringed seals, by age group, that provided dive data in each of the 12 months during 1996–98. Data are given in this format: Number of individual seals transmitting dive data in the month/average number of hours with dive data per seal (standard deviation of the average number of hours).

	No.	Jan	Feb	Mar	Apr	May	Jun
Adult	4	1/474	1/216	1/108	1/174		2/69(13)
Pubescent	3						2/159(38)
Subadult	16	3/68(35)	2/111(55)	2/177(30)	2/165(89)	2/228(85)	2/369(13)
		Jul	Aug	Sep	Oct	Nov	Dec
Adult	-	1/84	2/237(225)	2/327(412)	1/426	1/420	1/474
Pubescent	-	2/240(221)	1/498	1/732	1/606	1/150	
Subadult	-		13/423(218)	14/648(93)	14/475(188)	9/263(170)	7/226(145)

To detect whether there was a relationship between total body mass and the tendency of the seals to use different strata of the water column, a weighted (1/variance) regression was made of daily MDD regressed on total body mass (TBM).

Daily number of dives summed per month by the three age classes were not all normally distributed (Shapiro-Wilk test; adults: $p = 0.047$; pubescents: $p = 0.555$; subadults: $p = 0.018$); therefore, a Wilcoxon Signed Rank test was used to explore for differences among age classes in dive activity. A Kruskal-Wallis test was used to test for differences in dive activity among seasons (winter, summer, spring).

Statistical analyses were conducted using the software Statview for Windows 4.5 (1992–97, Abacus Concepts), Systat 9.0 (1999, SPSS Inc.), and SAS (1990, SAS Inst. Inc.).

RESULTS

Seals Studied and Performance of the Transmitters

Sixteen (70%) of the seals that we monitored were subadults, three were pubescent, and four were adults. Fourteen were males and nine were females. Total body mass ranged between 22 and 96 kg (Table 1).

Contact with the transmitters was maintained for an average of 108 days (SD = 96, range: 8 to 332 d, $n = 20$; three seals killed by hunters were not included; Table 1). Season of deployment was the only variable that significantly influenced the number of days of contact with the seals ($F = 5.54$, $p = 0.03$, $df = 4/1$). Contact was maintained longer with the transmitters that were deployed during the open-water season (mean = 130 d, SD = 95, range: 12–332 d, $n = 16$) than with those deployed during spring (mean = 17 d, SD = 10, range: 8–31 d, $n = 4$). Among transmitter types, the direction of the antenna was the only factor that was statistically significant ($F = 7.35$, $p = 0.02$, $df = 3/1$). The units with the antenna pointing backward transmitted longer (mean = 113 d, SD = 102, range: 8–332 d, $n = 17$) than those with the antenna pointing forward (mean = 78 d, SD = 59, range: 12–124 d, $n = 3$).

The satellite-transmitted data from all years combined allowed us to map the ringed seals' spatial use of the NOW for nearly an entire annual cycle (Table 2).

Horizontal Use of the NOW Area

Nineteen of the seals remained in the North Water area throughout the study period, and four seals left the area.

Two subadult seals (3985-96, 1858-96) emigrated from the NOW area in August 1996 (Teilmann et al., 1999), and one adult seal (11271-97) moved offshore around 15 August 1997. After the formation of landfast ice in the Thule area around 10 November 1997, the adult remained offshore in the polynya (Fig. 2B) until 2 December, when it moved south. This seal stayed at ca. 73°30' N, 58°50' W in NE Baffin Bay until transmission stopped on 11 April 1998 (Fig. 3B). The fourth emigrant was a subadult (1859-98) that left the tagging site in Wolstenholme Fjord on 5 August 1998 and moved south along the Greenland coast, where contact was lost on 16 August 1998 at 74°23' N, 64°26' W (Fig. 2C).

The seasonal variation in spatial use of the NOW area by the 19 seals that remained there was reflected in the distribution of relocations, in the monthly gross and net movement, and in individual swimming speed. Gross and net movement (Table 3) and speed did not differ between months, sexes, or age groups within any of the seasons (ANOVAs, $p > 0.05$), and this activity is therefore summarized for all seals, by season, from summer to spring:

Summer: During summer or the open-water season, the six seals that were monitored in 1996 stayed along the eastern shores of the NOW, primarily between 77° and 78°30' N (Fig. 2A).

Before seal 11271-97 emigrated from the North Water area, it stayed on the eastern side of the NOW area and in southern Kane Basin. Maximum dive depth readings down to 376 m and the relocations indicated that this seal visited the central parts of the NOW area, where the depths are greater than 500 m (Fig. 2B).

Of nine seals that stayed in the NOW area in 1998, six remained near the tagging site in Wolstenholme Fjord. The majority of the relocations from these "inshore" seals came from areas where water depths are less than 100 m (Fig. 2C). Three 1998 seals made excursions offshore into the central parts of the NOW area (Fig. 2D).

The four seals that left coastal areas in 1997 and 1998 spent widely different fractions of their total offshore time

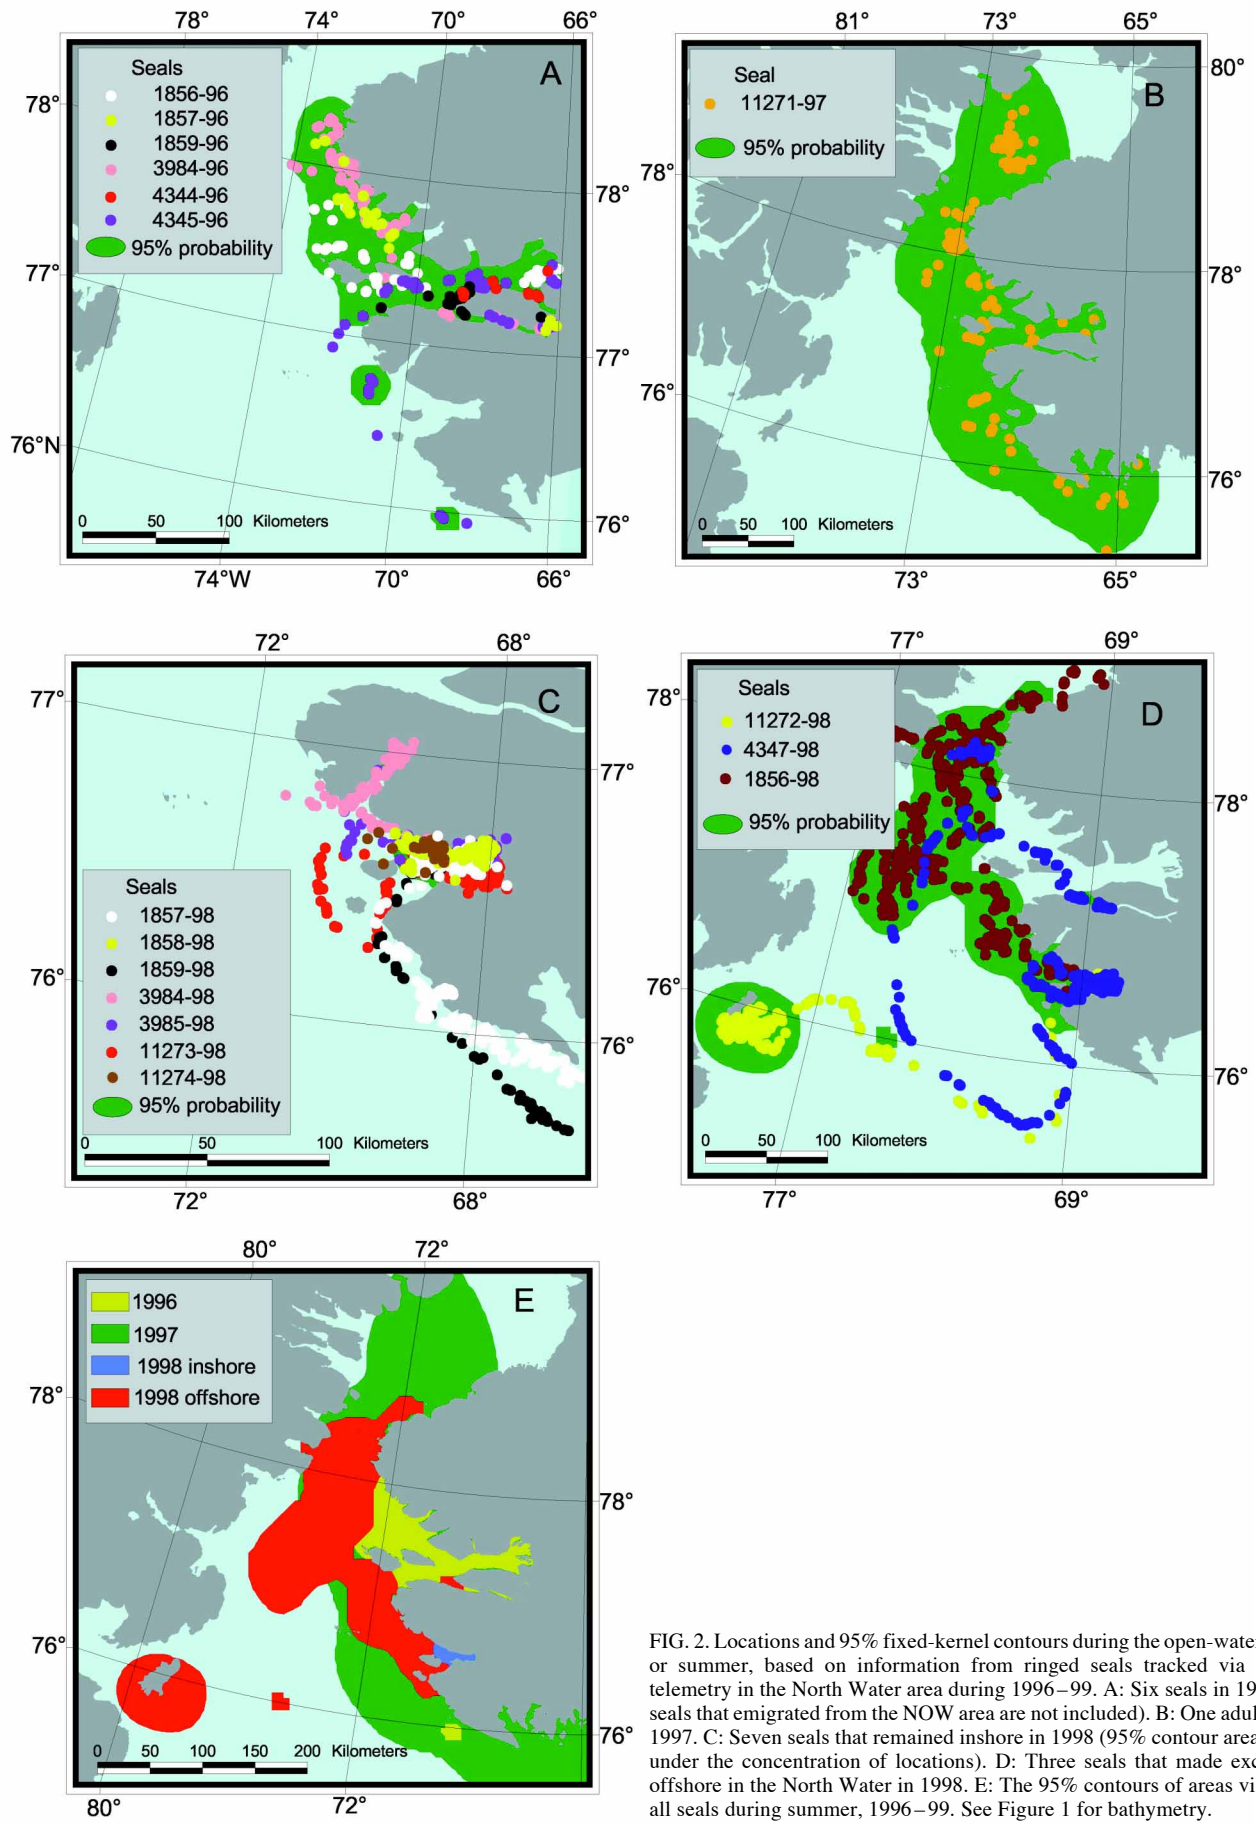

FIG. 2. Locations and 95% fixed-kernel contours during the open-water season or summer, based on information from ringed seals tracked via satellite telemetry in the North Water area during 1996–99. A: Six seals in 1996 (two seals that emigrated from the NOW area are not included). B: One adult seal in 1997. C: Seven seals that remained inshore in 1998 (95% contour area hidden under the concentration of locations). D: Three seals that made excursions offshore in the North Water in 1998. E: The 95% contours of areas visited by all seals during summer, 1996–99. See Figure 1 for bathymetry.

TABLE 3. Monthly gross and net movement distances (cf. Methods), by season, of ringed seals tagged with satellite transmitters in the NOW area, 1996–99.

Season	Open water		Winter		Spring	
	Gross	Net	Gross	Net	Gross	Net
Mean (km/month)	407	61	75	14	91	22
SD (km/month)	245	64	74	15	79	27
Seals (n)	13	13	3	3	3	3
Months (n)	28	28	4	4	6	6
Min (km/month)	49	2	4	0	12	1
Max (km/month)	940	222	164	31	201	68

TABLE 4. Fixed-kernel contour ranges, by season, of ringed seals that were tracked via satellite telemetry in the NOW area, 1996–99.

Year	Season	Number of Seals	95% Contour Area (km^2)
1996	Open-water	7	10292
	Winter (1996/97)	3	7097
1997	Spring	4	2104
	Open water	1	48950
1998	Open water (inshore)	6	569
	Open water (offshore)	3	17924
	Winter (1998/99)	2	2535
1999	Spring	2	815

in the central parts of the NOW area. (Time used offshore = % of days (n) in the NOW area: 11271-97: 97% (n = 99); 4347-98: 19% (n = 98); 1856-98: 50% (n = 124); 11272-98: 14% (n = 70).)

Overall, the distribution of locations received from all the seals during the open-water seasons of 1996, 1997, and 1998 clearly reflects their preference for the eastern parts of the NOW area (Fig. 2E).

Monthly mean gross movement (407 km/month) and mean net movement (61 km/month) were significantly higher during the summer open-water season than during winter and spring ($p < 0.01$; Table 3). Mean swimming speed during summer was 1.6 km/h (SD = 0.5, range: 1.0–2.8 km/h, $n = 14$ seals). Although the seals tended to travel faster during summer than during winter and spring, this tendency was not significant ($p = 0.79$).

Winter: During winter, the seals remained on the eastern side of the polynya, in areas that are covered with first-year fast ice during this season, or at the edge of this ice (Figs. 3A and 3D). Two subadult seals (1857-98, tracked for 332 days, and 1858-98, tracked for 320 days) were remarkably stationary during the entire survey period. Between 15 November and 6 June, seal 1857-98 transmitted regularly from a shallow-water location close to the coast (76°02' N, 67°34' W; Fig. 3D), probably in the shear zone between fast ice and moving pack ice. The monthly net movement of this seal during winter was only 0.03 km/month. Seal 1858-98 stayed for the entire period in Wolstenholme Fjord, where it wintered in fast ice at eastern Saunders Island (Fig. 3D). Monthly net movement of this seal during winter averaged 2.2 km/month.

For all seals during winter, mean gross movement was 75 km/month and mean net movement 14 km/month (Table 3), and swimming speed averaged 1.3 km/h (SD = 0.9, range: 0.9–2.7, $n = 4$ seals). These three estimators of movement did not differ between winter and spring ($p > 0.05$).

Spring: Seals were monitored during spring in 1997 and 1999. The four pubescent and adult seals that were monitored from late June 1997 (Table 1) remained in the fast ice–covered Bowdoin Fjord and Inglefield Bredning until transmissions stopped on 21 July (Fig. 3C).

The two subadult seals (1857-98; 1858-98) that transmitted during the spring of 1999 stayed close to their wintering sites (Fig. 3E). On 6 June, however, 1857-98 moved from the area where it had wintered north along the coast, and by 24 June, it had returned to the area where it was originally captured (Fig. 3E). The monthly net movements indicated increased movements of both seals during spring (km/month; seal 1857-98: April = 0.7, May = 68; seal 1858-98: April = 1.6, May = 1.4, June = 32).

Mean gross movement and net movement of all seals during spring were 91 and 22 km/month, respectively (Table 3), and mean traveling speed was 1.5 km/h (SD = 0.5, range: 1.1–2.2, $n = 4$ seals).

Total Ranges: The tendency of the seals to expand their use of the NOW area during summer was also reflected in the seasonal variation in the size of total areas visited. The ranges of the animals during the open-water seasons 1996 and 1998 were ca. 10 300 km^2 and 18 500 km^2, respectively (Table 4). The area visited by the single adult male that was tracked during summer in 1997 was ca. 49 000 km^2 (Table 4). The ranges of movement varied from ca. 2500–7100 km^2 during winter to ca. 800–2100 km^2 in spring (Table 4). Total ranges during the open-water season (inshore range in 1998 not included) were significantly larger (ANOVA, $p = 0.04$), than ranges during winter and spring (no difference between the two latter seasons; $p > 0.05$).

Vertical Use of the NOW Area

Generally, the dive data indicated that while non-adult seals occasionally explored the water column down to the sea floor, they spent much of their time foraging at depths shallower than 50 m. Adults, in contrast, spent much more time at greater depths.

The daily maximum dive depth reflects the vertical exploratory activity of the seals in a general way. The mean MDD of the 15 seals (TBM: 22–96 kg) with transmitters that recorded dives down to 500 m was positively correlated with TBM (MDD in m = 1.27 • (TBM in kg) + 85.52, $p = 0.002$, $r^2 = 0.398$). While moving around offshore in the eastern parts of the NOW area until early December, the 96 kg adult male (11271-98) dove regularly to between 300 and 376 m depth. This seal made the deepest dive recorded in this study—beyond the 500 m depth-reading capability of the instrument—on 28 January 1999 at 73°25' N, 58°55' W (i.e., in NE Baffin Bay south of the North Water area).

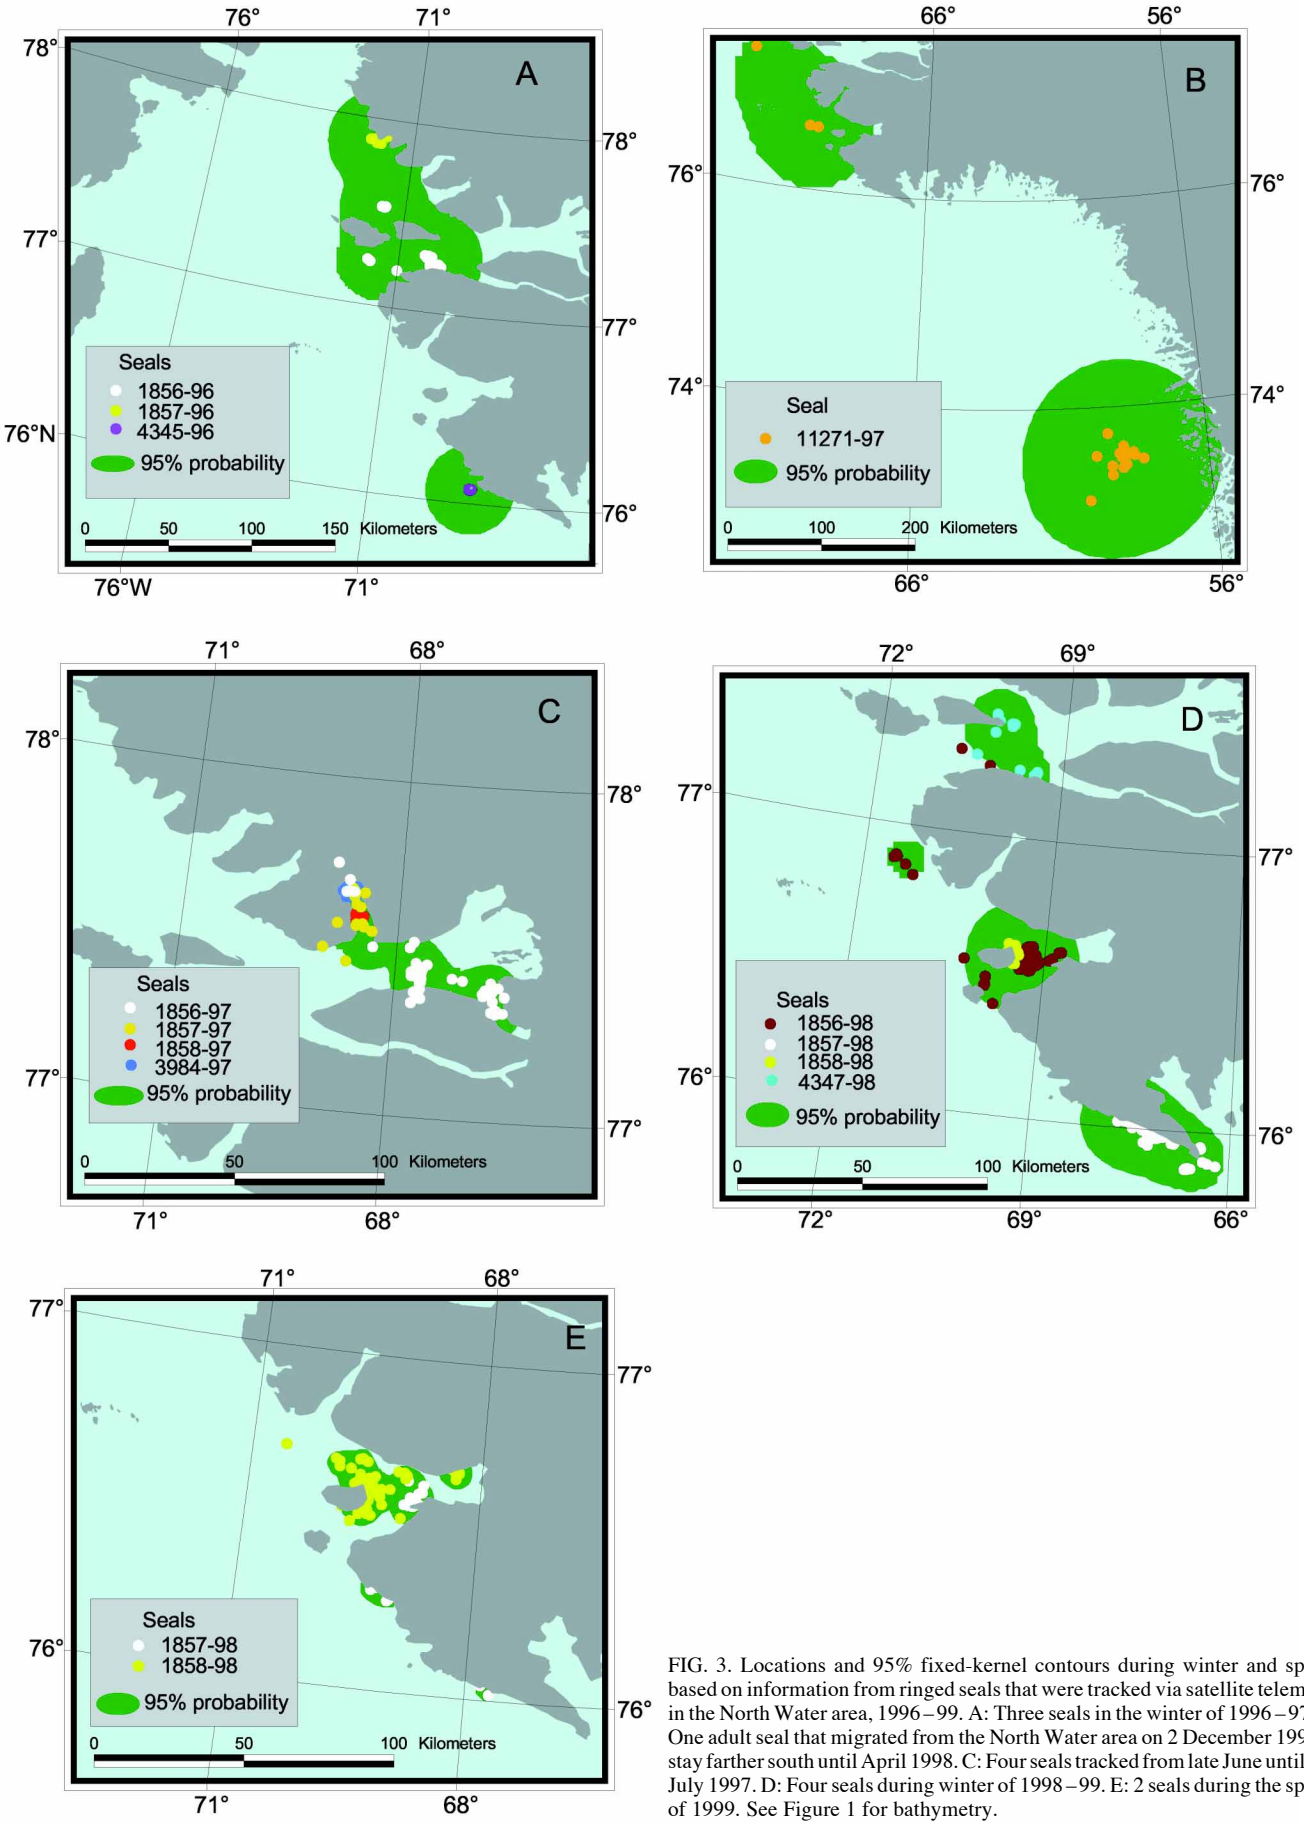

FIG. 3. Locations and 95% fixed-kernel contours during winter and spring based on information from ringed seals that were tracked via satellite telemetry in the North Water area, 1996–99. A: Three seals in the winter of 1996–97. B: One adult seal that migrated from the North Water area on 2 December 1997 to stay farther south until April 1998. C: Four seals tracked from late June until late July 1997. D: Four seals during winter of 1998–99. E: 2 seals during the spring of 1999. See Figure 1 for bathymetry.

TABLE 5. Correlations between daily maximum dive depth (MDD) and water depth in North Water areas visited by a seal the same day, as inferred from location data of seven seals.

Seal ID	*r*	*p*	No. of records of MDD with Map Depths (*n*)	No. of records of MDD > 100 m (% of all records *n*)	Highest daily MDD on Days with a Map Depth (m)	Highest Daily MDD on *all* days (m)
11273-98	0.40	**0.001**	73	16 (22)	156	156
3985-98	0.14	0.38	45	21 (47)	224	232
1857-98	0.40	**< 0.001**	101	23 (23)	252	252
3984-98	0.16	0.19	70	20 (29)	184	184
1856-98	-0.20	0.07	80	70 (88)	340	360
1858-98	0.63	**< 0.001**	80	23 (29)	320	320
4347-98	0.41	**< 0.001**	87	70 (80)	288	288

The four pubescent and adult seals that transmitted during June–July from Inglefield Bredning and Bowdoin Fjord, where water depths exceed 600 m (Fig. 1; Fig. 3C), did not dive deeper than about 250 m.

The seals that stayed in the NOW area in 1998 dove to MDD of approximately 156–360 m (Table 5). For some of these animals, the MDD was correlated with the maximum depth in the area visited during the same day (Table 5), indicating a tendency to explore the entire water column down to the seafloor.

Three subadult seals that made offshore excursions into the central parts of the NOW area (Fig. 2D), where water depths exceed 500 m, did not dive deeper than about 300 m while there (maximum depths recorded 220, 328, and 288 m, respectively).

There were no trends with time in MDD ($p > 0.05$) for 11 of the 15 seals equipped with transmitters that recorded dives down to 500 m. However, MDD did decrease with time for three seals, and increased for one. The MDD of seals 11272-98, 1857-98, and 1858-98 decreased gradually (r^2 between 0.13 and 0.50; p between < 0.001 and 0.06), indicating that they made shallower dives as time progressed. This was particularly pronounced in 1857-98 and 1858-98, which stayed in shallow coastal waters until late June 1999. During winter and spring, the MDD of seal 1857-98 averaged 15.2 m (SD = 7.3, range: 4–36 m, $n = 35$ days with MDD), and the MDD of 1858-98 averaged 19.6 m (SD = 13.5, range: 8–72 m, $n = 19$). The MDD of seal 3984-98 increased with time ($r^2 = 0.16$, $p = 0.008$) from 13 August to 27 October 1998. During August, this seal moved from shallow waters in Wolstenholme Fjord into Granville Fjord, where it spent September and most of October (until transmission stopped) in front of a glacier at the head of this fjord.

Adult seals generally made fewer dives than pubescent seals, and pubescents made fewer dives than the subadults (Wilcoxon Signed Rank tests, $p < 0.05$; Fig. 4). Overall, the average number of dives per day of adults was 182 (SD = 61.4, range: 120–312 dives/day, $n = 11$ months). Pubescent seals made an average of 324 dives per day (SD = 44.9, range: 264–384 dives/day, $n = 6$ months), whereas subadults dove 409 times per day on average (SD = 55.0, range: 336–528 dives/day, $n = 11$ months). In adults, the number of dives per day differed significantly with season

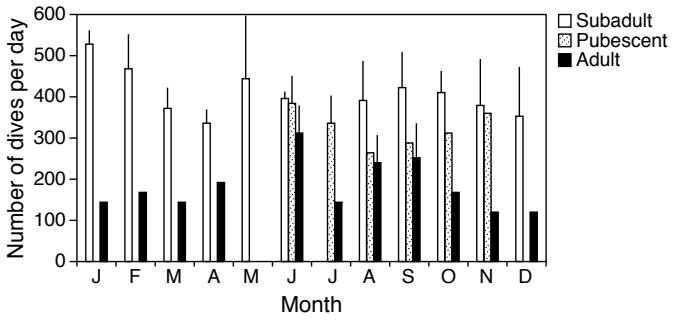

FIG. 4. Seasonal variation in number of dives per day of subadult, pubescent, and adult ringed seals in the North Water area (1996–99). For each seal, we calculated the monthly mean of number of dives per day. Bars represent the mean dive activity of all seals, and lines the standard deviations. For number of seals per month, see Table 2.

(winter lower than summer and spring; $p = 0.026$). The other two age groups showed no seasonal trend in the daily number of dives (subadults, $p = 0.69$; pubescent seals: $p = 0.39$).

The time-at-depth (TAD) data indicated that all age groups except for adults spent the majority of time in the upper 50 m of the water column, with limited seasonal variation. During the open-water season, subadult seals spent an average of 92% and pubescents 90% of the time between 0 and 50 m, whereas adults spent an average of only 66% of the time in this depth range (Fig. 5). During winter, subadults used 96% and pubescent seals spent 93% of the time in depths shallower than 50 m, whereas adults averaged only 47% of the time at depths shallower than 50 m. The single adult (11271-97) that was monitored during winter and early spring used progressively more time deeper than 50 m (Fig. 5). All seals foraged at similar depths in June and July (i.e., time of maximum haul-out on the ice) spending about 90% of their time at depths less than 50 m (Fig. 5).

The three subadult "offshore" seals (Fig. 2D) spent an average of 94% (SD = 1.62) of the time in the upper 50 m of the water column while visiting the central parts of the NOW. Overall, these seals spent only 0.5% of the time (SD = 0.20) deeper than 100 m. In contrast, the adult seal (Fig. 2B) spent an average of about 17.5% (SD = 3.1) of the time below 100 m while in the central parts of the NOW area (Fig. 5).

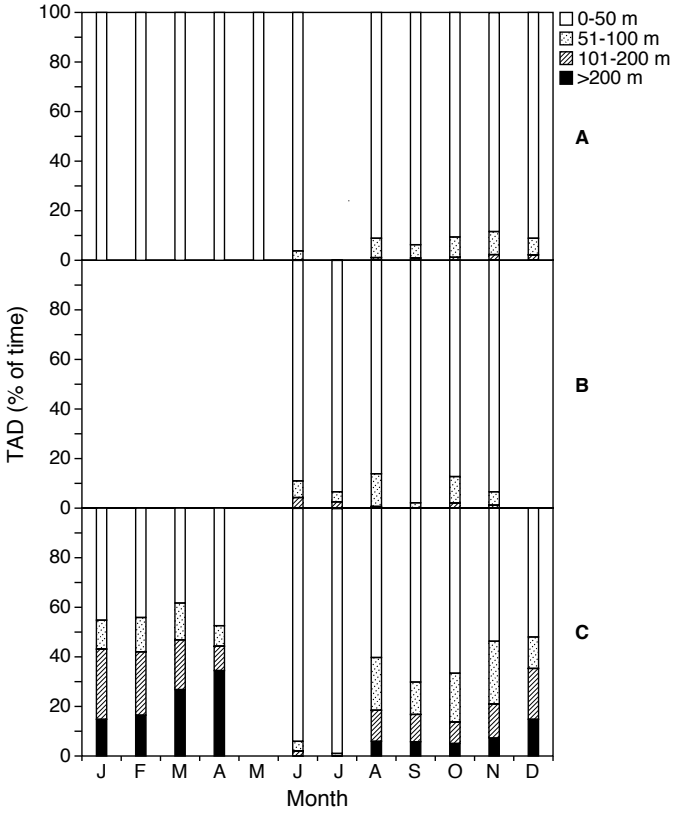

FIG. 5. Time allocation (% of total time monitored) to specified depth categories (Time-At-Depth, or TAD), by month and age group, in ringed seals in the North Water area, 1996–99. A: Subadults, B: Pubescent seals, C: Adults. Note that the depth intervals are not of equal size. The TAD per month was determined for each seal. A bar represents the average TAD for all individual seals in that month (for number of seals per month, see Table 2).

DISCUSSION

Limitations of the Study

The NOW study focused on the physical and biological processes, particularly during 1998, when an extensive, multidisciplinary icebreaker-based study was conducted (reviewed in Deming et al., 2002). We had hoped to be able to monitor the ringed seals during all of 1998. However, because the satellite transmitters did not operate long enough in 1997, and because seals were more difficult to catch then, our study overlapped with only the latter half of the NOW emphasis period. About 70% of the 23 study animals were immature seals (likely less than three years old at capture), and 14 (61%) were males. Thus the age composition of the study animals was representative of the catch of ringed seals in NW Greenland, which has a surplus of young seals and a sex ratio that is skewed towards males (cf. Teilmann and Kapel, 1998), and likely also of the ringed seal population, which generally has a high proportion of young individuals (e.g., Smith, 1973, 1987). However, because the transmitters on pubescent and adult animals generally performed less reliably, the present study mainly addresses the use of habitat by subadult seals.

We decided to catch the seals as close to the polynya area as possible and therefore operated in the populated Thule area that borders the North Water to the east. The effects of tracking seals that had been caught on only one side of the polynya area could not be assessed a priori, but it is possible that the picture of their movement patterns was influenced by a tendency of the seals to show fidelity to the area where they were caught. Although some long-distance movements of ringed seals have been reported (e.g., Heide-Jørgensen et al., 1992; Kapel et al., 1998; Teilmann et al., 1999), there are indications that ringed seals may show site tenacity both within and between years (Smith and Hammill, 1981; Kapel et al., 1998; Gjertz et al., 2000).

However, despite these limitations, we believe that the behavior of the seals monitored in this study allows for some general inferences about the spatial use of the NOW area by ringed seals.

Horizontal Use of the NOW Area

Our data indicated that the ringed seals tagged in the eastern part of the NOW area stayed in the eastern areas with relatively shallow water (< 100 m) and spent little time in the central polynya area in Smith Sound.

The icebreaker-based NOW study confirmed that the earlier ice breakup in the eastern parts of the NOW area favors marine production and animal abundance in general along the Greenland coast (Holst and Stirling, 2001; Klein et al., 2002; Ringuette et al., 2002 and references therein).

Despite the apparent site tenacity, we think that the distribution of the seals in our study was influenced by the general distribution and availability of prey, and we suggest that a key factor influencing the spatial use by the seals was the occurrence of polar cod (*B. saida*). In the Thule area, polar cod constituted 80% to 90% by mass of the diet of ringed seals (all age classes) in 1985 and 1998 (Siegstad et al., 1998). In Jones Sound, adult ringed seals mainly consumed arctic cod (*A. glacialis*), and polar cod comprised only about 16% of the diet by mass in 1998. In this area, subadults foraged mainly on the hyperiid amphipod *T. libellula* (Holst, 2000, cited in Hobson et al., 2002a; Holst et al., 2001). However, a study of stable isotope ratios ($\delta^{13}C$, $\delta^{15}N$) that likely represent dietary integrations over one to two months indicated that during late spring to early summer (1998), the diet of ringed seals on both sides of the NOW consisted primarily of polar cod (Hobson et al., 2002a).

Polar cod sometimes move in large shoals during the open-water season (Falk-Petersen et al., 1986; Born and Knutsen, 1988; Finley et al., 1990; Crawford and Jorgenson, 1996). Most polar cod ingested by ringed seals in Thule were young (age inferred from length; Gjøsæter and Ajiad, 1994; Siegstad et al., 1998), indicating that the seals fed on shoaling polar cod of uniform age class.

The crustacean *T. libellula* can also occur in swarms during summer and winter (Cross, 1982; Percy, 1993;

Wathne et al., 2000; Auel et al., 2002). A patchy distribution of crustaceans (including *T. libellula*) in the NOW was indicated in a study of the diet of dovekies (Pedersen and Falk, 2001).

The occurrence of their principal prey in localized shoals and swarms may govern the movements of predatory ringed seals during the open-water season, when they move around more to detect concentrations of food. Furthermore, during winter and spring, ringed seals are associated with their breeding holes in the fast ice and subnivean lairs, which in itself may reduce their horizontal mobility (Kelly and Quakenbush, 1990).

During the open-water season, harp seals (*P. groenlandica*) , narwhals (*Monodon monoceros*), dovekies, and thick-billed murres migrate in substantial numbers to the coastal areas and fjords of the Thule area to exploit the same prey as ringed seals (Vibe, 1950; Born, 1986; Kampp, 1990; Born et al., 1994; Heide-Jørgensen et al., 1994; Kampp et al., 2000; Pedersen and Falk, 2001; Hobson et al., 2002b). However, despite increased competition for food during summer from other marine mammals and sea birds, the ringed seals in our study stayed near the coast of the Thule area.

One seal moved from Thule to spend September and the first half of October at Coburg Island at the entrance to Jones Sound (Fig. 2D), where there is a large colony of thick-billed murres. The enhanced marine productivity in this area (Hobson et al., 2002b) was probably the reason that the seal stayed there.

Vertical Use of the NOW Area

The upper water layers in the NOW area are relatively active biologically (e.g., Ringuette et al., 2002). We found that ringed seals foraged in the upper 100 m of the water column almost exclusively, with a clear preference for the upper 50 m. Our findings were similar to those of Gjertz et al. (2000) at Svalbard, where about 50% of all dives between July and May were to depths less than 20 m, and about 90% to depths less than 100 m. For two seals that visited offshore pack ice areas, diving was significantly shallower there than in coastal areas (Gjertz et al., 2000).

There is probably no real need for ringed seals to use time at greater depths in the NOW area. First-year polar cod generally occur between 0 and 80 m, typically associated with ice (Craig et al., 1981; Bradstreet et al., 1986; Falk-Petersen et al., 1986; Lønne and Gulliksen, 1989), whereas older and larger polar cod can be found between 200 and 400 m depth (Falk-Petersen et al., 1986; Wathne et al., 2000). Like the polar cod, the crustacean *T. libellula* occurs in concentrations in the upper 100 m of the water column (Cross, 1982; Percy, 1993; Wathne et al., 2000; Auel et al., 2002). In the northeastern Barents Sea, at latitudes comparable to those of the NOW (about 77° and 79° N), about 80% of the standing biomass (including important ringed seal food) was distributed in the upper 200 m, while less than 1% was below 300 m (Wathne et al., 2000). The fact that huge concentrations of thick-billed murres find food in the upper layers of the water column in the North Water (Falk et al., 2002) reflects the high productivity of those strata, particularly on the eastern side.

The dives in the NOW by subadult, pubescent, and adult seals were very shallow during June and July, when the seals also spend a greater proportion of time on the ice (Born et al., 2002). The two subadults that were studied in the fast ice habitat during winter and spring dove only to shallow depths. This may reflect the fact that during these periods, the seals prey upon polar cod and crustaceans directly under the ice. In contrast, the 96 kg adult continued to make deep dives during winter.

Records of the daily maximum dive depth indicated that the seals occasionally dove to the sea floor. Lydersen and Hammill (1993) found a similar positive correlation between MDD and bottom depths for three ringed seal pups that were monitored with time-depth recorders at Svalbard. These excursions to the bottom may be in search of benthic prey. Ringed seals are known to take benthic food in the NOW area (Siegstad et al., 1998; Holst et al., 2001). In Thule, the third most important prey by weight was the bottom-living sea snail, *Liparis* spp. (Siegstad et al., 1998).

Dive duration and depth are positively correlated with body mass in ringed seals (Kelly and Wartzok, 1996; Teilmann et al., 1999; Kunnasranta, 2001). Hence, the MDD may reflect the physical limits of the diving capability of the individual seals (Teilmann et al., 1999). In the present study as well, daily maximum dive depth was correlated with total body mass. The diving capability of ringed seals increases with age (synonymous with total body mass), so older and larger seals can dive deeper than smaller seals and consume more fish (e.g., older polar cod), as indicated by the studies of Bradstreet and Cross (1982) and Holst et al. (2001). Adult 11271-97 spent more time at depths beyond 200 m during winter and early spring, when located in NE Baffin Bay at about 73°30' N, 58°50' W. Bottom-trawling in October 2001 at 73°41' N, 58°59' W, close to where 11271-97 wintered, showed that polar cod of 8.5–21.0 cm length made up ca. 40% of the biomass at 150 m. At another trawling station in NE Baffin Bay (73°46' N, 59°40' W), polar cod made up ca. 80% of the biomass at 350 m (O. Ankjær Jørgensen, pers. comm. 2002). Although this survey did not get farther north (Jørgensen, 2002), it indicated that polar cod is available as ringed seal prey at greater depth in northern Baffin Bay and probably also in the NOW area.

Cephalopods have also been reported in the diet of ringed seals from the North Water. Holst et al. (2001) reported finding *Bathypolypus arcticus* in the stomachs of ringed seals from the Thule area. This species is typically found between 200 and 600 m depth (O'Dor and Macalaster, 1983). Another cephalopod, *Gonatus fabricii*, which is widely distributed around Greenland (Kristensen, 1984) and can occur at great depths (Lu and Clarke, 1975), has been found in stomachs of ringed seals in NW Greenland

(Siegstad et al., 1998). We think that cephalopods are also likely prey of ringed seals — probably adult seals — at greater depths in the NOW area.

ACKNOWLEDGEMENTS

This paper is a contribution to the International North Water Polynya Study. The present project received financial support from the Danish Environmental Protection Agency as part of the environmental support program DANCEA (Danish Cooperation for Environment in the Arctic), the Greenland Institute of Natural Resources, and the National Environmental Research Institute, Department of Arctic Environment, Denmark. We wish to thank the following for valuable assistance in the field and their inspiring company: Kristian Eipe, Kurt Thomsen, Tornge Qaviaq, Sven-Erik Ascanius, Kim Diget Christensen, and Nina C. Born. Drs. Christina Lockyer (Age Dynamics, Lyngby, Denmark) and Michael Kingsley (Greenland Institute of Natural Resources, Nuuk) are thanked for offering useful comments on the manuscript. The constructive comments offered by three reviewers (Dr. Robert E.A. Stewart, Department of Fisheries and Oceans, Winnipeg; Dr. Andrew Derocher, Department of Biological Sciences, University of Alberta; and one anonymous reviewer) are gratefully acknowledged.

PREFACE

The exploitation and conservation status of Atlantic walruses (*Odobenus rosmarus rosmarus* L.) has never become an issue of widespread public controversy, as it has for whales, and some seals. However, a coordinated approach to walrus conservation was given some impetus in 1987 when the government of the Netherlands proposed that the walrus be listed in Appendix II of the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES). Although this proposal was withdrawn before being put to a vote at the 6th Conference of the Parties to CITES, an agreement was reached among the walrus range states to exchange scientific information on a regular basis (Stewart *et al.*1993:56). An International Workshop on Population Ecology and Management of Walruses, held in Seattle, Washington, USA, in March 1990 (Fay *et al.*1990), constituted the first meeting of the Walrus International Technical and Scientific Committee, which includes representatives from Norway, Greenland/Denmark, the USA, Canada, Russia and the Netherlands. This workshop, which was followed by a second in January 1993 in Winnipeg, Manitoba, Canada (Stewart *et al.*1993), was the first attempt to address concerns about walrus conservation on an international, range-wide basis.

No formal bilateral, multilateral or international body had been assigned, or had assumed, the responsibility for assessing and conserving the stocks of Atlantic walruses until the North Atlantic Marine Mammal Commission (NAMMCO) included Atlantic walruses on its list of priority species (Anon. 1993a). In 1994 the Council of NAMMCO requested advice from its Scientific Committee on matters relating explicitly to the Atlantic walrus. Specifically, the Commission asked for: 1) advice on stock identity for management purposes, 2) an assessment of abundance in each stock area, 3) an assessment of the long-term effects on stocks caused by present removals in each stock area and 4) an assessment of the effects of recent environmental changes (*e.g.* disturbance, pollution) and changes in the walrus's food supply.

The present report, which was prepared in response to a request from the Scientific Committee, was intended to provide the background of available information needed to evaluate the present status of the Atlantic walrus at the meeting of the NAMMCO Scientific Committee in Copenhagen, 31 January – 2 February 1995. The report covers the entire range of *Odobenus rosmarus rosmarus*.

ABSTRACT

This report summarizes available information on distribution, numbers and exploitation of Atlantic walruses (*Odobenus rosmarus rosmarus* L.) for an assessment of their present status. The effects on walruses of various human activities other than hunting (*e.g.* disturbance, pollution, fishery interactions) are also evaluated. Although few studies have been done to explicitly address questions of the genetic relatedness of different groups of Atlantic walruses, eight putative stocks have been proposed on the basis of distribution, history of exploitation, and the existence of independent management regimes. These stocks are: 1) Foxe Basin, 2) Southern and Eastern Hudson Bay, 3) Northern Hudson Bay – Hudson Strait – Southeastern Baffin Island – Northern Labrador, 4) Western Greenland, 5) North Water (Baffin Bay – Eastern Canadian Arctic), 6) Eastern Greenland, 7) Svalbard – Franz Joseph Land, and 8) Kara Sea – Southern Barents Sea – Novaya Zemlya. Several of these stocks are shared by different countries (*i.e.* Canada, Greenland, Norway and Russia).

Throughout their range Atlantic walruses were heavily exploited, primarily by European whalers and sealers, causing reductions in their range and numbers. Atlantic walruses are still hunted by residents of Canada and Greenland. In nearly all areas Atlantic walruses apparently remain well below historical levels of abundance. An evaluation based on estimates of current population size, landed catch and loss, and an annual net recruitment rate of 2-5% indicates that the Western Greenland (4) and North Water (5) stocks are currently subject to over-exploitation and probably are declining. The Foxe Basin (1) stock appears to be stable, whereas the status of other Canadian stocks (2, 3) is unknown. There are recent signs that the eastern Atlantic stocks of walruses (6, 7, 8) are either stable or increasing. Although walruses can be negatively affected by various human activities apart from hunting, quantification of the long-term effects of these activities cannot be achieved with the data presently available. This report emphasizes that serious gaps exist in the information necessary for assessing the current status of Atlantic walruses. More and better data are needed in relation to population delineation and size, landed catch, unreported kill and losses, reproduction rates, natural mortality and population responses to human activities other than hunting.

INTRODUCTION

The walrus, *Odobenus rosmarus*, has a disjunct circumpolar distribution. Two subspecies – the Atlantic walrus, *O. r. rosmarus*, and the Pacific walrus, *O. r. divergens* – have long been recognized. A third subspecies, *O. r. laptevi*, confined to the Laptev Sea, was suggested by Chapskii (1940). The status of this taxon is, however, questionable (Fay 1982, 1985).

The Atlantic walrus, which is the focus of this report, ranges from the eastern and central Canadian Arctic eastward to the Kara Sea. Several more or less well defined subpopulations or stocks exist within this range (Figs 1 and 3, Reeves 1978).

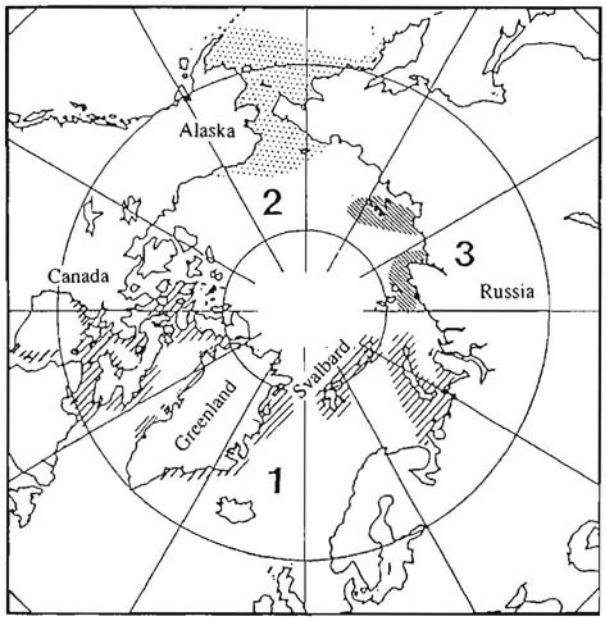

Fig. 1. Approximate normal limit of present distribution of walruses. 1: Atlantic walruses, 2: Pacific walruses, 3: Laptev walruses; taxonomic status uncertain (modified from Fay 1985).

The total population of Atlantic walruses prior to the European discovery of North America (including Greenland), Svalbard, and the islands of far northern Eurasia must have been at least in the hundreds of thousands. This conclusion is inescapable when one considers the observations reported by early explorers, whalers and sealers, as well as the magnitude of the killing. The commercial exploitation of walruses for their oil, tusk ivory and hides proceeded on an enormous scale, with no checks whatsoever to ensure sustainability. As a result, by the mid 20th century the aggregate population of the Atlantic walrus had been reduced in nearly all areas and its range had shrunk substantially. Large herds that once hauled out on island and mainland beaches in cold temperate and subarctic latitudes have been exterminated, and the bulk of the population is now confined to remote parts of the Arctic.

The walrus was always important to Inuit economy; in many areas it was a critical subsistence resource. Walrus meat is excellent food for sled dogs as well as people; the hide is strong and durable; the blubber produces good-quality oil for burning; and the ivory has always been popular for constructing tools and weapons and, more recently, for carving. Availability of walruses, particularly during winter, influenced settlement patterns in the eastern Canadian Arctic and Greenland. The rapid depletion of walrus stocks by foreign commercial hunters severely compromised the resource base of many northern communities. This loss, or at least greatly reduced availability, of a valuable resource has helped limit the options of northern people as they seek to re-establish economic self-sufficiency and political independence.

We stress that certain biological characteristics of walruses make them particularly vulnerable to exploitation and to changes in the environment:

Walruses have a comparatively narrow ecological niche. Their populations probably depend on: 1) the availability of large areas of shallow water (80 m or less) with suitable bottom substrate to support a productive bivalve community, 2) the presence of reliable open water over rich feeding areas, particularly in winter when access to many feeding areas is denied due to ice cover, and 3) the presence of haul-out areas in close proximity to feeding areas. Haul-out platforms are usually ice pans although terrestrial haul-out sites (uglit; ugli in singular – terminology borrowed from Inuktitut) are used in the ice-free summer and autumn period (Davis *et al.* 1980).

Their narrow trophic niche and restricted distribution make walruses vulnerable to environmental changes and also relatively easy to hunt. These animals' gregariousness and dependence on uglit made it possible for European and American whalers and sealers to exploit them very intensively even before the development of mechanized transport and modern weapons. Their tusks make them economically valuable to present-day Inuit hunters. With modern hunting technology involving

Fig. 2. A male walrus hauled out at Andréetangen, Edgeøya, in Svalbard. Male Atlantic walruses may grow as heavy as their Pacific counterparts (Wiig and Gjertz in press). The stout tusks and numerous skin tubercles are characteristic of adult males. Photo: I. Gjertz

long-ranging boats and powerful firearms, hunters now have access to nearly all of the habitat that is still occupied by walruses. Adult females and males, with their comparatively high yields of ivory and meat, are hunted selectively. Furthermore, in all areas where walruses are hunted, losses appear to be high. This harvesting pattern involves a high risk of further depleting the stocks of Atlantic walruses.

Structure of this Report

1. Overview: A brief summary of the status of Atlantic walruses, by region, is presented at the front of the report for readers who wish only to have such an overview. In the main body of the report, following the summary, we present the detailed information on which the summary is based.

When the available information was considered sufficient, we attempted a crude analysis of sustainable yield and compared the result with the estimated removal rate for the stock. Simulation of a hypothetical walrus population indicated that maximum net productivity (MNP) ranges between 2 and 5% of the total population size (DeMaster 1984). For a population at carrying capacity, K, MNP may be lower than 2% (Fay *et al.*1989), whereas under favorable environmental conditions (and low density of walruses in relation to K) MNP may perhaps be as high as 7% per year (Sease and Chapman 1988). In our crude analyses of the effects of removals we assumed that annual sustainable yield – or replacement yield – of Atlantic walruses ranges between 2 and 5% of the stock estimate.

The overview also includes the conclusions of our assessment of the effects on walruses of disturbance, pollution and changes in food availability.

2. Distribution, Catch History and Status, by Region: Separate sections are devoted to geographical regions which may or may not represent "stock" areas in a strict sense (see Report of *ad hoc* Working Group on the Atlantic Walrus; NAMMCO 1995). The partitioning into stocks was made on the basis of our knowledge of major ecological factors that determine distribution of walruses such as ice cover, polynyas, distribution of shallow banks with suitable walrus habitat, migration routes and availability of terrestrial haul-out sites. Within each of the geographically defined sections, we tried to include information on historical and current distribution, seasonal movements, age and sex composition, stock identity, population size (past and present), hunting methods, catch levels and composition of catches and hunting loss (for estimation of total removals).

3. Summary of Regulatory Actions: Regulations applying to walrus stocks in each of the range states are summarized.

4. Assessment of Environmental Problems: Separate summaries are given for the various types of known, suspected or potential threats to Atlantic walrus stocks, other than hunting. These summaries are not subdivided by geographical region.

5. Walrus Life History and Parameters: This brief overview of the biology and ecology of walruses is provided as background only.

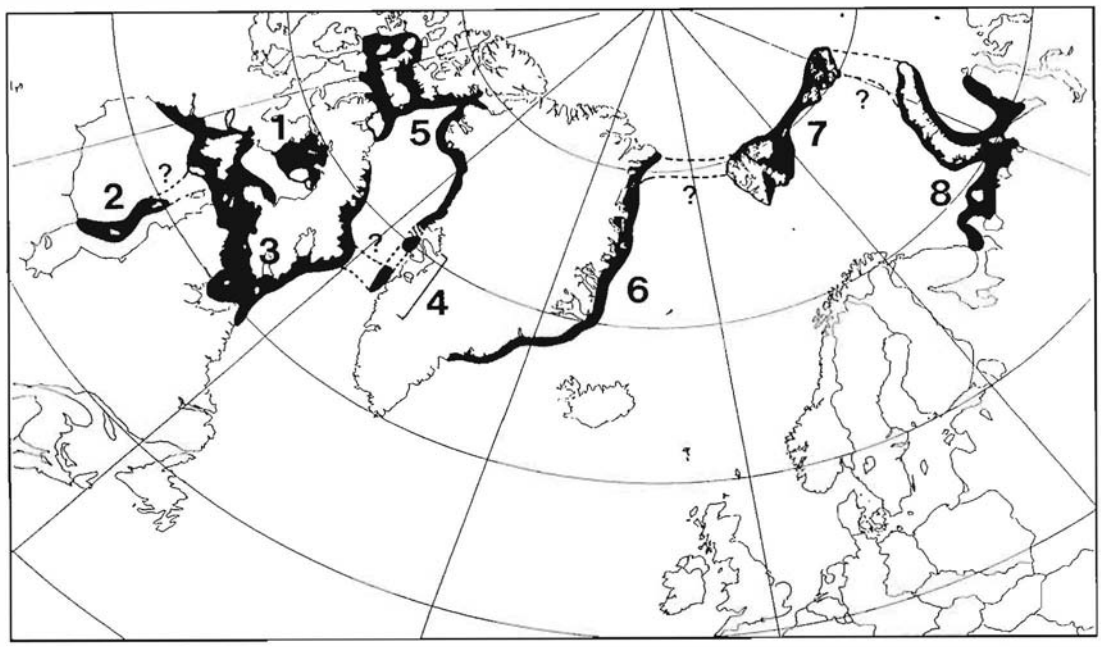

Fig. 3. Delineation of proposed stocks (sub-units) used in this review of the status of the Atlantic walrus.

SUMMARY OF STATUS

The status of eight presumed stocks of walruses (see also Report of *ad hoc* Working Group on the Atlantic Walrus; NAMMCO 1995) is reviewed in this report. These stocks are:

1. Foxe Basin, 2. Southern and Eastern Hudson Bay, 3. Northern Hudson Bay – Hudson Strait – Southeastern Baffin Island – Northern Labrador, 4. Western Greenland, 5. North Water (Baffin Bay – Eastern Canadian Arctic), 6. Eastern Greenland, 7. Svalbard – Franz Joseph Land, and 8. Kara Sea – Southern Barents Sea – Novaya Zemlya (Table 1, Fig. 3).

Stock 1 – Foxe Basin

Walrus distribution, movements and body growth patterns indicate that the group in Foxe Basin is largely isolated from other groups to the north (via Fury and Hecla Strait) and south (western Hudson Strait and Southampton Island area).

Aerial surveys have confirmed that walruses are now distributed mainly on the east side of northern Foxe Basin during the open-water season (Orr *et al.*1986). Although it is generally believed that the distribution of walruses has changed since the 1940s and 1950s so that they are now much less common on the western side of Foxe Basin, the stock is still large relative to those in other parts of the subspecies' range.

Available data are not sufficient for rigorously assessing trends in the population in northern Foxe Basin. Cosens *et al.*(1993:12) indicated that the population numbers about 5500 animals based on incomplete aerial surveys in 1988 and 1989. The estimated current removal rate of about 300 animals per year may exceed sustainable yield (Table 1).

Stock 2 – Southern and Eastern Hudson Bay

The large gap in walrus distribution along the west coast of Hudson Bay (approximately from Dawson Inlet south to Cape Henrietta Maria) provides a basis for considering the walruses in southern and eastern Hudson Bay as separate from those in northwestern Hudson Bay. However on the east side of the bay the distribution of walruses may have been continuous historically from the Belcher Islands northward to the mouth of Hudson Strait. The apparent decline in numbers and reduced range of walruses in eastern Hudson Bay, with no obvious corresponding changes in northern Hudson Bay and western Hudson Strait, can be interpreted as suggesting that there is limited exchange between eastern Hudson Bay and these areas.

We have no recent information on the status of the groups of walruses that hauled out, at least until the 1970s, on the Belcher, King George, Sleeper, and Ottawa islands. They are undoubtedly fewer in number and less widely distributed than earlier this century, but it is possible that hunting pressure is now less severe than it was during the days when sled dogs were the primary means of winter transportation.

The walruses in southern Hudson Bay are not hunted off the Ontario coast, when they haul out in

Table 1. Assessment of Atlantic walrus by stock area. The current status (D) of different stocks of Atlantic walruses is evaluated based on estimates of stock size (A) and total annual removal (landed catch plus losses, B and C.) Qualifiers are added to indicate quality of underlying data.

STOCK AND AREA	Stock size (A)	Quality of (A)*	Landed catch (B)	Quality of (B)*	Loss# % (C)	Total removal (B and C)	Females % of (B)	SY	Stock status (D)	Assess-ment quality*

*: G = Good (minimal bias, acceptable precision)
F = Fair (problems with quality of data, precision uncertain)
P = Poor (considerable uncertainty, bias or few data)
**: These stocks have been protected since the 1950s, there are indications of some catch (see text).
#: Percentage lost of all struck
##: Where no stock-specific data were available, 30% was used (similarity with Foxe Basin in hunting methods).
SY: Sustainable yield is based on the stock size estimate (A), times the maximum net productivity of the population (2% to 5% of the stock).

summer and autumn in the vicinity of Cape Henrietta Maria. The reference to about 1000 walruses at Cape Henrietta Maria in 1955 (Loughrey 1959) is not particularly reliable, so no decline should be inferred from the maximal recent direct count of 310.

Available information suggests that the number of walruses in southern and eastern Hudson Bay is in the hundreds (perhaps about 500). The current removal of about 50 animals likely exceeds the sustainable yield (Table 1). Data for this region are, however, very limited.

Stock 3 – Northern Hudson Bay – Hudson Strait – Southeastern Baffin Island – Northern Labrador

In the absence of any direct evidence for stock identification (*e.g.* genetic analyses, tagging, morphometry), it may be inferred from the evidence on distribution and movements that the walruses in northern Hudson Bay, Hudson Strait and southeastern Baffin Island and off northern Labrador comprise a common stock. This stock may have some connection with southern and eastern Hudson Bay and with Central West Greenland. It cannot be ruled out that sub-units exist within the range of Stock 3.

Available information is insufficient for assessing the status of walruses along the Keewatin coast of western Hudson Bay, but all evidence indicates that they are now much less common there than they were earlier in the present century.

Crude comparisons of counts in 1954 (Loughrey 1959), 1961, and 1976-77 in areas around Southampton and Coats islands (Mansfield and St. Aubin 1991) could be interpreted as suggesting a decline, but the basis for comparing these counts and estimates is very weak.

Walruses are apparently much less abundant along both the Baffin Island and northern Québec coasts of Hudson Strait today than they were 50-100 years ago, as evidenced by the fact that hunters from Cape Dorset, Ivujivik, Salluit and other settlements travel long distances to hunt them on the offshore islands.

Walruses occur year-round along portions of the coast of eastern Baffin Island south of Clyde Inlet and in Hudson Strait. Although areas of summer concentration have been identified (*e.g.* outer parts of Cumberland and Hall peninsulas, Lady Franklin Island group, Loks Land) the walruses tend to occur in small, scattered groups in these areas. Some of these groups may undertake fairly long migrations while others are thought to move relatively short distances according to ice conditions and availability of food. Although connections have been suggested between the walruses in these areas and

those found year-round in Hudson Bay and during winter in Central West Greenland, the present distribution indicates that walruses along eastern Baffin Island and in Hudson Strait may have become more sedentary, or at least that the populations are now discontinuous rather than continuous.

Walruses have been eliminated from some areas where they were known to be present historically. For example, Soper (1928:9) reported that they had been common at one time around Bon Accord Harbour in upper Cumberland Sound but that none had been seen there for many years by the time of his visit in the mid 1920s (also see Stevenson 1993). Walruses may have declined in upper Cumberland Sound already by the 1870s (Kumlien 1879:63-64). They are said to have become "very rare" in the Clyde area due to commercial hunting during the 1930s and 1940s (Wenzel 1991:93). The availability of walruses has declined off Labrador since the "pre-settlement period" (before 1960) (Brice-Bennett 1977:129), but details are lacking. Nowadays the southern limit of walruses along northern Labrador appears to be in the Hebron-Okak Bay area.

Although commercial hunting driven by demand for hides, ivory and oil was stopped by governmental regulation in 1931, substantial catches continued to be made by Inuit, police, missionaries and traders in order to secure winter supplies of dog food. The availability of large boats made it possible to travel to offshore islands where walruses were still relatively abundant in the 1930s and 1940s. With the decline of dog teams in the 1960s, the urgency of obtaining large amounts of walrus meat abated. At some settlements much less effort was devoted to walrus hunting, and it is possible that stocks had a chance to make some recovery. We are unaware of any clear recent evidence of trends in the walrus population off eastern and southern Baffin Island.

We estimate that the population of walruses in northern Hudson Bay, including about 3000 around Southampton and Coats islands and at least 1000 in western Hudson Strait and southeastern Foxe Basin (Orr and Rebizant 1987, Richard and Campbell 1988, Richard 1990, Mansfield and St. Aubin 1991), totals about 4000 animals. Available information indicates that perhaps 2000 walruses are found along eastern Baffin Island, in Ungava Bay and in eastern Hudson Strait. The estimated current total removal rate of about 330 walruses per year may exceed the sustainable yield of the combined stock in area 3 (Fig. 3, Table 1).

Given the great amount of uncertainty about stock identity, population size, total removals (including hunting loss), and age/sex composition of the kill, however, any judgment about sustainability of the present harvest is highly speculative. It is important to bear in mind the possibility that the same population of walruses is hunted off Central West Greenland.

Fig. 4. Adult male walruses hauled out on Coats Island in mid-August 1967. Note the broken tusks and wrinkled skin, signs of old age, of the upper animal. Photo: F. Bruemmer.

Stock 4 – Western Greenland

Walruses winter off Central West Greenland. Apparently the walruses that winter along the western coast of Disko Island belong to a different stock than those found farther south off Aasiaat-Sisimiut. The northern group is thought to belong to the North Water stock (Stock 5), whereas the southern group perhaps is connected with walruses along eastern Baffin Island (Stock 3).

Vibe (1956) and Mansfield (1973) stated that the decline in the Greenland catches of walruses after 1940 reflected a decline in the walrus population. There is no evidence of a reduced hunting effort during the period of declining catches after approximately 1940. On the contrary, despite the difficulty of selling walrus hides on the European market (experienced already by the late 1930s; Anon. 1937), and despite the drop in international oil prices in 1930 (Anon. 1946), the trade of walrus hides and oil to the Royal Greenland Trade Department remained high in Central West Greenland (Born *et al.* 1994a). This supports the statements by Vibe (1956) and Mansfield (1973).

The shallow feeding banks off Central West Greenland provide important wintering habitat for walruses. A comparison between historical and recent information on occurrence, abundance and exploitation indicates clearly that the number of walruses in this area and the extent of undisturbed wintering habitat available to them have declined during the 20th century. Increased fishing activities since the 1960s in areas where walruses winter, and catches which remain high relative to the estimates of abundance, pose a threat to the survival of walruses in Central West Greenland.

The number of walruses on the Central West Greenland wintering grounds is estimated to be about 500 animals (Born *et al.* 1994a), or in the low hundreds (Heide-Jørgensen and Born 1995). The reported catch in Central West Greenland (from Uummannaq south) in the period 1980-1987 averaged about 46 walruses per year. This figure likely underestimates the actual landed catch. To the reported catch figure an overall loss of 30% is added (see Born *et al.* 1994a), resulting in an estimated total removal of about 65 walruses per year. We therefore believe that walruses in Central West Greenland are being harvested above their sustainable (= replacement) yield.

Fig. 5. A dog team is used for hauling a walrus onto the ice at Saunders Island (Avanersuaq/Thule area, NW Greenland) in May 1978. Photo: T. Kristensen.

Fig. 6. A group of adult male walruses at Tusenøyane, Svalbard. The majority of walruses in Svalbard are males. The females tend to occur further east, in Russian waters. Photo: I. Gjertz

Stock 5 – North Water (Baffin Bay – Eastern Canadian Arctic)

The walruses in the North Water (NOW) area probably belong to one population which has its main summering grounds along the southeast coast of Ellesmere Island, in Jones Sound and along the north shore of Lancaster Sound. Some, presumably few, walruses may summer farther north – in the Kane Basin region, and west – in the Canadian high arctic archipelago. The NOW population is thought to include walruses that winter in the eastern Canadian Arctic and along the west coast of Greenland as far south as Disko Island. The NOW population apparently no longer makes large-scale spring and fall migrations along either the northeast coast of Baffin Island or the west coast of Greenland.

No complete population estimate is available for the NOW stock but the available data suggest that it may contain no more than perhaps 3000 individuals.

During this century walruses have abandoned their uglit on the Greenland side of the NOW area and their summering range has diminished. Decreased access to two important ecological elements – undisturbed haul-out sites and summer feeding grounds – is thought to have had a negative impact on this population.

Historically, large catches of walruses in the NOW area were made by foreign commercial sealers and whalers. Since about the 1960s the effort devoted to walrus hunting by local Inuit has increased in the Avanersuaq (Thule) area (NW Greenland), where the bulk of the catch of walruses from this stock is normally made.

The actual catch of walruses in northern Baffin Bay is not well documented. However, we estimate that during the last two decades the annual removal rate (including loss) in the Avanersuaq and Upernavik areas (Greenland) and the eastern Canadian high Arctic has averaged about 375 walruses. To ensure sustainability an annual yield of 375 walruses necessitates the presence of a population of between about 7500 and about 19000 animals. Our estimate of the size of the walrus stock in the NOW area is only a few thousand. Thus the current exploitation appears to be unsustainable (Table 1).

Stock 6 – Eastern Greenland

Walruses occur along the east coast of Greenland north of about 63° N. Their main distribution is, however, north of about 70° N. Information on seasonal and geographical distribution indicates that walruses in eastern Greenland form a geographically separate unit. This stock apparently has some exchange, presumably infrequently, with walruses at Svalbard-Franz Joseph Land and in Davis Strait.

Large catches around the turn of the last century led to the disappearance of walruses at several of their uglit, and these catches presumably also caused a serious reduction in overall numbers. Recent surveys indicate that the recovery has been slow, perhaps reflecting the low productivity of these regions. It is estimated that the stock now numbers 500 to 1000 walruses. The estimated current removals from this stock are 20-30 animals per year, primarily males. This removal rate may approximate sustainable (= replacement) yield of the stock (Table 1).

Stock 7 – Svalbard – Franz Joseph Land

In Svalbard (Norway) and Franz Joseph Land (Russia), and possibly also in the other areas within Russian jurisdiction, stocks of Atlantic walruses are in an early phase of recovery from severe depletion. Their present numbers are, however, only a fraction of what they once were.

It has been demonstrated that Svalbard and Franz Joseph Land have a common walrus population. A possible connection with groups of walruses in other parts of the western Russian Arctic cannot be excluded. Walruses are in the process of repopulating the Svalbard archipelago from the east. The majority of animals summering in Svalbard are males; the rest of the population is distributed primarily east of Svalbard and in Franz Joseph Land. This stock of walruses is estimated to number at least 2000 animals. The stock probably has a very good food supply and is likely experiencing optimal feeding conditions (Table 1).

Stock 8 – Kara Sea – Southern Barents Sea – Novaya Zemlya

The situation for the stocks of Atlantic walruses in other parts of the eastern section of their range is less well known. The relationships between groups of walruses at Novaya Zemlya and in the southern Barents Sea, White Sea and Kara Sea areas are not well understood. Surveys to determine distribution and size of populations have not been conducted recently, and comprehensive population figures are not available. The limited available information indicates that some hundreds, or perhaps more than a thousand, walruses are now present in these regions. Presumably, walruses in these parts of their range have a more than adequate food supply, but recovery of their population(s) is probably being slowed or prevented by other limiting factors, such as the effects of marine nuclear waste, large-scale shipping and pollution. Some hunting occurs in these areas, but it is poorly documented. The available information is too limited to allow for an evaluation of the effects of hunting on the populations (Table 1).

Anthropogenic effects apart from those due to hunting

In response to the questions raised by the NAMMCO Council concerning the potential effects on walruses of recent environmental changes (*i.e.* disturbance, pollution), and changes in food supply, we reviewed the following topics:

1. Disturbance from different sources of noise
   1a: Aircraft and vessel traffic
   1b: Offshore hydrocarbon exploration and operational activities
   1c: Military activity
2. Pollution
   2a: Oil spills etc.
   2b: Heavy metals and chlorinated hydrocarbons (CHCs)
   2c: Radioactivity and nuclear activity
3. Changes in food abundance and interactions with fisheries

Our conclusions are summarized below.

1. Disturbance from different sources of noise

1a. Aircraft and vessel traffic

Although their reactions are variable, walruses usually flee into the water when an aircraft gets close. In some cases this can lead to stampeding, with the result that calves are crushed to death. Walruses also react to noise from boats and ships and they usually exhibit an escape response if a vessel gets too close. However, the degree of responsiveness is highly influenced by the type of noise and its source level, the social and behavioral situation of the walruses, and their previous experience with vessel noise, especially whether it was associated with more drastic effects such as hunting. Cases in which walruses have permanently abandoned uglit (*e.g.* western and eastern Greenland) have involved factors in addition to noise disturbance, such as hunting and the smell of humans, dogs, offal etc., that could have been as or more significant.

We are not in a position to evaluate whether walruses, like many other species, habituate to noise from aircraft, ships and boats. Nor do we have sufficient information for evaluating the long-term effects of such disturbance.

Because most walrus populations have been subjected to hunting pressure, in many cases intensive and over many years, and because various other human activities have modified walrus habitat through time, it will be very difficult to demonstrate long-term effects,

Fig. 7. Walruses are highly gregarious. When frightened by aircraft noise, they flee into the water. During such stampedes calves are sometimes crushed to death. Photo: I. Gjertz

at the population level, caused specifically by exposure to noise.

1b. Offshore hydrocarbon exploration and operational activities

Oil and gas exploration is now occurring in many offshore areas inhabited by Atlantic walruses. This activity is large-scale in some areas, for example around Svalbard and in the western Russian Arctic. In the latter the oil fields overlap the summer distribution of walruses and therefore large-scale petroleum activities pose a potential threat to walruses.

In a study of the effects on Pacific walruses of offshore drilling, the animals were found to exhibit only weak short-term behavioral responses to the drilling activities *per se*. They reacted more strongly to the icebreaking activities associated with these operations by moving away for a brief time. However we are not aware of any studies that support conclusions about the long-term effects of various exploration and operational activities on walruses.

1c. Military activity

We are not able to evaluate to what extent military activity (*e.g.* rocket launching, explosions) in different areas (*e.g.* southern Barents Sea) may have adversely affected walruses.

2. Pollution

2a. Oil spills etc.

Apparently no studies have specifically addressed the direct or indirect effects of oil on walruses.

Studies of seals have shown that surface contact with oil causes stress, and temporarily irritates the eyes, skin and lungs. Ingestion of oil leads to physiological and chemical changes, possibly affecting reproduction. Inhalation of aromatic hydrocarbons from an oil spill caused mental debilitation in harbor seals (*Phoca vitulina richardsi*) in Prince William Sound (Alaska). Most evidence of internal organ and tissue damage from oil ingestion by seals is, however, inconclusive for walruses. Walruses exposed to an oil spill are likely to show some of these reactions. However, walruses depend almost entirely on blubber to minimize heat loss. Their sparse pelage presumably is of little value as insulation, and their skin is thick and very tough. It is therefore unlikely that exposure of the skin to oil would have any appreciable thermal effect except perhaps in newborn walruses. Oiling of newborns that have not yet accumulated a thick insulating blubber layer could affect their ability to keep warm. Consequently, oil spills during the walrus calving season (late May-early June) in areas where females and young are present could, theoretically, have a greater adverse impact than spills at other times and in other areas.

We believe that some features in the ecology of walruses make them more vulnerable to the harmful

effects of spilled oil than are many other marine mammals:

1. Due to the high level of gregariousness in walruses, an oil spill that affected one would likely affect at least several individuals. Furthermore, the oil from a spill in one area could be transferred by individuals to other walruses on clean sites (for example oil-fouled walruses will rub oil onto the skin or into the eyes of other individuals during haul out).

2. Walruses tend to inhabit coastal areas and areas of relatively loose pack ice. Spilled oil is likely to accumulate in such areas. Walruses therefore have a high risk of being fouled not only in the water but also when they haul out on land.

3. Because they are benthic feeders, walruses may be more likely to ingest petroleum hydrocarbons than are most other pinnipeds. Benthic invertebrates are known to accumulate petroleum hydrocarbons from food, sediments and the surrounding water. The implications for walruses may be serious since contaminants in their food are certain to build up in their own tissue. Oil contamination may also reduce the biomass or productivity of the invertebrate communities that sustain walruses, forcing the animals to seek alternative food or feeding areas. It cannot be assumed that such alternatives are actually available, however.

2b. Heavy metals and chlorinated hydrocarbons (CHCs)

Two classes of pollutants are of particular concern in marine mammals: heavy metals and chlorinated hydrocarbons (CHCs). Few studies have been made of these pollutants in walruses, however.

The three metals of greatest concern are mercury (Hg), cadmium (Cd) and lead (Pb). Levels of heavy metals have been found to be very high in Pacific walruses; in certain organs they exceed the levels considered safe for human consumption. In Atlantic walruses, however, heavy metal levels have generally been found to be less than in Pacific walruses. High concentrations of some metals have been found in walruses from Foxe Basin (Cd), southern Hudson Bay (Pb and Hg) and northwestern Greenland (Hg).

CHCs are anthropogenic chemicals which accumulate mainly in blubber. They are of concern because of their potentially harmful effects on walrus reproduction, the walrus immune and hormone systems, and human health through consumption of contaminated walrus tissue. Walruses have generally low concentrations of CHCs. Especially high concentrations have been found, however, in eastern Hudson Bay compared with other parts of Canada, northwestern Greenland and Alaska. These high concentrations might be due to the fact that these individuals consumed significant amounts of ringed seal (*Phoca hispida*) blubber. It is worrisome that comparatively high levels of CHCs have been found in some Atlantic walruses, but the significance to walruses or people who consume them is unclear.

2c. Radioactivity and nuclear activity

Only a few studies have been made on radioactive elements in walruses. However, the levels of plutonium and other radionucleides such as ^{137}Cs reported so far from analyses of marine mammals are not considered high enough to pose a health risk to the animals.

No documentation is available concerning the effects on walruses of nuclear activities in the Novaya Zemlya region. Second-hand Russian sources indicate, however, that certain walrus haul-out sites in Novaya Zemlya were deserted in the 1960s due to the nuclear testing on this island.

3. Changes in food abundance and interactions with fisheries

Changes in the density and availability of food will likely influence the size of walrus stocks. Fluctuations in stocks of walrus prey might be caused by changes in both abiotic and biotic conditions driven, for example, by predator-prey relationships or anthropogenic factors. There is no information available to determine whether or to what extent such changes have influenced the stocks of Atlantic walruses. It is worth noting, however, that mere abundance of walrus prey does not necessarily trigger or sustain population growth. Despite the fact that walrus food must have been abundant in the Svalbard region for a long time, and that walruses have been completely protected there since 1952, they have only recently moved into the area. This may indicate that in the case of a walrus population which has been seriously reduced by hunting, factors other than prey density and availability govern the animals' ability or willingness to exploit a food resource. Walruses are conservative in their choice of food and selection of habitat. So factors such as the need to learn or inexperience may have played a role in the evident failure of the walruses at Svalbard to take full advantage of the rich feeding areas available to them.

Although the direct and indirect effects of fisheries on Atlantic walruses are basically unknown, some effects probably do occur. Fishing with

bottom draggers has destroyed potential walrus feeding habitat at Svalbard. The noise from fisheries in or near walrus habitat and the disturbance of the sea floor caused by trawling have probably contributed, perhaps synergistically, to the continued depletion of the stock of walruses wintering off Central West Greenland. Intensive fisheries along the coasts of Svalbard and elsewhere in the Barents Sea also may have prevented walruses from repopulating areas that, from a purely trophic perspective, appear still to be suitable walrus habitat.

DETAILED DESCRIPTIONS OF THE PUTATIVE STOCKS

1. Foxe Basin

Distribution and Stock Identity

Summer and winter distributions of walruses in Foxe Basin are shown in Figs 8-9, respectively. Places mentioned in the text and locations of uglit are shown in Fig. 10.

The shallow waters of northern Foxe Basin have always been known to support large numbers of walruses (Tremblay 1921, Loughrey 1959, Crowe 1969, Brody 1976). Walruses are present in northern Foxe Basin year-round and they are widely distributed in this area (Crowe 1969:7, Riewe 1992). Their movements are apparently local in response to changing ice conditions. Loughrey (1959) stated that walruses wintered from the northern tip of Melville Peninsula to Cape Wilson, and especially off the floe edge at Foster and Parry bays. In contrast to the situation at Southampton and Coats islands and at the islands in western Hudson Strait, walruses in northern Foxe Basin apparently haul out on land relatively infrequently, *e.g.* at South Ooglit Island in autumn (Mansfield 1958). On the east side of northern Foxe Basin, concentrations occur in summer off the Spicer Islands and around Koch, Rowley and Bray islands (Riewe 1992:195). Beaubier (1970) and Vestey (1973) provided some details on the seasonal distribution of walruses in northern Foxe Basin. The possible uglit shown on Fig. 10 are based on information supplied by H. Ivaluardjuk (pers. comm. 1995).

The distribution of walruses has changed since the 1950s when Hall Beach and Igloolik became major settlement sites (*cf.* Brody 1976). Large herds no longer occur along the east coast of Melville Peninsula, and walruses are much less common in the Foster Bay area than they were in the 1930s (Beaubier 1970). Crowe (1969:5) stated that boat traffic and hunting had "driven the walrus from

Fig. 8. Approximate summer distribution of walruses in Canada and Central West Greenland.

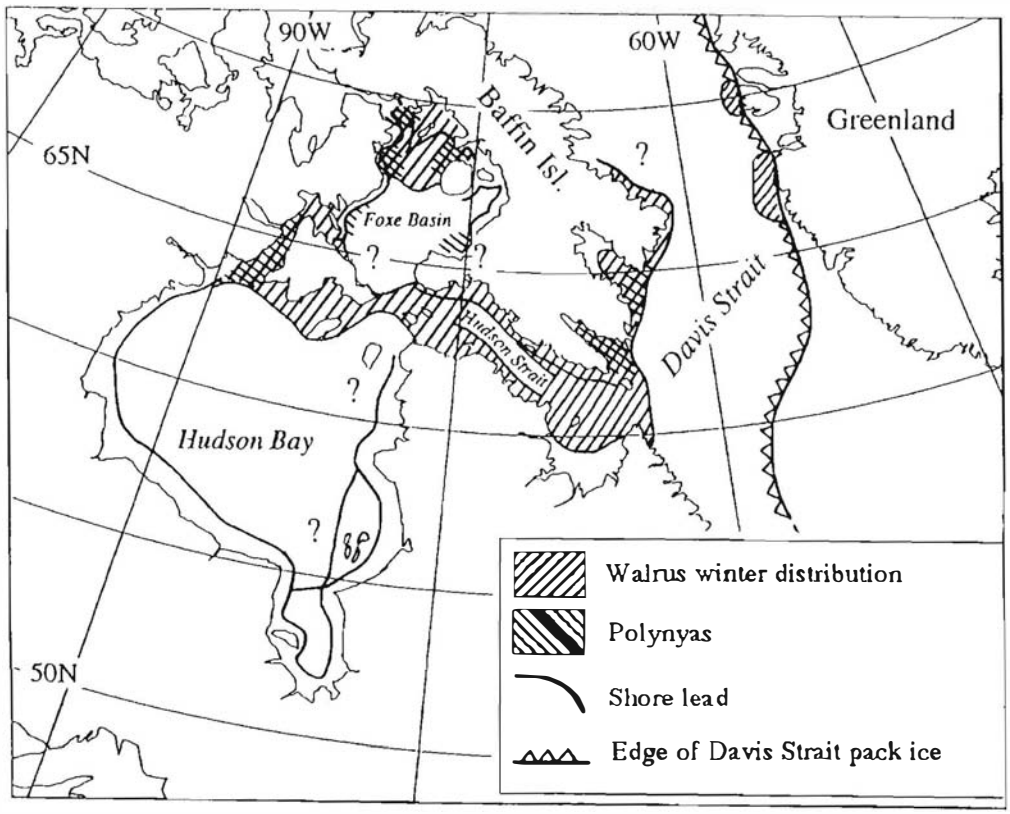

Fig. 9. Approximate winter distribution of walruses in Canada and Central West Greenland. The Davis Strait pack-ice limit is shown. An overlap between walrus wintering areas and locations of polynyas is indicated.

Richards Bay and other former haunts, eastward to the less accessible islands". He also noted that the walruses whose presence had once made boat crossings of Hooper Inlet dangerous had been "driven from there or exterminated by 1948" (Crowe 1969: 69). At the time of Mathiassen's (1928) visit in the early 1920s walruses were abundant in Hooper Inlet.

Mansfield (1958) proposed that the walruses in the northern half of Foxe Basin were effectively isolated from those at Southampton Island, arguing that deep water in the southern areas precluded their dispersal in that direction. Inuit knowledge indicates that there is a hiatus in walrus distribution in southern Foxe Basin (Riewe 1992), thus supporting the hypothesis of separate stocks. Garlich-Miller (1994) corroborated, with new specimen material collected at Igloolik and Hall Beach 1983-93, Mansfield's (1958) finding that walruses in northern Hudson Bay are smaller than those in northern Foxe Basin.

In the southeastern corner of Foxe Basin, walruses sometimes occur along the north coast of Foxe Peninsula and they haul out in summer and fall at capes Dorchester and Weston (Soper 1944, Riewe 1992:198). Soper (1944) claimed that there was no evidence that walruses were present along the west coast of Baffin Island from Bowman Bay to Murray Maxwell Bay, but Inuit told him that good catches had been made in the past (pre 1920s) on islands many miles north of Cape Dorchester. There is little evidence of movement by walruses through Fury and Hecla Strait (Riewe 1992), so the northern Foxe Basin population is also effectively separate from that in northern Prince Regent Inlet (which we assume to consist of migrants from the Lancaster Sound region). It should be noted, however, that at least small numbers of walruses were observed in Fury and Hecla Strait in the 1920s and early 1930s (Bethune 1934:79), so the apparent lack of movement through the strait may be a recent development.

Population Size

Crowe (1969:5) cited the guess of Mansfield (1973) that there were about 4000-5000 walruses in northern Foxe Basin during the 1960s. Helicopter surveys in August 1983 produced a count of 2722 walruses (Orr *et al.*1986), which accounts for Richard and Campbell's (1988) assignment of "2725+" to this area. Even though Orr *et al.*(1986) considered their helicopter survey to have been done under optimal conditions for detecting and counting walruses, they recognized that their count did not represent the entire northern Foxe Basin population.

Visual surveys using systematic strip transects flown in Foxe Basin resulted in estimates of 5200 (95% CI 900-30500) animals at the surface in 1988,

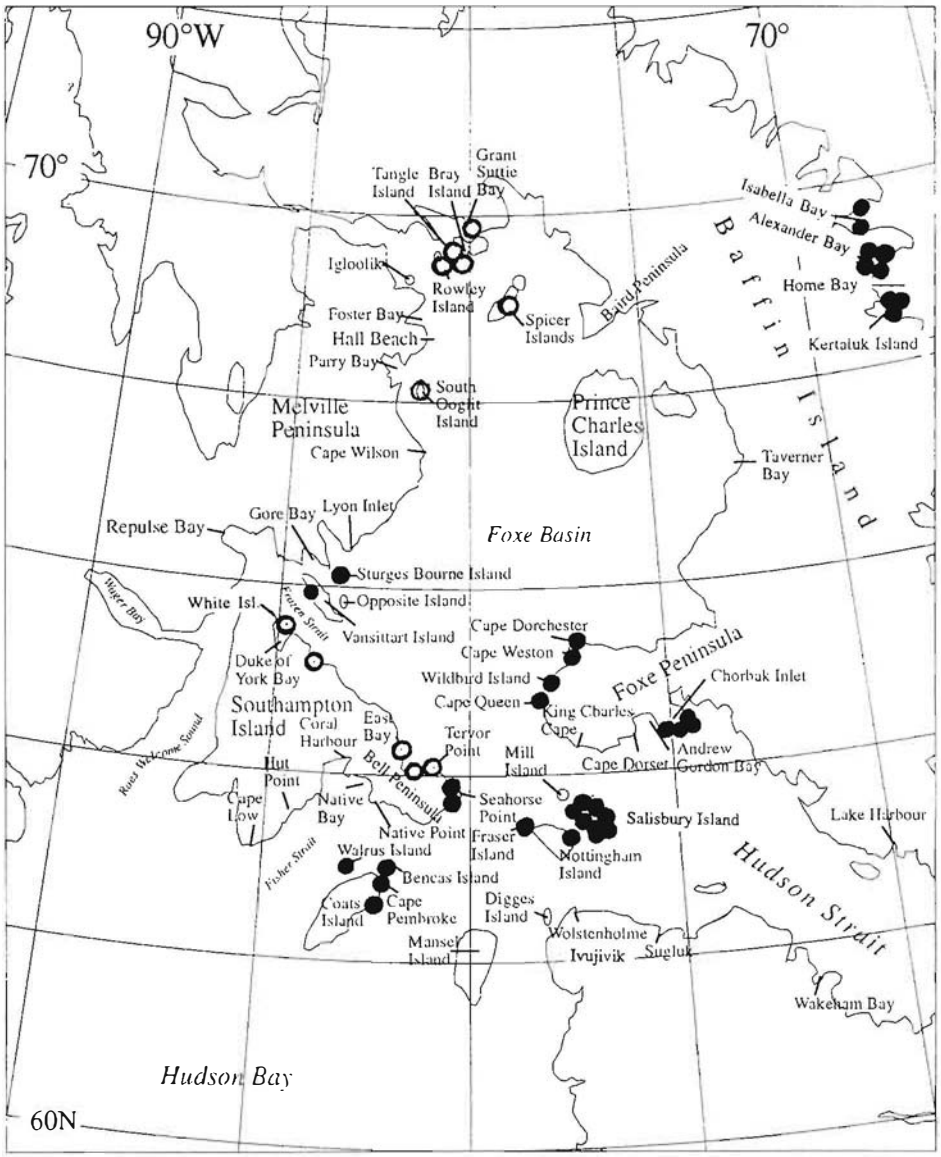

Fig.10. Locations of terrestrial haul-outs (uglit) in Foxe Basin, northern Hudson Bay, western Hudson Strait and parts of eastern Baffin Island (see also Figs. 12 and 16). Legend: Black dots = haul-outs still known or believed to be used by walruses. Open circles = historical haul-outs; present status unknown.

Note: Canadian haul-out sites in this and subsequent map figures are indentified and classified on the basis of information in Anon. (1981-87), Riewe (1992), and personal communications cited in the text.

and 5500 (95% CI 2700 – 11200) in 1989 (Cosens *et al.*1993). As the surveys did not cover the entire walrus distribution area and as no correction has been made to account for diving animals, these estimates are believed to be negatively biased (R.E.A. Stewart pers. comm. 1995).

Exploitation

Hunting methods: Descriptions of hunting methods for western Hudson Bay and Hudson Strait (see Manning 1944, Beaubier 1970, Vestey 1973) apply more or less equally to Foxe Basin. Brody (1976) referred to a major change in the pattern of walrus hunting in this area when whale boats were introduced during the 1920s. The hunting range expanded as hunters were then able to hunt walruses in open water. More recently (1940s-1950s?) the hunting shifted farther offshore, "away from the coastal areas around Jens Munk and Igloolik islands, and Foster and Parry bays, following changes in the animal's seasonal movements – fewer and fewer walruses were coming into the bays and along the coastal areas" (Brody 1976:164; also see Crowe 1969, Beaubier 1970). Whale boats and Peterheads were largely replaced by motorized freighter canoes in the 1960s (Beaubier 1970).

In the 1980s walrus hunting at Igloolik was done mainly from large canoes with outboard motors (20-90 hp) during July and August. Hunters hunted selectively for the larger tusked animals, and they preferred to hunt those hauled out on ice pans. When walruses were hunted in the water, an attempt was made to wound them with body shots and then to harpoon them before killing (Orr *et al.*1986).

The main products from contemporary walrus hunting in northern Foxe Basin are meat and organs for human consumption or dog food. The value of the tusks was high enough in the 1980s to approximately cover the costs of obtaining a walrus at Igloolik (Orr *et al.*1986). Nevertheless "head chopping" (*i.e.* saving only the head and discarding

Fig. 11. A whale boat with sail hunting walruses at Igloolik (northern Foxe Basin) probably at the middle of this century. Photo: Archives of Eskimo Museum, Churchill, Manitoba.

the rest of the carcass) was apparently a "rare practice" with Igloolik hunters (Orr *et al.*1986).

Catch levels: The annual landed catch in northern Foxe Basin was estimated as about 425 in the 1950s (Loughrey 1959) and was reported as 203 between 1973 and 1985 (Orr *et al.*1986). Assuming that about a third of the animals killed are lost, the average annual removals would appear to have declined from 637 in the 1950s to 305 in the 1970s and early 1980s. As pointed out by Orr *et al.*(1986), the crudeness and incompleteness of the catch data make the usefulness of such comparisons highly questionable. It should be noted that Beaubier (1970; also see Beaubier *et al.* 1970) summarized four years of data from the Royal Canadian Mountain Police (RCMP) from 1964-69 indicating catches at Igloolik ranging between 100 and 180 walruses. Moreover, Donaldson (1988:63), after analyzing the data obtained from a harvest study during the early 1980s, concluded that the official catch statistics for Igloolik and Hall Beach in the early 1980s were too high. The harvest study estimated the combined landed catch for these two settlements during 1981-83 as about 169 per year, while the official combined estimate from Department of Fisheries and Ocean (DFO) was somewhat more than 300 per year (Donaldson 1988:table 8).

The reported landed catches for Foxe Basin during 1988-93 (5 years) averaged about 200 (range: 124-319. Hall Beach: ca. 75; Igloolik: ca. 125) (Anon. 1991...94; R.E.A. Stewart *in litt.* 1995). Anderson and Garlich-Miller (1994 *fide* Garlich-Miller 1994) estimated the annual catch in 1992-93 in Foxe Basin as 215.

Hunting loss: A dead walrus with no air trapped in its lungs has a negative buoyancy. Consequently it easily sinks if it has not been harpooned or otherwise anchored to a float. Because walruses usually are not harpooned before being shot nowadays (except during the thin ice hunt in Avanersuaq, NW Greenland; see section Regulations), losses during walrus hunting are sometimes substantial.

Beaubier (1970) sampled the walrus hunt at Igloolik in 1968-69 and recorded that of 19 walruses shot, 3 were "wounded" and lost, while 3 more were "sunk" and lost. These data suggest a loss rate of 16-32%. During hunts observed at Igloolik in 1982-84, 40 out of 124 walruses shot were lost (32%; Orr *et al.*1986).

Catch composition: The sample of the catch at Igloolik examined by Orr *et al.* (1986) in 1982-84 consisted of 33% females.

2. Southern and Eastern Hudson Bay

Distribution and Stock Identity

Summer and winter distributions of walruses in southern and eastern Hudson Bay are shown in Figs 8-9, respectively. Places mentioned in the text and locations of uglit are shown in Fig. 12.

Walruses formerly hauled out on the Paint

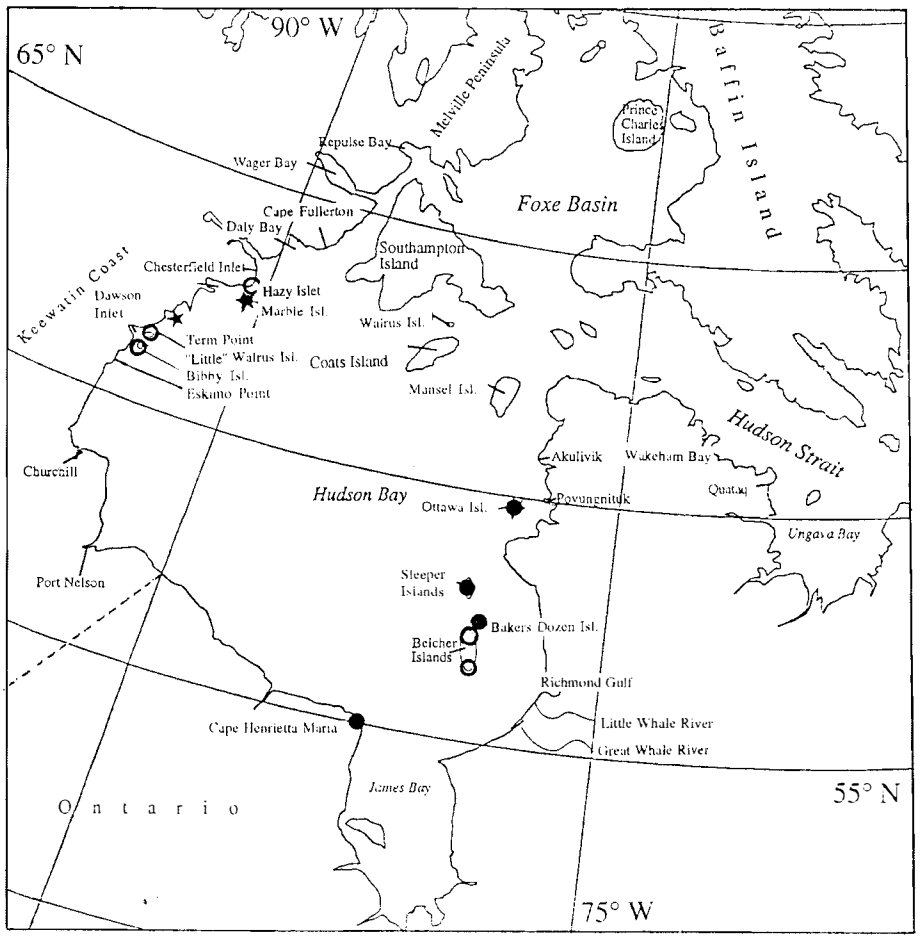

Fig. 12. Locations of terrestrial haul-outs (uglit) in southern, eastern and northwestern Hudson Bay. Legend: Black dots = haul-outs still known or believed to be used by walruses. Open circles = historical haul-outs; present status unknown. Stars = Abandoned haul-outs.

Islands in eastern James Bay but are now essentially absent south of about 57°N along the east coast of Hudson Bay (the Belcher Islands; Tremblay 1921:177).

We have found little evidence that walruses approached the mainland coast of eastern Hudson Bay (the Eastmain), although late 19th and early 20th century trade records occasionally refer to walrus catches or products in connection with Little Whale River, Richmond Gulf and Great Whale River (Francis and Morantz 1983:148, HBC Archives). Already by 1847 the mainland Inuit were said to travel to the "Sea Horse Islands" (Belcher Islands) to hunt walruses (Francis and Morantz 1983:142). Preble (1902) cited a report from 1879 indicating that walruses had formerly been seen "occasionally" as far south along the mainland coast as Little Whale River. They apparently have not been hunted by the Inuit south of Great Whale River in recent times (*cf.* Schwartz 1976).

Walruses were still plentiful on various islands off the Eastmain coast during the late 19th century (Bell 1885:14, Wakeham 1898:73) and probably until well into the 20th century. As elsewhere, in northeastern Hudson Bay walrus meat, blubber and skin were important sources of winter dog food. Thus much of the hunting by Inuit, trading companies, and police detachments was driven mainly by the need to secure their annual supply of dog food (*e.g.* May 1942). Loughrey (1959) speculated that the relocation of Inuit from the Sleeper Islands to the Québec mainland in 1954 could have had a beneficial effect on the walruses around the Sleepers.

Walruses were still sufficiently common at the Belcher Islands in the 1940s and 1950s for the Inuit from Port Harrison (Inukjuak) to come there (as well as to the Sleeper Islands) for walrus hunting (Manning 1946, Evans 1958). The main hunting areas were near the North Belcher Islands, south and east of Split Island, the south coast of Johnson Island, south of Kugong and Flaherty islands, and the Sleeper Islands (Twomey 1939, Twomey and Herrick 1942, Evans 1958, Schwartz 1976). At the Belcher Islands, the availability of walruses had become substantially reduced by the late 1950s/ early 1960s, and their importance in the local subsistence economy had become "almost negligible" (Freeman 1964:62). This change in availability was attributed by Freeman (1964) to a shift in walrus distribution: "It appears that very recently the herds shifted their location and now occur in the extreme southwest of the archipelago in the fall only. They are no longer found at other seasons on the Islands,

apart from the time they are migrating along the western coast en route to the southwestern hauling-out sites". According to Schwartz (1976) the hunting areas were reduced by the early 1970s "because some walruses have reinhabited the Sleeper Islands [?], and because people have moved to Sanikiluaq." The Belcher Islanders still hunted walruses in a small area at the southeastern extremity of Churchill Sound and another at the southern extremity of Robinson Bay, as well as at the north end of Moore Island, around the King George Islands, and most importantly at the southern and northern ends of the Sleeper Islands (Schwartz 1976, Freeman 1982).

The statement by Manning (1976), that Belcher Island hunters had to consider going to the Sleeper Islands for walruses because of a decline in local availability, was contradicted by Riewe (1992:161), who stated: "Good populations of walrus occur around the Belcher Islands and Bakers Dozen Islands [NE of the Belchers]. Frequent walrus haulouts occur on Bakers Dozen Islands." Riewe (1992:47) mapped walrus sites in the northern Belchers off northern Kugong, Flaherty, and Tukarak islands, in the northern and southern Bakers Dozen Islands, and at the King George and Sleeper islands. He also indicated that walruses were "particularly common" in the southern Belchers at the southeastern extremities of Churchill Sound and Robertson Bay (pp. 93, 203). The time scale of Riewe's (1992) observations is uncertain.

Walruses were traditionally hunted at the Ottawa Islands in the northeastern corner of Hudson Bay. Special expeditions were made in late summer or autumn (late August through October) from Povungnetuk and Port Harrison on the mainland (May 1942, Evans 1958:23).

Most walrus hunting at the offshore islands apparently was conducted in summer and autumn. Walruses of both sexes and various ages, including mothers with dependent calves, were present on the islands at this time (*e.g.* Twomey and Herrick 1942:334).

We have found no evidence to contradict Loughrey's (1959) speculation that the walruses occurring in summer and autumn on the chain of islands in eastern Hudson Bay overwinter in nearby leads and are thus basically non-migratory. It is reasonable to regard them, tentatively, as comprising a separate stock for management. We regard the walruses formerly found to the north of the Ottawas – at Digges and Mansel islands – as being part of a wider northern Hudson Bay-Hudson Strait population. The evidence for a separation of stocks in northeastern Hudson Bay is, however, not strong.

A few hundred walruses haul out in summer and fall on shoals off Brant River, Ontario, near Cape Henrietta Maria in southern Hudson Bay (Preble 1902, Loughrey 1959, Richard and Campbell 1988). This group of animals apparently includes females and young. Their stock affinities are entirely unknown. Mansfield (1958) considered them to be associated with eastern Hudson Bay (see above), while Loughrey (1959) mentioned them in connection with the population in western Hudson Bay. The group of walruses which occur near Cape Henrietta Maria may winter in the vicinity of the Belcher Islands and thus mix with the eastern Hudson Bay population (*cf.* Mansfield 1958).

Population Size

Virtually nothing is known about historical or current sizes of walrus populations in this area. Richard and Campbell (1988) assigned the number "100?" to the area. Twomey and Herrick (1942:334) estimated that the herd they observed and hunted at the northern Sleeper Islands in the late 1930s had at least 400 individuals (at least 50 are pictured in a scene at one ugli – Twomey 1939, Twomey and Herrick 1942). Manning (1976) reported seeing about 75 walruses hauled out on the Sleeper Islands and another 25 on Kidney Island, about halfway between the Sleeper and King George islands, in early August 1971.

The highest count of the Cape Henrietta Maria group was 310 walruses in October 1978 (from photographs taken during a goose survey; K.F. Abraham, Ontario Department of Natural Resources, *in litt.* to P. Richard 1985; N. Wilson, DNR, pers. comm. 1995).

Exploitation

Hunting methods: The hunt at the Sleeper Islands in the late 1930s described by Twomey (1939) and Twomey and Herrick (1942) involved the shooting and harpooning of animals in the water, from aboard an engine-powered boat. Although the Twomey expedition was mainly to obtain museum specimens, local Inuit and their equipment were used for the hunt. Another powered vessel from Port Harrison on the mainland, manned by an Inuit crew, was hunting at the same time in the same area using the same methods. Hunters at least occasionally went ashore on the offshore islands and stalked the walruses, shooting them at close range on shore (May 1942). The group of Inuit from Povungnetuk with whom May hunted apparently harpooned swimming walruses before shooting them.

Kayak, floe-edge, and on-land hunting of walruses at the Belcher Islands was described by Freeman (1964).

Catch levels: Information on historical catch levels is sketchy. As noted previously, no systematic compilation of walrus catch data has been attempted. For such a compilation, it would often be necessary to estimate catches from production data, including boatloads of walrus products, pounds of hide or ivory, gallons of oil etc. A Peterhead boat, fully loaded, could have on board the products (meat, hides, and tusks) of up to 32 walruses (Russell 1966:6 reported 65 walruses in two boats). A boatload of walruses obtained at the Sleeper Islands in 1939 included the remains of at least 23 walruses (Twomey and Herrick 1942:328). Freeman (1970:163) estimated that the hold of a Peterhead could carry the remains of about 20 adult walruses, while a whaleboat could carry only three or four. Mansfield (1966) gave 15 walruses as a full load for a Peterhead.

May (1942) reported securing a full boatload of meat during an autumn walrus hunt at the Ottawa Islands in 1939, suggesting a catch of perhaps 15-25 animals (May's account documents the capture of at least five). Such hunts were a regular feature of life at the trading posts in northwestern Québec, so it can be assumed that similar kills were made in most years.

Evans (1958:23-24) estimated annual catches during the 1950s as 20 at the Ottawa Islands, 20 at the Sleepers, and 30 at the Belchers for a total of about 70 from the region. This compares with the estimate of 60-80 given by Loughrey (1959:see p. 78 and appendix II) for this area. [Note that the figure of 169 per year cited from Loughrey by Reeves (1978), for "western Québec", includes the catches from settlements that hunt mainly in western Hudson Strait (Wakeham Bay, Sugluk, and Ivujivik).] Expeditions in August-September 1953 (3 from Povungnetuk and 3 from Port Harrison) accounted for 24 walruses at the Ottawas and 22 at the Sleepers (RCMP game report from Port Harrison 1953).

By the end of the 1950s the catch at the Belcher Islands had greatly declined (3 in fall 1959, 4 in fall 1960; Freeman 1964). The annual catch at the Belcher Islands was reported to be about 10 in the early 1970s (Reeves 1978), and it appears to have declined to about 5 since then (Richard and Campbell 1988; R.E.A. Stewart *in litt.* 1995). The combined average annual catch at Akulivik, Povungnetuk, and Inukjuak in the latter period was 35 (range 0-65) (Richard and Campbell 1988). The catch statistics for these areas are, however, of poor reliability (R.E.A. Stewart pers. comm. 1995).

Estimated annual landed catches of walruses during the mid 1970s are as follows (NHRC 1976): Great Whale 1, Inukjuak 6 and Akulivik 14. Data were not available for Povungnetuk and Ivujivik where the catches were probably greater.

Hunting loss: We have no recent information on hunting loss in these areas. Evans (1958:23) described walrus hunting in northern Québec as "extremely inefficient," with as many as two thirds of the shot animals sinking [also see Tremblay 1921:178].

Catch composition: We have been unable to locate any recent information on the catch composition for this area.

3. Northern Hudson Bay – Hudson Strait – Southeast Baffin Island – Northern Labrador

Distribution and Stock Identity

Summer and winter distributions of walruses in these areas are shown in Figs 8-9, respectively. Places mentioned in the text and locations of uglit are shown in Figs. 10, 12, 16 and 17.We describe the situation for Stock 3 going from west to east.

Keewatin coast: Along the west coast of Hudson Bay (Keewatin) walruses apparently have always been scarce south of Dawson Inlet. Only a few stragglers occurred as far south as Churchill (Preble 1902). For this reason it seems unlikely that there is (or perhaps has ever been) regular exchange with the eastern Hudson Bay population via a southern route. On the other hand, it seems likely that the groups of walruses along the west coast of Hudson Bay northward from Dawson Inlet would be continuous with the walruses of northern Hudson Bay (and possibly with those in at least southern Foxe Basin and western Hudson Strait as well).

Walruses were formerly common on Bibby Island, Term Point, "Little" Walrus Island, and Marble Island (Preble 1902, Loughrey 1959). They were formerly hunted during winter and spring along the floe edge of the Keewatin coast to the north of Dawson Inlet (Welland 1976). In summer they were hunted in the Rankin Inlet area and among the coastal islands, particularly "Little" Walrus Island, and occasionally as far south as Eskimo Point (Welland 1976:86). Farther north, they were hunted at uglit from Cape Jones in the south to just south of Karmarvik Harbour in the north, and in the Bury Cove area. Hunters were said to venture as much as 30 miles offshore in open boats to hunt walruses in this area (Welland

1976:88). Welland (1976:104,110) noted that walruses were formerly hunted from Bibby Island in the south to Baker Foreland and Cape Fullerton in the north, and seaward to a distance of 10 miles from Marble Island. Although they were scarce by the 1970s south of Chesterfield Inlet, they were still said to be common in the Daly Bay area (*Ibid.*:110). Hunting records reported in Ross (1984) demonstrate that walruses wintered near shore around the southern entrance of Roes Welcome Sound. They were also present in the sound, as well as in Wager Bay, in summer (Welland 1976:90).

According to Welland (1976:102) walruses have become "very scarce" in areas along the southern Keewatin coast, *e.g.* among the islands east of Bibby Island where they were formerly common (also see Loughrey 1959). People from the Rankin Inlet area must now travel in large boats to Roes Welcome Sound or to Walrus Island near Southampton Island to get walruses (Welland 1976:104).

Hazy Islet near Rankin Inlet (ca. 62°50'N) and "Little" Walrus and Bibby islands may still be used by a small number of walruses (Riewe 1992:63,81,175,191), but there is no evidence of significant numbers farther south along the Keewatin coast. Riewe (1992:145,256) indicated that a "small population" is present year-round between Eskimo Point and Wager Bay.

Northern Hudson Bay and western Hudson Strait: The area around Southampton Island has always had large numbers of walruses (Tremblay 1921:338, Mansfield 1958, Loughrey 1959). Major uglit were (and still are) on Coats, Bencas and Walrus (Akpatorardjuk; in Fisher Strait) islands and at Seahorse Point on the east coast of Southampton Island (Mansfield 1958, Freeman 1970, Riewe 1992). Other uglit were on the north side of Southampton Island, in Frozen Strait, and near the entrance of Lyon Inlet (Mansfield 1958:figure 1). Walruses were available in winter at the floe edge near Native Point and were hunted in winter at the floe edge in Smith, Native and Duke of York bays and between Hut Point and Cape Low (Welland 1976:95,112). Large numbers have been reported at the floe edge off Ruin Point and in South Bay, and groups of less than 100 are commonly observed in winter between Leyson and Hut points (Orr and Rebizant 1987). In spring and early summer walruses were hunted from Native Point to Ruin Point, in the Duke of York Bay area and along the coast of Bell Peninsula as far north as Terror and Gore points, as well as on Walrus, Bencas and Coats islands (Welland 1976:96,112). Walruses were also present in the water all the way across the channel between Southampton and Coats islands and in Duke of York Bay (*Ibid.*). Spring concentrations have been reported in recent years (mid 1980s) at the floe edge near Renny Point and at break-up near Leyson Point (Orr and Rebizant 1987). The recent summer and fall distribution was, according to Orr and Rebizant (1987), among the floating pack ice in Evans Strait, near the islands, along the coast of

Southampton Island from Seahorse Point to Ruin Point, and in Duke of York Bay.

Brice-Bennett (1976) gave the following detailed information on where walruses were hunted by Repulse Bay Inuit (who, incidentally, were not known as major walrus hunters): Walruses were hunted at the spring floe edge and in open water off the west coast of Vansittart Island to Gore Bay, in Hurd Channel, Repulse Bay and the southwestern part of Roes Welcome Sound, off the south coast of Opposite Island, around the Sturges Islands, in Duke of York Bay and around the Savage Islands at the mouth of Wager Bay. They were "most intensively hunted" (pre-1962) around the Sturges Islands, Bluhme, October and Bushnan islands in Frozen Strait, and the Harbour Islands and Ubliardjuk area near Gibson Cove in Repulse Bay, and along the southwest coast of Roes Welcome Sound in the Ublialuk area north of Bury Cove. After 1962 most walruses were apparently taken around the Harbour Islands and near Gibson Cove in Repulse Bay (Brice-Bennett 1976:66).

To determine movement patterns and stock identity, tagging studies were conducted in the summers of 1954, 1955 and 1956 at Bencas, Coats and Southampton islands (Mansfield 1955, 1958, Loughrey 1959). However, these studies provided little information on movements. Of a total of 115 (Mansfield 1958) and 32 (Loughrey 1959) walruses tagged with harpoon-head tags (Figs 14-15), only three were recovered during the fall of 1954. The tag-recoveries revealed only local movements in the Southampton – Bencas islands area (Loughrey 1959).

The distribution of walruses in the northern Hudson Bay-western Hudson Strait region apparently has changed little during the past half-century. Donaldson (1988) claimed that the Baffin Island harvesting study of the 1980s led to discovery of "a previously unknown wintering area for walrus," by virtue of the relatively high catches at Cape Dorset during February-April. Walruses are believed to drift eastward on the ice from south-eastern Southampton Island during late summer and fall, passing Cape Dorset and dispersing into Hudson Strait where many overwinter (Riewe 1992: 198). They are also found along the floe edge of southern Foxe Peninsula throughout the winter.

Although walruses formerly occurred in East Bay, their continued use of this area has not been confirmed by recent surveys (Riewe 1992:243). In addition to the former hunting areas described above, Welland (1976:112) stated that walruses were still found along the shores of Bell Peninsula north to Terror Point, all around Coats Island and in the straits between Southampton and Coats islands. Some walruses ("a small population") are still present in Roes Welcome Sound year-round (Riewe 1992:244). They also remain year-round in Frozen Strait, hauling out on ice pans or rocky shores in summer and keeping in leads through the winter (Riewe 1992:244).

Researchers studying seabirds in the region of Digges Sound during 1979-82 (Gaston *et al.* 1985) observed no walruses (or even old walrus bones) on or near Digges Island; they were told by residents of Ivujivik that walruses are never seen there today (A.E. Gaston *in litt.* 1985), yet Roy (1971) indicated that walruses were hunted occasionally around

Fig. 15. A walrus being tagged off Seahorse Point (eastern Southhampton Island, Hudson Bay) in 1954. Photo: H. Norden-Andersen.

Digges Island and along the mainland coast in summer and fall as well as along the east coast of Mansel Island and among the Imiliit Islands in fall. Bell (1885:33) had found walruses "numerous" at Digges Island during late summer.

Historically walruses were always abundant and widespread in northern Hudson Bay and western Hudson Strait. Particular areas were noted as reliable sites for finding them at specific times. Mansfield (1958) suggested that there was a gap in walrus distribution along the north side of Hudson Strait, from about Amadjuak to the Middle Savage Islands.

Along the north shore of Hudson Strait walruses were fairly common off Amadjuak Bay at any season as long as the ice conditions were right (Soper 1928:48) as well as in Andrew Gordon Bay and Chorkbak Inlet (Soper 1944). They were even more common, however, at Mill and Salisbury islands and off King Charles Cape (Gordon 1885: 301, Soper 1928:48). The most reliable site for walruses near Salisbury Island was said to be 25-30 km east of the Island, "where a reef runs east and west, with part of it a rock about 400 yards long by 250 wide, called Nooshwetuk" (Russell 1966:4).

Walruses usually arrived at Nottingham Island on the ice in late August (Manning 1944:148), and this island, along with Salisbury Island, was a favorite hunting ground for communities in southwestern Baffin Island and northwestern Québec. Occasionally the animals were caught on land, but most of the hunting was done on the ice or in the water (Manning 1944:144). Bell (1885:30) reported seeing only a few walruses near Nottingham Island but many in the ice south of it on 20 September.

The walruses at Nottingham Island have continued to be relatively intensively exploited in recent years. People from Ivujivik carry out an annual walrus hunt there (Roy 1971), and people from Cape Dorset, Sugluk, Wakeham Bay and possibly Koartak also hunt them there (A.J. Gaston, *in litt.* 1985). In general it seems fair to conclude that the necessity of making long, costly trips to offshore islands for walruses demonstrates the unavailability of these animals along mainland shores. This is apparently the situation on both the north and south shores of western Hudson Strait today.

Orr and Rebizant (1987) reported that walruses were present in winter all along the floe edge near Foxe Peninsula, from Cape Dorchester to Chamberlain Island, with concentrations around Cape Dorchester and the offshore islands. The main seasonal change in distribution is apparently that walruses become less common in the vicinity of Cape Dorset during summer and fall, when they are particularly abundant along the west coast of Foxe Peninsula from Lloyd Point to the islands north of Cape Dorchester, as well as around the south, west, and north coasts of Salisbury Island and the southeast coast of Nottingham Island.

Ungava Bay, central and eastern Hudson Strait: Much information about the occurrence of walruses in the Ungava Bay – Hudson Strait – eastern Baffin Island – Labrador region was summarized by Loughrey (1959), Reeves (1978), Davis *et al.* (1980) and Richard and Campbell (1988). Few studies focusing on walruses have been carried out in this large area. Land use studies during the 1970s (Freeman 1976) and 1980s to early 1990s (Anon. 1981-87, Riewe 1992) have provided traditional knowledge and incorporated much of the survey data from consulting companies and government scientists. Systematic aerial surveys of marine mammals were conducted during the late 1970s and early 1980s in late winter (McLaren and Davis 1982) and in summer and fall (MacLaren Atlantic Ltd. 1978, MacLaren-Marex 1979, 1980a, 1980b) in Hudson Strait and Ungava Bay, along the southeast coast of Baffin Island and off northern Labrador. These surveys provided useful information on the recent distribution and relative abundance of walruses.

There is ample evidence that walruses were formerly common in parts of Ungava Bay, including Akpatok Island (winter: Elton 1942; summer: HBC Archives, see below) and the Gyrfalcon Islands (summer: Dunbar 1955). Except possibly at the Gyrfalcon Islands they have apparently always been rare in southern Ungava Bay (Mansfield 1959). Human communities living along the shores of Ungava Bay made annual walrus hunts at the offshore islands, especially Akpatok in June-September (HBC Archives, post journals from Diana Bay, Payne Bay, Leaf River, and Fort Chimo). Loughrey (1959) and Currie (1968) provided detailed speculations about walrus movements in Ungava Bay based on information obtained from local Inuit and long-time white residents of the area. It was suggested that walruses arrived at Akpatok from the east in late June and July, then swam westward or northwestward in late July and August. They supposedly passed Cape Hopes Advance and dispersed into Hudson Strait during August. Although Loughrey (1959) considered most of the

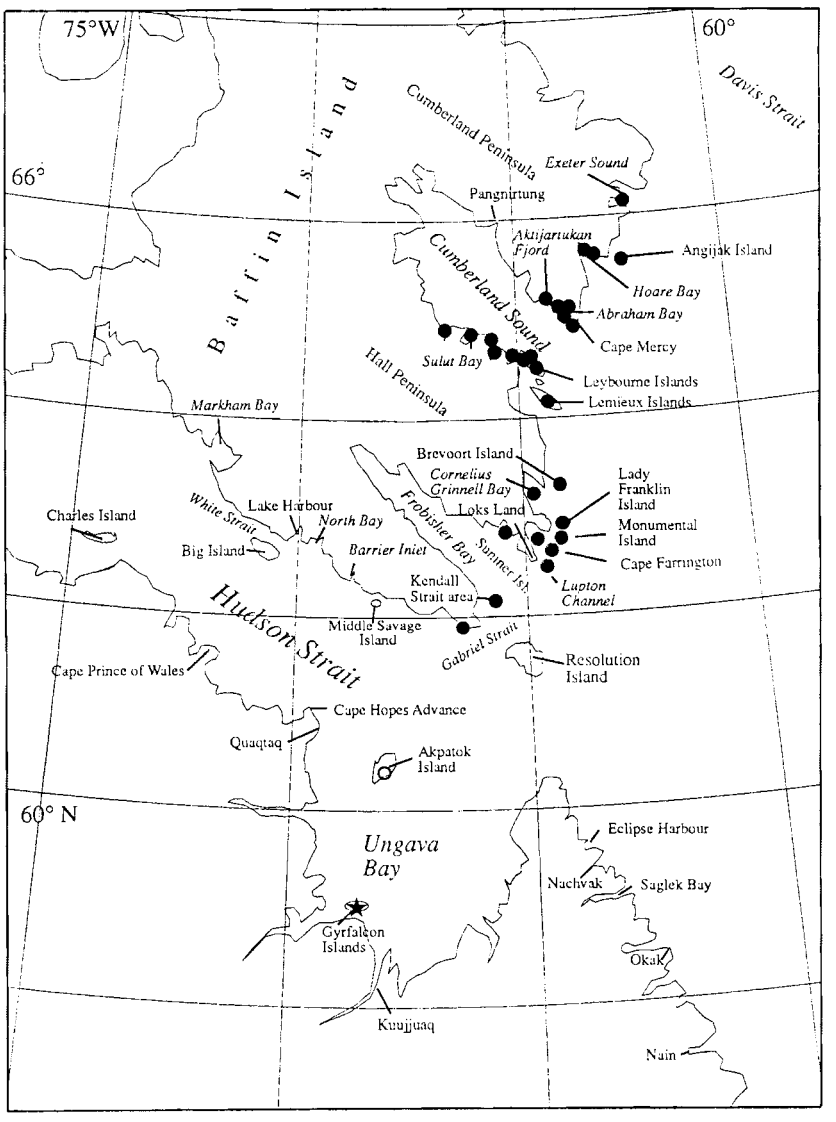

Fig. 16. Locations of terrestrial haul-outs (uglit) on southeastern Baffin Island (see also Fig. 10) and in Ungava Bay. Legend: Black dots = haul-outs still known or believed to be used by walruses. Open circles = historical haul-outs; present status unknown. Stars = Abandoned haul-outs.

eastward movement of walruses in autumn to be along the north shore of Hudson Strait, Currie (1968) referred to a southeasterly migration past Cape Hopes Advance in September-October, well offshore.

The historical distribution and movements of walruses along the south coast of Hudson Strait are poorly known. Bell (1885:27-28) was told by Inuit living at Cape Prince of Wales that it was a good site for walrus hunting "at most seasons of the year". He observed walruses there and in Ashe Inlet in mid August and was told that Ashe Inlet was also a good place for walrus hunting in winter (Bell 1885:25). Walruses were observed and hunted year-round in Stuparts Bay and Fisher Bay during the 1910s and 1920s, but by the 1930s the hunting from the Stuparts Bay HBC post seems to have been done mainly in late summer and fall at Nottingham Island (HBC Archives).

In the northeastern part of Hudson Strait, walruses were said to frequent Gabriel Strait from November to May but to be present between Gabriel Strait and Lake Harbour for only a short period during winter (Public Archives of Canada, RG85, Vol. 1045, file 540-3, part 3-C). In at least some years small groups were present off Pritzler Harbour through the winter. A small group of walruses was said to occur around the Middle Savage Islands between Resolution and Big islands, mainly from October until May (Mansfield 1958, Higgins 1968:150). Higgins believed that this group was separate from the walruses at Resolution Island and Loks Land at the entrance of Frobisher Bay. Rather, he believed that these walruses occasionally drifted on ice westward to North Bay, near Lake Harbour.

Inuit knowledge, as summarized by Kemp (1976), identified two sites in the Lake Harbour region as especially good for walrus hunting: 1) a narrow zone from Pritzler Harbour to Shaftesbury Inlet, especially in Pritzler Harbour and Observation Cove; and 2) at East Bluff on the southern tip of Meta Incognita Peninsula. Walruses were also hunted along the floe edge of Juet Island and at Fair Ness. They were also said to occupy uglit in North Bay and White Strait during summer and to be present in North Bay in winter (Kemp 1976).

The present distribution mapped by Riewe (1992:91,129) off southern Baffin Island is approximately as described by Kemp (1976) and others, with the suggestion that walruses migrate east and west along the south coast of Baffin Island. His descriptions of the current range (pp. 202-203, 237) indicate that they occur "in large numbers" around the Middle Savage Islands in spring and late fall, winter along the floe edge and throughout the offshore pack ice of Hudson Strait and in North Bay and White Strait, and occasionally enter Markham Bay in late summer after break-up. Riewe also refers to an ugli on Spicer Island, and to the fact that walruses occasionally drift westward on ice from the Middle Savage Islands to North Bay during winter.

Aerial surveys in March 1981 showed that walruses winter in Hudson Strait and Ungava Bay (McLaren and Davis 1982). The sightings reported by MacLaren-Atlantic (1978), MacLaren-Marex (1979), and McLaren and Davis (1982) indicate that walruses are still present at Akpatok Island and elsewhere in central and eastern Hudson Strait.

The almost complete lack of observations of walruses by Finley *et al.*(1982) during a shore-based survey of belugas, mid October to early December 1980, at Cape Hopes Advance (one eastbound walrus sighted on 3 December) is consistent with the widely held view that the eastward fall migration of walruses through Hudson Strait (assuming that it occurs) is either well offshore or along the north side of the strait.

Mansfield (1990) noted the absence of any recent information, other than that from the aerial surveys mentioned above, on the distribution of walruses in Hudson Strait and Ungava Bay.

Generally, information about migration and relationships among groups of walruses in these areas is difficult to interpret, and sometimes seems contradictory. Aerial surveys in March showed that walruses winter in Hudson Strait and Ungava Bay (McLaren and Davis 1982), which is consistent with Inuit knowledge and historical information. Inuit at Cape Dorset observe walruses during winter along the south coast of Foxe Peninsula, between Nottingham and Salisbury islands and at Chamberlain Island in western Hudson Strait (Orr and Rebizant 1987). According to Elton (1942) walruses wintered in Ungava Bay near Akpatok Island. Although walruses winter in Hudson Strait there apparently is also an eastward migration out of Hudson Strait in fall. This outmigration in October may be two pronged, with some groups moving south along the northern Labrador coast and others (probably the greater proportion) following the coast of Baffin Island (Loughrey 1959) and perhaps dispersing offshore. Walruses were seen off the northern tip of Labrador during aerial surveys in March (McLaren and Davis 1982). Local people of Labrador were of the opinion that the Akpatok Island summer population winters along north-eastern Labrador (Anon. 1978).

Apparently walruses in these areas winter in

small groups in cracks and leads among the ice, in the shore lead along southeastern Baffin Island, and in polynyas off northern Labrador, at the entrance to Frobisher Bay and off Hall Peninsula (and possibly Cumberland Peninsula).

Southeastern and eastern Baffin Island: Historically, walruses apparently occurred along the entire east coast of Baffin Island (Freuchen 1921, Vibe 1950, Loughrey 1959). This is also indicated by the location of walruses killed by British whalers along the east coast of Baffin Island. However, citing Inuit informants from the Pond Inlet area, Bisset (1968) stated that walruses very infrequently occurred along the northeast coast of Baffin Island between Cape Macculloch and Clyde Inlet. The current near-absence of walruses along this stretch of coast was confirmed during aerial surveys in both 1978 and 1979 and during coastal watches in the fall of 1978 (Koski and Davis 1979, Koski 1980).

Kills made by British whalers indicated that walruses were especially numerous in inshore areas in September and October in the Cape Searle-Home Bay area (Ross and MacIver 1982). Freuchen (1935) and Loughrey (1959) mentioned Clyde Inlet as an important haul-out area. Padloping Island had an important ugli. Hjort and Ruud (1929) observed "great numbers" of walruses in Exeter Sound on 24 July 1924.

The coastal areas to the north and south of the mouth of Cumberland Sound, Nuvuk Point to Cape Mercy and the Leybourne Islands to Abraham Bay, respectively, are important areas for walruses today (Schledermann 1975:27, Stevenson 1993). Kumlien (1879:63) reported that walruses had been much more common in the upper parts of the sound in the past. Judging by catch records of commercial whalers, the areas around Kekerton and Blacklead islands also had good numbers of walruses in the second half of the 19th century and early in the 20th. Although walruses have been mapped as occurring off and southeast of Bon Accord and in Kingnait Fiord, upper Cumberland Sound (Anon. 1981-87), they are no longer common in Cumberland Sound north of Nuvuk Point (Anders 1967); only occasional individuals are encountered towards the head of the sound, *e.g.* off Nettilling Fiord (Schledermann 1975:27, Stevenson 1993).

A hunter from Pangnirtung reported that walruses still occur all around Cape Mercy and westwards to Kingnait Fiord and northwards to Angijak Island (A. Papatsie pers. comm. 1995). Five uglit are still used by walruses in the Cumberland Sound area: 1) just west of the mouth of Ujuktuk Fiord, 2) on an island in Ujuktuk Fiord, 3) on an island between Angijak Island and Ingnit Fiord (north of Hoare Bay), 4) on a little island west of Kekertuk Island and near the mainland in the mouth of Exaluin Fiord, Hoare Bay, and 5) on an island on the east side of the mouth of Tonak Fiord, Hoare Bay (A. Papatsie, *op cit.*). The same hunter indicated that two uglit in this region were no longer used by walruses: one on Miliakdjuin Island (allegedly abandoned after 1947 because of disturbance by motorboats) and the other on a little island off Kekertukdjuak in the mouth of Kingnait Fiord. Walruses are said to winter in parts of Abraham Bay and to move into Ujuktuk Fiord with spring break-up. Those in the Hoare Bay area are said to winter off the coast between Muingmak and Angijak islands and to begin moving into the fiords in spring (A. Papatsie, *op cit.*).

Walruses are present throughout the Lemieux Islands from August to November, and perhaps year-round (Anon. 1981-87). The mouth of Winton Bay in outer Robinson Sound is an important walrus site (Anon. 1981-87). Walruses were hunted during the period 1928-62 along the south shore of Cumberland Sound, from near Iglootalik and all the way to the Leybourne Islands (Kemp 1976:138). Kipisa and Utusivik have been mapped as areas where Inuit from Pangnirtung go for walruses in this area (Anon. 1981-87). The general pattern was for the walruses to move close to shore in spring and summer and out into Cumberland Sound in winter (Kemp 1976:138). Some overwinter in outer Cumberland Sound (Anon. 1981-87). Hundreds of walruses are said to haul out at Cape Mercy, and there is another ugli on an island at the mouth of Ujuktuk Fiord (in Abraham Bay) (Anders 1967, Anon. 1981-87). The Leybourne Islands and Sulut Bay have been mapped as good walrus areas (Anders 1967, Anon. 1981-87). On the opposite side of Cumberland Sound, during the period 1928-82, walruses were hunted from the mouth of Kingnait Fiord all the way to Cape Mercy, with hunting especially good in Abraham Bay, Ujuktuk Fiord and the mouth of Aktijartukan Fiord (Kemp 1976). Along the east coast of Cumberland Peninsula they were hunted during summer in Hoare Bay and north to Clephane Bay and Exeter Sound (*Ibid.*). From 1962 to 1974 walruses were hunted in southern Cumberland Sound mainly near Kipisa, Utusivik, the mouth of Salut Bay and among the Leybourne Islands; along the eastern sound from the mouth of Iqalujuak Fiord to Kumlien Fiord and Wareham Island; and south of there from the mouth of Aktijartukan Fiord and near Kekertaluk Island in Hoare Bay (Kemp 1976:142). Broughton Island hunters hunted walruses during 1927-55 mainly in

the Alexander Bay area of Home Bay, northwest of Kekertaluk Island, in the mouth of Okoa Bay and the Nedlukseak Island area, between the northwestern headland of Kivitoo Peninsula and Nedlukseak Island, and among the islands in the southwest part of Kivitoo Bay (Kemp 1976:143). Important summer and fall walrus hunting sites were the southeast corner of Broughton Island, the islands directly south of Broughton Island, Duck and Padloping Islands, Cape Searle and Durban Island in Merchants Bay, as well as in a narrow zone southward from Cape Durban to Cape Dyer. Less important hunting areas were in the Totnes Road part of Exeter Sound, throughout Kairolik Fiord, near Kekertuk Island and in Hoare Bay (Kemp 1976:143).

Walruses are said to have become "much less plentiful" in the Padloping area during the late 1950s and early 1960s but to have increased in numbers there during the late 1960s and early 1970s (Kemp 1976:144). They were hunted during this latter period around Durban and Padloping islands, Cape Searle and occasionally just west of the islands in Canso Channel, near the southeastern corner of Broughton Island, and off the south shore of Kivitoo (*Ibid.*). In some years they were also taken around Nedlukseak Island and Brodie Bay, just north of Kekertaluk Island, in Nudlung Fiord and around some of the smaller islands in northwestern Home Bay (*Ibid.*).

Frobisher Bay was traditionally an important walrus hunting area. Besides hunting walruses intensively in the mouth of Hudson Strait (from the Middle Savage Islands southeast along the coast of the Meta Incognita Peninsula to the vicinity of Nanuk Harbour), the Inuit from this area also hunted them during 1925-55 in Ward Inlet and just south of Fletcher Island, both areas towards the head of Frobisher Bay, in a large area from Hamlen Bay, south along the east coast of Frobisher Bay, around Loks Land, and north to Beekman Peninsula, terminating at Cape St. David (Kemp 1976:134). Although walrus hunting remained intensive after 1955 in Hamlen Bay, Lupton Channel, and along Beekman Peninsula, the decline of dog teams during the 1960s and early 1970s made this activity less important. By the early 1970s most of the walrus hunting by the people of Frobisher Bay was limited mainly to areas along the east and west coasts of Blunt Peninsula, including Cyrus Field Bay (Kemp 1976:136). Records of the Hudson's Bay Company post in upper Frobisher Bay during the late 1920s to late 1930s indicate that walruses were hunted in summer and fall (July-November) as well as in winter (February-March) (HBC Archives, unpublished data).

A detailed report of a walrus hunt in September 1942 by the RCMP detachment at Lake Harbour (Public Archives of Canada, RG85, Vol. 1045, file 540-3, part 3-C) contains useful information on walrus distribution. The motorboat left Lake Harbour on 7 September and followed the coast east to Resolution Island, then north to Loks Land and finally Brevoort Island. Walruses were scarce when the vessel arrived (16 September) but began appearing from the north within several days. The total catch was 26 walruses, taken between 17 and 26 September at Brevoort Island, Loks Land, and in Robinson Sound. At least 8 animals were killed and lost due to poor weather. The meat, blubber, and skin were cached for dogfood on winter police patrols. All apparently were harpooned and killed in the water. A similar hunt in 1937 produced 21 walruses between 13 and 29 September in Jackman Sound (Frobisher Bay) and Cyrus Field Bay at Loks Land, and near the foot of the glacier on Grinnell Peninsula. RCMP records indicate that walruses were consistently "plentiful" in Cyrus Field Bay and Robinson Sound and along the coast from Robinson Sound to the Lemieux Islands during the 1930s and 1940s, especially in the autumn.

According to a local hunter, walruses are found today in spring at several sites along the west sides of Blunt Peninsula and Loks Land (E. Papatsie, pers. comm. 1995). In summer and fall they are present among islands off eastern Loks Land and in the mouth of Cyrus Field Bay (*Ibid.*). Land use maps call attention to many areas around the mouth of Frobisher Bay used by walruses (Anon. 1981-87, Riewe 1992). These essentially agree with previously published information, but there are some inconsistencies with the fine details. It is not possible to reconcile these inconsistencies here. Walruses may still occur during summer and fall in Ward Inlet, and there is a summer or fall ugli on some very small islands just southwest of Sumner Island (Riewe 1992).

According to Smith *et al.* (1979) walruses overwinter in the open areas of Frobisher Bay, where they are hunted along the floe edge in late winter and spring (Anon. 1981-87). During aerial surveys in March walruses were observed in this area, off Hall Peninsula and at northern Labrador(MacLaren-Marex 1979, McLaren and Davis 1982), and approximately 50 were seen along the floe edge just north of the western entrance of Chappell Inlet in January 1984 (Anon. 1981-87). Uglit on islands at the south end of Lupton Channel are occupied in autumn (*Ibid.*). Some of the walruses from these areas may move across Davis Strait to winter off central West Greenland at the edge of the Davis

Strait pack ice – the West Ice (Freuchen 1921, Dunbar 1956, Vibe 1967).

During aerial surveys walruses were observed in April and May at the entrance to Hudson Strait, and along the northern Labrador and Hall Peninsula coasts (MacLaren-Marex 1979). Between June and September, walruses occur along the outer coastline of southeastern Baffin Island, from Gabriel Strait north to Clyde Inlet (MacLaren Atlantic Ltd. 1978, MacLaren-Marex 1979, 1980a, 1980b, Smith *et al.*1979). They were observed in June at Akpatok Island in Ungava Bay (MacLaren Atlantic Ltd. 1978). During summer concentrations have been observed off Hall Peninsula, around Lady Franklin and Monumental islands (where they apparently feed), and near Brevoort Island and Cape Dyer (MacLaren- Marex 1980b). Walruses were present in the Loks Land and Lemieux Islands areas from early July. A large number of walruses, apparently coming from Hudson Strait, entered the Hall Peninsula area in mid-September (Smith *et al.*1979). Other terrestrial haul-out sites are found in the Lemieux Islands, on the west side of Brevoort Island, in Cyrus Field Bay, and in Hoare Bay (MacLaren Atlantic Ltd. 1978, MacLaren Marex 1979, 1980a, 1980b).

Uglit on eastern Baffin Island (see Figs 10 and 16): In the Hudson Strait-Ungava Bay area walruses are reported to have hauled out on Akpatok Island, the Eider Islands near Cape Hopes Advance, and several of the islands along the southern coast of Hudson Strait such as Wales, Weggs and Charles (Loughrey 1959). They were formerly found on islands near Sugluk, in Deception Bay and on Digges Island but apparently had been largely killed off at (or driven from?) these sites some time after 1909 (*Ibid.*). The most populated uglit in the Hudson Strait region are unquestionably those at Nottingham and Salisbury islands, which are discussed more fully under the section on Northern Hudson Bay and Western Hudson Strait.

In the early part of this century, the biggest ugli along the east Baffin coast may have been at Padlei, just south of Padloping Island (Mansfield 1958). Bethune (1934) mentioned a second-hand report that one company took over 4000 skins per year, but the catch locality (or localities), and the period or number of years involved, were not clearly stated. Mansfield (1958) and Reeves (1978) interpreted Bethune's text to mean that this very large number of walruses was taken annually at Padlei. However, without corroborating evidence of some kind, Bethune's statement, and the subsequent interpretations of it by other authors, need to be viewed with a degree of skepticism. Nevertheless it is certainly true that the Padloping Island area had a great many walruses at one time.

Recent information on uglit in the Padloping Island area and elsewhere along the east coast of Baffin Island is summarized in Figs 10 and 16. A relatively large number of sites are reported as still being used, at least sporadically by a few walruses. These are primarily on islands near the outer coasts of Hall and Cumberland peninsulas. Lady Franklin Island has one of the largest uglit at present.

Gulf of St. Lawrence and Nova Scotia: Walruses were historically abundant in Canadian east coast waters from Labrador south as far as Sable Island (approximately 43°N) and the Gulf of St. Lawrence (Fig. 17). It has been claimed, in fact, that the walrus herds on the Magdalen Islands, Gulf of St. Lawrence, represented "the greatest concentration of walruses in the world" before their discovery by Europeans in the 16th century (Bruemmer 1992). The crew of one ship reportedly killed 1500 walruses in one season at Sable Island in 1591, and kills of similar or greater magnitude were reported at the Magdalen Islands as recently as the 1770s (Allen 1880). Mowat (1984:304, 318) claimed that the Magdalen Islands had 100,000 walruses as late as the mid 18th century and that Sable Island had "at least that many". He referred to a catch of 25,000 walruses in one year (1760s), made from only three of the 11 uglit at the Magdalen Islands. Mowat is prone to exaggerate numbers and as a secondary source is not particularly reliable. Before trusting his account, it would be necessary to examine his primary sources, which we have not done. However regardless of whether Mowat's (and Bruemmer's) statements are literally true or not, the numbers of walruses in the Gulf of St. Lawrence and off the coast of Nova Scotia must have been very large, by any standard.

Walruses in southeastern Canada were said to haul out and give birth on islands between April and June (Allen 1880). Whether these large herds migrated over long distances, and whether their distribution was continuous northward along the Labrador coast, is uncertain. There is no evidence that walruses have begun to recolonize this part of their former range (Reeves 1978), and we accept the judgment of Richard and Campbell (1988) that the Atlantic walrus is now extinct in this part of its range.

Labrador: Walruses were formerly present along much of the Labrador coast and were regularly observed and hunted in winter and spring (mid February to June) to at least as far south as Okak Bay (Hawkes 1916:32, Hantzsch 1932, Taylor 1974, 1977, Taylor and Taylor 1977, Brice-Bennett 1977,

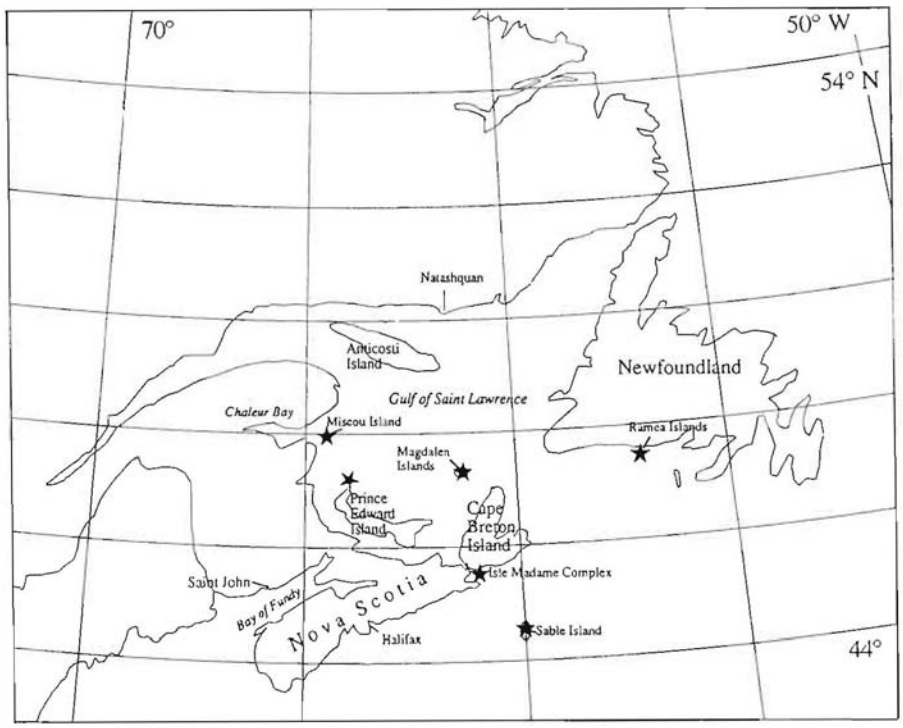

Fig. 17. Locations of abandoned terrestrial haul-outs (stars) in the Gulf of St.Lawrence and Nova Scotia region.

HBC Archives). The main hunting areas were in the northern Okak and Hebron districts (Brice-Bennett 1977:121). According to an archaeologist the traditional walrus hunting grounds were at the Galvano Islands and at Chance Rocks and Ashe Rocks off Mount Bache Point, both at the mouth of Eclipse Harbour (S. Loring, pers. comm.).

All accounts suggest that the animals were migratory and occurred off central Labrador only in winter and spring. It is not known how far south walruses migrated on the Labrador coast. Hawkes (1916:32) observed a large herd in heavy ice off Davis Inlet in 1914, and Freuchen (1935) claimed that females and young moved all the way south to Battle Harbour, near the Strait of Belle Isle. It appears, however, that by the 1920s and 1930s only stragglers reached as far south as Okak. Brice-Bennett (1977:173) concluded on the basis of interviews with Inuit elders that walruses had never been abundant as far south as Hopedale. Loughrey (1959) gave the normal southern limit as Hebron (= Nachvak). In February 1977 walruses were observed at 59°N, 62°W, about 50 km east of Saglek Bay (Anon. 1978).Although walruses were hunted "occasionally" near Port Burwell prior to 1960, they were no longer hunted there by the early 1970s (Val 1976).

Hunting methods: Taylor (1974:46) described the methods used for walrus hunting in the Okak area during the early 20th century. The animals were killed with harpoons and lances while hauled out on an ugli at the east end of the island Operngevik-soakh. They were also hunted at aglus (*i.e.* breathing holes in ice) by Inuit working cooperatively. Near Uvingayokh Island walruses were harpooned at the floe edge, sometimes by solitary or paired hunters. Kayak hunting of walruses occurred in the 19th century; for example the Inuit at Okak killed 10 walruses, apparently using this method, in spring 1844 (Taylor 1974:47).

Inuit in the area of Nachvak, Labrador, regularly hunted walruses during winter and spring in the early 1900s. HBC journals document catches of at least 11 walruses between 7 March and 5 May 1903, one in April 1904, two in February 1905, and eight between 26 February and 31 May 1906. Walrus hunting was clearly seasonal in this area, beginning in February and lasting into May most years (HBC Archives, unpubl. data).

Population Size

Western Hudson Bay: A report from the early 1930s at Chesterfield Inlet refers to at least 1500 walruses hauled out in early October on an unspecified island (Currie 1987:10). It is not clear which island is meant, and it could have been one of the large uglit in the Southampton – Coats Island area rather than along the west coast of Hudson Bay. As many as 40 walruses were seen at "Little" Walrus Island in late September 1956 (RCMP game report from Eskimo Point), and 400-500 were said to be present at Depot Island near the coast north of Chesterfield Inlet in spring 1961 (RCMP game report from Chesterfield).

We are not aware of any recent counts or estimates of walrus numbers from the Keewatin coast.

Northern Hudson Bay and western Hudson Strait: The Southampton Island area is one of the few in Canada where relatively intensive studies of walrus numbers have been attempted, beginning with the efforts of Mansfield (1958) and Loughrey (1959), followed most recently by those of Mansfield and St. Aubin (1991). Vessel surveys in 1953 and 1954 suggested a population of at least 3000 walruses on and around the major uglit at Southampton and Coats islands (Mansfield 1966). Aerial and boat surveys in 1961 resulted in an estimate for the population at Coats Island and Seahorse Point of 2650 walruses (Mansfield 1962), a figure close to the 3000 observed by Loughrey (1959) from an aerial survey in August 1954. These figures would not account, of course, for the walruses present elsewhere in the region at the time, including those in the water, on ice and at other uglit.

Aerial surveys of Fisher and Evans straits and the coasts of southeastern Southampton Island and Coats Island in 1976-77 (July-August) produced a maximal count of about 2400 animals (Mansfield and St. Aubin 1991). Miller (1982), whose purpose was to study behavior rather than to census walruses, counted more than 1500 hauled out on the northeast coast of Coats Island in early August 1978, and he counted about 500 at a different haul-out site (Cape Pembroke) on Coats Island at the end of July 1980 (Miller and Boness 1983). Numbers for the Southampton-Coats Island area summarized by Riewe (1992:244-45, 249) include: 29 in the entrance of Duke of York Bay and near Cape Deas in July 1982, 12 in the Peterson Bay area in August 1981, up to 1500 hauled out at Coats and Bencas islands in July and August 1981, as many as 2000 hauled out at Walrus and Bencas islands "in some years", and 2000 at Seahorse Point in 1954.

The number assigned to the southern Southampton-Coats Island area by Richard and Campbell (1988), "2350+", refers only to the animals counted during an aerial survey and is therefore negatively biased. Richard (1990) reported "total sightings" of about 1500 walruses during aerial surveys in both 1988 and 1989, indicating a "best estimate" that the population of walruses in northern Hudson Bay "may be as large as" 2600.

Richard and Campbell (1988) assigned numbers of "500-1000?" and "1000?" to the areas of western Hudson Strait and southwestern Foxe Basin, respectively. Their basis for these numbers was: 1) reported observations of about 200 walruses at Salisbury Island in fall of 1985 and 1986; 2) reports by hunters of seeing herds containing 500-1000+ walruses hauled out at Mill, Salisbury, and Nottingham islands in late summer and autumn (Orr and Rebizant 1987); and 3) other reports by hunters indicating that groups of 1000+ walruses had been seen in summer along the west coast of Foxe Peninsula, especially between Cape Dorchester and Cape Queen (Orr and Rebizant 1987).

During aerial surveys for seabirds along the west coast of Nottingham Island in the early 1980s, walrus counts in the "low hundreds" were recorded (A.J. Gaston, *in litt.* 1985). These seabird surveys covered only the northwest and southeast ends of Salisbury Island, and no walruses were sighted.

Ungava Bay and central and eastern Hudson Strait: Currie (1968) estimated that at least 1000 to 2000 walruses visited Akpatok Island each year. It is not known what proportion of the Hudson Strait population now uses Ungava Bay. From aerial surveys conducted in late winter it was estimated that a minimum of 850 animals wintered in Hudson Strait and Ungava Bay (McLaren and Davis 1982). According to Mansfield (1990) the number of walruses in Ungava Bay and most of Hudson Strait appears to be small at present.

Southeastern and eastern Baffin Island: On 15 August 1978 an estimated 600-700 walruses were hauled out on a small island in the Lady Franklin Island group directly east (but far offshore) of Cape Haven (MacLaren-Marex 1980b). This group of walruses is thought to make seasonal onshore-offshore movements (*e.g.* Anon. 1981-87) and thus may be related to the concentrations in the Loks Land, Cyrus Field Bay and Lemieux Islands areas. We have no reliable information on the age or sex composition of the walruses hauled out at Lady Franklin Island.

From aerial surveys conducted in late winter it was estimated that a minimum of 223 walruses were present in southwestern Davis Strait (McLaren and Davis 1982).

Richard and Campbell (1988) assigned the number "1000+" to the area of southeastern Baffin Island from Gabriel Strait north to Clyde Inlet, as a guess at the current population size. The apparent basis was the series of aerial surveys noted above.

We suggest that the aggregate population of walruses found during summer in northern Labrador, Ungava Bay and Hudson Strait and along the east coast of Baffin Island south of Clyde numbers between 1000 and 2000 walruses. The actual number is probably nearer the high than the low end of this range, and we emphasize that there could be considerably more than 2000 walruses in this large region. The basis for any estimate of walrus abundance is, in this instance, extremely weak. Moreover, it is possible that regular movement of walruses takes place through the entire length of Hudson

Strait, which could mean that the walruses in southeastern Baffin Island, northern Labrador and eastern Hudson Strait/Ungava Bay are part of a much larger and wide-ranging stock.

Exploitation

Hunting methods: Before the introduction of whaleboats and rifles, walruses were hunted cooperatively by harpoon and lance from the floe edge; by stalking them on shore, cutting off their access to water, and attacking them with lances; and by approaching them in kayaks and harpooning them while they were hauled out on ice pans or the floe edge (Ross 1975:105). Guns were introduced in northwestern Hudson Bay in the middle of the 19th century, whaleboats somewhat later. By the end of the century both were widely distributed in both northwestern Hudson Bay and along the north shore of Hudson Strait. They made walrus hunting "less dangerous and more productive" (Ross 1975:105; Fig. 18).

Kayaks had been entirely replaced by whaleboats and Peterhead boats in western Hudson Bay and on Melville Peninsula by the early 1940s (Manning 1944). Canvas freight canoes were used more at Repulse Bay than elsewhere, "perhaps because walrus are rarely hunted" (Manning 1944:140).

Freeman (1970, 1975) provided detailed information on the methods used by Inuit at Southampton Island to catch walruses. These included floe-edge hunting from canoes in spring and open-water hunting from larger boats in summer and autumn. In the open-water hunts if the walruses were encountered over deep water, the hunters tried to drive them into shallower water before killing them.

Walruses hunted in late September near the HBC post at Wolstenholme during the 1920s were shot in

Fig. 18. The "Agpa", a boat used at the Hudson's Bay Company post at Wolstenholme (near present-day Ivujivik, western Hudson Strait) for autumn walrus hunting at Nottingham Island during the 1920s. Photo: courtesy of Hudson's Bay Company Archives, Public Archives of Manitoba, A. 74/34, fo. 440, taken in 1924 by Ralph Parsons.

the water to wound them, then harpooned. Two or three animals were taken at a time, tied alongside the boat and cut up in the water (Lyall 1979:47- 48).

Inuit traditionally hunted walruses in Hudson Strait from kayaks, using harpoons, lances, and later rifles (Gordon 1887:64). The killing of walruses on land, by cordoning them off from the water with a row of hunters with rifles, took place in Hudson Strait as recently as the late 1940s and 1950s (Russell 1966:7). Manning (1944:140) noted that kayaks were still used by some Inuit living along the coasts of Hudson Strait. However they increasingly were obtaining Peterhead boats that could be used to reach the offshore walrus grounds, "undoubtedly contributing to destruction of the walrus at the more accessible places" (Manning 1944:149).

At Koartak (Diana Bay, near Cape Hopes Advance) the Inuit shot walruses from land and pursued them in kayaks as recently as the early 1960s (Currie 1968:19, 69). At this and other settlements in western Ungava Bay (Hopes Advance Bay, Payne Bay, and Koartak) the availability of Peterheads essentially determined whether walrus hunts took place at Akpatok Island (Currie 1968).

Loughrey (1959) described the walrus hunt in the Southampton Island region, and stated that similar hunting methods were used throughout the eastern Canadian Arctic. The bulk of walruses were taken during the open water season.

Communities on the east and south coasts of Baffin Island (to as far west as Lake Harbour and including the present-day settlements of Clyde River, Broughton Island, Iqaluit (Frobisher Bay) and Pangnirtung) may hunt walruses that belong to the same stock as those hunted by Inuit from Central West Greenland. The possibility that people from Cape Dorset in western Hudson Strait, as well as residents of northern Labrador, Ungava Bay and northern Québec also hunt from this stock cannot be entirely excluded.

During the days when dog teams provided the main means of winter transportation, police detachments, mission stations, and trading establishments depended, as did the Inuit, on walrus catches in the autumn to provide winter supplies of dog food and to a lesser extent fox bait. The use of walrus meat and organs as human food seems to have varied by locality. In some areas, such as northern Hudson Bay and Foxe Basin, walrus meat is reasonably popular as human food. On the other hand, Kemp (1976) reported that many Inuit at Lake Harbour had an aversion to walrus meat. As a consequence their interest in walrus hunting declined substantially with the introduction of snowmobiles to replace dog teams in the 1960s. By the early 1970s most walrus hunting at Lake Harbour was done in conjunction with hunts primarily for seals and ducks.

Catch levels – Walrus catch by commercial whalers: Walrus hunting became commercialized to some extent at the end of the whaling era (late 1800s and early 1900s). Ross (1975:109) noted that some 3000 walrus hides were obtained in trade by Scottish whalers/traders between 1900 and 1915, presumably mainly from northwestern Hudson Bay (as well as from stations along the north shore of Hudson Strait; see Lubbock 1937 for some returns). Commercial whalers, sealers, traders and explorers caught walruses, at least opportunistically (*e.g.* Wakeham 1898:72-73, Vollan 1951), along the east coast of Baffin Island (especially around the mouths of Cumberland Sound and Frobisher Bay; Ross and MacIver 1982) and in Hudson Strait. A "considerable number" of walruses were killed at the British trading and whaling stations (*e.g.* Low 1906), either by white employees or by Inuit hunters for credit in trade goods. For example catches of 150 in 1899, 138 in 1900, and 149 in 1901 walruses were reported for the Cumberland Sound stations (Lubbock 1937). To date, however, no attempt has been made to compile the commercial walrus catches from this and other areas of eastern Canada in a systematic and comprehensive manner.

The Hudson's Bay Company post at Churchill sent an expedition north along the west coast of Hudson Bay each spring to obtain walrus blubber, hides and ivory (Tuttle 1885:208). Walruses were also hunted by the commercial whalers in northwestern Hudson Bay, and Inuit catches contributed to the food supply of overwintering whalers during the late 19th and early 20th centuries (Ross 1975, 1984). Although plenty of data are available in archives and literature, no systematic effort has been made to compile historical catches of walruses for this area.

Inuit subsistence hunting: Inuit along the northern Keewatin coast hunted walruses for subsistence, depending on the meat for dog food and the blubber oil for heat and light (Welland 1976:88, 91).

Loughrey (1959:appendix II) gave the following averages and ranges of annual walrus catches along the Keewatin coast during the 1950s: 10 (2 to 15) at Eskimo Point, 6 at Tavani, 20 (4 to 26) at Chesterfield Inlet and 12 at Repulse Bay. These were based on sporadic RCMP, Canadian Wildlife Service and missionary reports. Catches at Chesterfield Inlet ranged to as high as 18 in the 1960s (RCMP Game Report from Chesterfield, 1960-61).

For settlements in western Hudson Bay the

following annual average catch levels have been reported officially: in 1973-75 (from D.H. Dowler *in litt.* 1976) no catch at Eskimo Point and Whale Cove, 10 at Repulse Bay, 4 at Chesterfield Inlet, and 2 at Rankin Inlet; in 1972-85 (Richard and Campbell 1988) no catch at Eskimo Point, 2 (0 to 6) at Whale Cove, 12 (0 to 35) at Repulse Bay, 4 (0 to 15) at Chesterfield Inlet, and 5 (0 to 15) at Rankin Inlet; in 1988-93 (Anon. 1991...94) no catch at Churchill, 2 in 1988-89 but otherwise none at Whale Cove, 3 in 1988-89 but otherwise none at Arviat (Eskimo Point), 13 (11 to 18) at Repulse Bay, 10 (9 to 11) at Chesterfield Inlet, and 4 (3 to 5) at Rankin Inlet. A harvest study based on hunter recall in 1983-85 (years expressed as, *e.g.* October 1983 to September 1984) gave the following estimates of landed catch (Gamble 1987a, 1987b): 0 in 1983-84 and 1 in 1984-85 at Eskimo Point, 0 at Whale Cove, 5 and 18 at Repulse Bay, 7 and 16 at Chesterfield Inlet, and 1 and 5 at Rankin Inlet. The months of catch reported in the harvest study were May at Eskimo Point, July-September at Repulse Bay, January-March and June at Chesterfield Inlet, and February, May and July at Rankin Inlet (Gamble 1987a, 1987b).There is little information on magnitude of the walrus catches by subsistence hunters before the 1950s.

Northern Hudson Bay and western Hudson Strait: The subsistence use of walruses by Inuit living on or near Southampton Island is especially well documented. "Large caches of walrus meat were stored along the coast of Southampton Island in areas where people expected to camp or trap during the winter" (Welland 1976:96). In more recent times, with the declining reliance upon dog traction for winter transportation, fewer walruses have been taken. They are important in the Southampton Island area mainly as human and dog food and for their ivory. Walrus meat was also traditionally important as fox bait (Welland 1976:112).

Loughrey's (1959:appendix II) estimate of the annual walrus catch at Southampton Island, 1950-54, was 204 (range: 101-261). The total subsistence catch during 1951-61, according to Freeman (1970), averaged 187 (range 101-172, excluding the 77 in 1957 when effort was reduced) (Freeman 1970). Calves, however, which constituted an estimated 20% of the catch, were not reported (or claimed against the quota?) (Freeman 1970). The quota of 7 animals per married hunter and 3 per unmarried hunter was apparently observed during the 1950s and early 1960s. Between 1961 and 1972, with the declining need for dog food as snowmobiles replaced dog sleds, the reported average annual catch of walruses at Southampton Island declined substantially (Freeman 1975).

Official statistics on the annual average landed catch at Southampton Island (Coral Harbour) in 1973-75 was 110 (D.H. Dowler *in litt.* 1976), and Richard and Campbell (1988) listed the average during 1972-85 as 46 (range: 11-103). Most recently (1988-93) the reported catch has averaged 48, ranging between 41 and 60 (Anon. 1991...94, R.E.A. Stewart *in litt.* 1995). Gamble (1987a, 1987b) estimated the landed catch at Coral Harbour (based on hunter recall surveys) in 1983-84 and 1984-85 as 44 and 29, respectively. Although the highest catches were in August and September, some walruses were taken in every other month except February, June, November and December.

The settlement quota for Coral Harbour under the Marine Mammal Regulations is 60 walruses per year (Richard and Campbell 1988).

Catches at the offshore islands in western Hudson Strait have not been compiled systematically or comprehensively, so it is difficult to make meaningful estimates of removals there during the first three quarters of the 20th century. We can present only some examples that may or may not be representative. Soper (1944) reported that one hunter near Cape Dorset killed 25 walruses one autumn (apparently in the 1920s), providing his family with enough meat for humans and dogs, and enough lamp oil, to last the winter. It is fair to say that subsistence hunting of walruses was intensive throughout much of the region. At Nottingham Island in 1953, 117 walruses were taken by people from Sugluk and Ivujivik in organized hunts using boats supplied by the RCMP and the Roman Catholic mission, respectively (RCMP game report from Port Harrison). The estimated annual catch at Ivujivik during the late 1960s was somewhat more than 30 walruses, taken principally at Nottingham and Salisbury islands (Roy 1971).

Donaldson (1988:62-63) noted that official statistics on the landed catch at Cape Dorset were negatively biased. For the years 1981-83 the official catches were reported as 10, 35 and 59, respectively, whereas the estimates made from hunter recall surveys were 89, 54 and 66, respectively. The hunters sampled during the harvest study actually reported catches of 40, 74, 33 and 57 for 1980-83, respectively (*Ibid.*).

Ungava Bay and central Hudson Strait: In addition to one exceptionally large pre-1950 catch of 800 walruses made in one year at Akpatok Island (Currie 1968), catches of 150-200 were made there during the 1950s when trips from coastal settlements were feasible (*i.e.* when seaworthy Peterhead boats were available). Without Akpatok trips, the

average annual total catch in western Ungava Bay during the early 1960s was only about 40 walruses (Currie 1968). A catch of 20 was made at Cape Hopes Advance in 1956 (Evans 1964:17).

We have scattered records from other areas along the south coast of Hudson Strait. In the 1970s annual estimated landings were (NHRC 1976): Sugluk 58, Wakeham Bay 4, Koartak 11, Payne Bay 13, Leaf Bay 0, Fort Chimo 0, George River 1 and Port Burwell 3. It should be noted that much or all of the large catch at Sugluk was probably made at Nottingham or Salisbury Island in western Hudson Strait.

Southeastern and eastern Baffin Island: Loughrey (1959) estimated the annual catch of walruses along the east and south coasts of Baffin Island (from Cape Christian to Lake Harbour) at about 219 per year during the 1950s. It is not clear whether this includes all commercial and subsistence catches (by Inuit, police, and trading companies). During the 1960s the RCMP post at Pangnirtung had a quota of 12 walruses per year, taken for dog food. Most of this catch was made at the Leybourne Islands (Anders 1967). It was noted at the time that the Inuit of Cumberland Sound did not find it "profitable" to hunt walruses because of the great distances to the areas where walruses were still found (Anders 1967:43).

Dowler (1976, *in litt.*) gave an estimate of 156-206 per year landed during 1973-75 at Lake Harbour, Iqaluit (Frobisher Bay), Pangnirtung and Broughton Island, combined. The combined estimate for these same settlements (plus Clyde River) given by Richard and Campbell (1988) was 108 per year for the period 1972 to 1985. Adding the "minimum" and "maximum" catches recorded during the latter period for these settlements, the lowest potential catch in one year would be 17, the highest 298 (Richard and Campbell 1988:table 1). The catches for 1981-83 estimated from hunter recall surveys agree reasonably well with the official figures although in a few cases there are substantial discrepancies – *e.g.* in 1981, 35 vs. 58 for Iqaluit and 36 vs. 62 for Pangnirtung (Donaldson 1988:62). In the period 1988-93 (5 years) the reported average catch in these areas totaled about 62 walruses per year (range: 29-110; Anon. 1991... 94, R.E.A. Stewart *in litt.* 1995). The reason for the apparent decline in the reported landed catch is not clear.

Hunting loss: Most observers of walrus hunting in Canada have commented on the high losses (*e.g.* Manning 1944, Dunbar 1949), with estimates ranging from as high as three or four animals killed for every one secured (Low 1906) to as "low" as one or less than one being lost out of every four killed (Loughrey 1959). Smith and Taylor (1977:7) described a hunt (locality not specified) in which 50-70% of the walruses shot [and killed?] were lost, with "further considerable wounding loss" likely.

Manning (1944) observed that less than 10% of the walruses taken in northern Hudson Bay were killed on land. Although some were still harpooned in the water before being killed, the proliferation of hunting from whaleboats and Peterhead boats meant that increasingly the animals were shot first, then harpooned if possible. Manning estimated that 75% of the walruses killed could be secured if the hunters worked in an organized and cooperative manner. Since they did not, the loss rate was high. Manning implied that this would not necessarily be the case at a place like Coats Island where the animals were usually shot in shallow water and retrieved at low tide.

At Southampton Island 40 of 50 walruses that were "hunted" during the summer open-water hunt in 1961 were "actually killed", and of these none were lost (Freeman 1970). In this hunting, walruses were harpooned after being wounded with body shots. In the same year 5 of 13 walruses killed in the spring hunt from canoes were lost (Freeman 1970).

Even when walruses were harpooned before being killed, there could be significant hunting loss. For example, during a hunt near Salisbury Island Russell (1966:6-7) and his crew were forced to abandon seven walruses that had been harpooned and were ready to be taken on board. Thus the catch actually delivered to the trading post was less than what was in fact secured.

In the absence of rigorously collected recent data from the area of interest, we consider the general average of 30% loss to be appropriate for estimating total removals.

Catch composition: Freeman's (1970) data from Southampton Island indicate a ratio in the annual catch of three adults to one subadult and one calf. However, since calves were not reported in the catch statistics, the pro-ration is not straightforward. Freeman (1970) also noted that the sexual dimorphism in body and tusk size is not as extreme in the walruses at Southampton Island as it is elsewhere. From this, one can infer that selectivity on the basis of sex may not have been a prominent feature of walrus hunting there. During the period of his study, walruses were hunted at Southampton Island for the meat which was needed as dog food. Freeman (1970:170) stated that the value of ivory and walrus meat and blubber for household consumption was "secondary if not negligible at the present time."

No useful information was available for

assessing the catch composition in a meaningful way in other areas within the range of Stock 3. Official catch statistics are reported in terms of numbers of animals killed. However assuming that the hunters are constrained by the Marine Mammal Regulations (*cf.* Richard and Campbell 1988) allowing each licensee to take no more than four walruses per year, it is reasonable to suppose that the catch in most areas of Stock 3 is selective for large animals with large tusks (*cf.* Orr *et al.* 1986).

4. Western Greenland

Distribution and Stock Identity

The approximate summer and winter distributions of walruses in western Greenland are shown in Figs 8 and 9, respectively. Places mentioned in the text are shown in Figs 19-21.

Based on a variety of sources, Born *et al.*(1994a) summarized the historical and current status of walruses in western Greenland south of 76°N (Melville Bay). The following description is based largely on Born *et al.*(1994 a). Only when it is judged particularly relevant is the original source cited.

Southwestern Greenland south of 65°30' N: Walruses are not known ever to have been common in southwestern Greenland but stragglers occasionally were reported in the past as well as in recent years. Apparently walruses sometimes hauled out on land in two places near Nuuk (Fig. 19-20).

Central West Greenland (65°30' N to 70°30'N): Historically, the coastal waters between Nordre Isortoq and Attu (Figs 19 and 20) comprised the most important area for walruses in West Greenland.

From fall until spring, walruses occurred at the entrance of Kangerlussuaq (Søndre Strømfjord), close to the town of Sisimiut (Holsteinsborg) and at the entrance to Nassuttooq (Nordre Strømfjord). Mainly mixed herds of adult females with young and subadults occurred in the shallow coastal waters of these areas. Adult males were reported to prefer offshore areas with deeper water.

Beginning in September, both male and female walruses hauled out on uglit situated on small islands and on the mainland coast between approximately 67° 25' N and 67° 47' N, an area devoid of humans between October and April-May (Fig. 20). Apparently the walruses left the uglit in November-December. According to Freuchen and Salomonsen

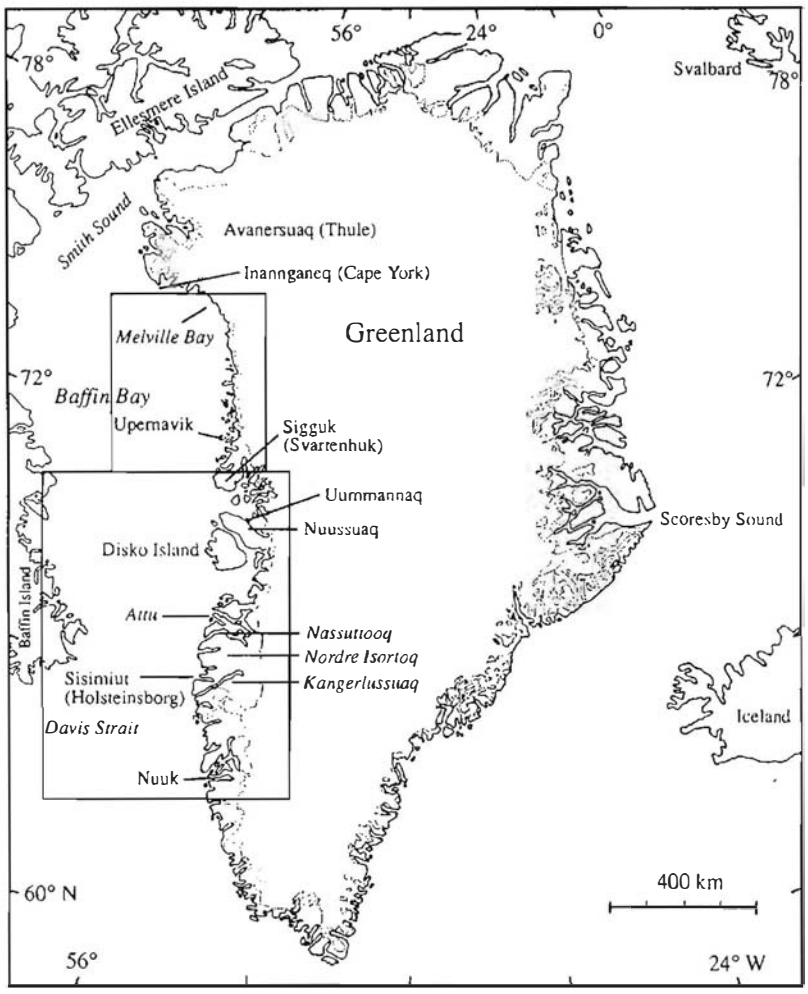

Fig. 19. Names of places in western Greenland (see also Figs. 20-21)

(1961) the number of walruses in this area increased in February, presumably due to immigration of animals from the Canadian side of Davis Strait.

Walruses rarely frequented the uglit after the late 1930s, and since the early 1950s no one has reported them as having hauled out on land in this region. Undoubtedly, the increased hunting at the uglit caused the walruses to abandon them. However, it cannot be determined with certainty whether the group of walruses that hauled out on land was extirpated or, instead, these animals learned to avoid the uglit and began wintering in the edge of the Baffin Bay-Davis Strait pack ice (the "West Ice").

In April the walruses retreated from the coastal regions to the eastern edge of the Davis Strait pack ice. Apparently they followed the westward retreat of the edge of the West Ice during spring. From around mid-June walruses were no longer found at the margins of the West Ice.

Information on the biology of walruses in these areas is scarce. In February males and females occurred together, whereas by late April adults were segregated by sex. By then the adult males occurred farther offshore and in denser ice than females with young.

Walruses were rarely seen near Aasiaat and in Disko Bay. They wintered, however, along the western coast of Disko Island. The walruses appeared in this area in October, and were reported to be abundant at the entrance to Kangerluk (Diskofjord) and were often observed near Kangersooq (Nordfjord) on the northwest coast of Disko. Since 1932, walruses have been caught from April until mid-June, 50-80 km west of Disko Island, at the margin of the pack ice. Large herds have been observed in June near Qeqertarssuatsiaq (Hare Island).

Occasionally, walruses hauled out on the small island of Saattut at the entrance to Kangerluk (Fig. 20). Apparently they no longer hauled out there after the 1950s. Walruses were also reported to haul out on land occasionally at Qeqertarssuatsiaq and on the north coast of Disko Island.

Systematic aerial surveys conducted in 1981, 1982, 1984, 1990, 1991, 1993 and 1994 (McLaren and Davis 1981, 1983, Born *et al.*1994a, Heide-Jørgensen and Born 1995) showed that walruses still occupy their former wintering range in the margin of the West Ice, between approximately 66° N and approximately 70°45' N. Apparently their occurence in this area is due to the availability of shallow feed-

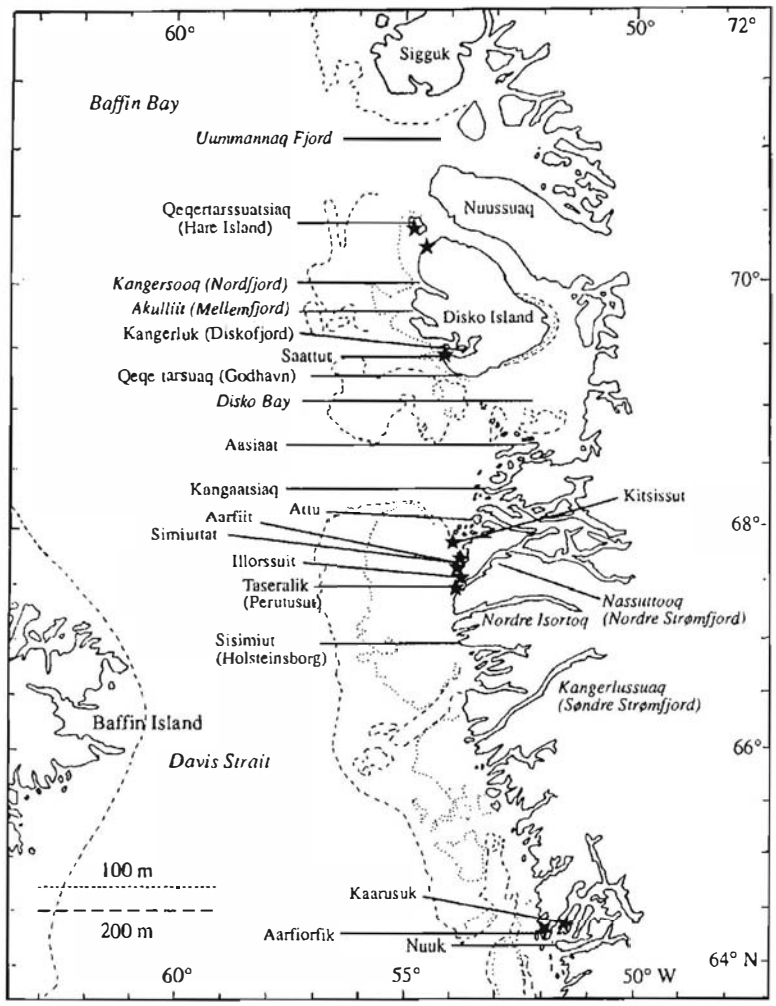

Fig. 20. Locations of abandoned terrestrial haul-outs (stars) in Central West Greenland.

ing grounds and suitable ice for hauling out. Walruses are absent from the entrance of Disko Bay where water depths exceed 200 m. Hence, their recent winter distribution off Central West Greenland is similar to that indicated by historical information. The major differences are their present absence from uglit, and the timing of migration.

From February until late May walruses are found in the pack ice about 30 to 100 km off the coast between Sisimiut and Kangaatsiaq (approx. 68°15' N).

Walruses are reported to arrive at the banks off the west coast of Disko in October-November. During winter they occur along the coast of northwestern Disko Island and around Qeqertarssuatsiaq (Hare Island). Subadults and females with young are generally reported to occur closer to the coast than males.

The walruses off Central West Greenland prefer areas with dense pack ice (usually more than 60% ice cover) in water that is less than 100 m deep. Several of the walrus's prey species inhabit these shallow banks. Most walruses observed during the aerial surveys were either single or in pairs. Larger congregations numbering one to two hundred have occasionally been reported from Central West Greenland.

Observations of newborn calves in this area are extremely rare. The walruses apparently have left these regions prior to the calving season. Recordings of underwater sounds indicate that walruses mate in these areas.

According to informants in Qeqertarsuaq (Godhavn) walruses are never observed moving southward south of the town of Qeqertarsuaq during fall, whereas those wintering near the northwest coast of Disko Island are believed to move north in May. Observations made during aerial reconnaissances flown along the coast between southwestern Disko and Sigguk (Svartenhuk) during spring 1982 indicated that the walruses wintering along the west coast of Disko progressively moved north in the shear zone between the fast ice and the pack ice. The timing of the catches in the Uummannaq and Upernavik areas, compared with that of catches farther south, supports this finding. However, scattered observations offshore in Davis Strait in March-July suggest that some walruses may migrate across Davis Strait from western Greenland to eastern Baffin Island during spring. The absence of walruses at the entrance to Disko Bay and in the bay proper, the information about migration and the differing response to exploitation indicate that the walruses that winter in Central West Greenland belong to two groups: one along the west coast of Disko representing the southern extreme of the North Water population (Stock 5), and a southern group off Attu-Sisimiut, presumably connected with Stock 3.

Northwestern Greenland (70°30' N to 76°N): Between Nuussuaq (70°45' N) and Inannganeq (Cape York) at the margin of the "North Water" polynya, the dense Baffin Bay pack ice lies close to the shorefast ice, leaving the walruses only limited space to overwinter in the Uummannaq and Upernavik areas.

Generally, the historical and present distribution of walruses in the Uummannaq and Upernavik areas appear similar. Walruses are not numerous in these areas and they appear to be mainly transient. A limited number can occur during winter in cracks and leads in the shear zone between the fast ice and the Baffin Bay pack ice. Northward migrating walruses are observed along the edge of the fast ice in the Uummannaq area during spring, but they rarely enter Uummannaq Fjord where the water is deep.

Farther north, migrants occur along the ice edge at the outer archipelago of the Upernavik area during spring (Fig. 21). Occasionally, walruses also are observed closer to the mainland coast. Walruses are more likely to be encountered in certain areas: Kiatassuup qeqertarsui (Ryders Islands, approx. 74°45' N), and between Kiatassuaq (Holms Island) and Nuussuaq (Kraulshavn), and at Kitsissorsuit (Ederfugle Islands).

Walruses were reported to haul out occasionally on the small islands near Eqqorleq.

According to Freuchen (1921) and Vibe (1950) the walruses crossed Melville Bay/Qimusseriarsuaq far offshore during their spring migration north into the Smith Sound region.

Although there are indications that some walruses move north in the shear zone between the shorefast ice and the Baffin Bay pack ice during spring, a "large scale" spring migration north along the western coast of Greenland as indicated in Freuchen (1921) is not witnessed nowadays.

The connection between walruses occurring in parts of the Baffin Bay and Davis Strait area is poorly known. However, in some areas walruses were caught with harpoon heads or rifle bullets that originated from other areas. This was interpreted to mean that a connection existed between walruses in different areas of northern Baffin Bay; for example between Avanersuaq (Thule) and the Ummannaq area in western Greenland, and between Pond Inlet in Canada and western Greenland (Freuchen 1921, 1935, Vibe 1950, Bisset 1968).

Freuchen (1921) and Vibe (1950, 1956) suggest-

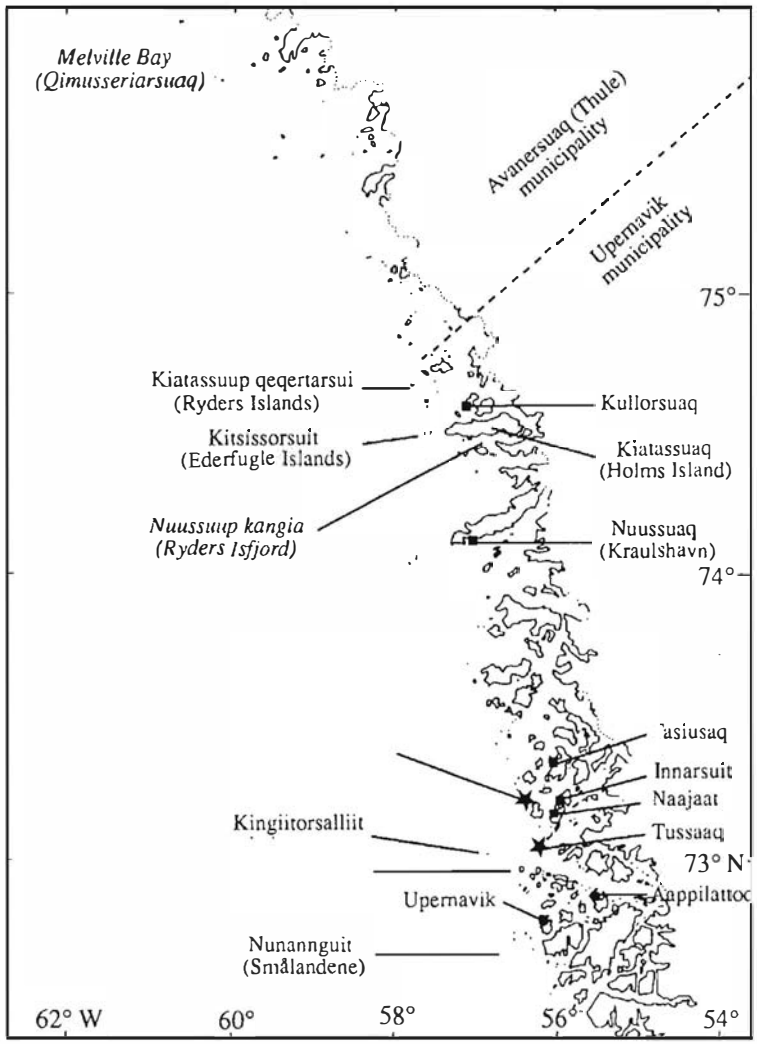

Fig. 21. Locations of abandoned terrestrial haul-outs (stars) in the Upernavik municipality in northwestern Greenland. Villages are shown as black squares.

ed that the walruses from Central West Greenland moved northward during May and June to join the walruses wintering in the northern Baffin Bay - Smith Sound region. In October there appeared to be a southward movement along the east coast of Baffin Island and the northwest coast of Greenland. From Baffin Island the animals were believed to move across Davis Strait to reappear in the central parts of West Greenland in the fall. Vibe (1967) assumed that the majority of the Baffin Bay summering population moved from the Avanersuaq (Thule) area in the fall to Lancaster Sound, and that from there some crossed Baffin Bay to western Greenland. Walruses off Central West Greenland were believed to stay in the Davis Strait pack ice or to cross the strait and join the population at south-eastern Baffin Island in severe winters (*Ibid.*).

Loughrey (1959) and Mansfield (1973) suggested that Atlantic walruses had more sedentary habits than Pacific walruses, and Mansfield (1973) questioned whether the large-scale, counter-clockwise migration cycle in the Baffin Bay-Davis Strait area suggested by Freuchen (1921) and Vibe (1950) actually occurred. Mansfield (1973) also indicated that walruses apparently had become scarce along the northeast coast of Baffin Island. In this area the Inuit did not witness any southward movement according to Bisset (1968). Nor did Koski and Davis (1979) and Koski (1980) during their systematic aerial surveys find any indication of a major southward fall movement along the northeast coast of Baffin Island. The absence of a substantial southward migration during fall along this coast was confirmed by the fact that there was only one sighting of walruses (seven on an ice floe on 5 October) during 260 h of observations for marine mammals conducted from Cape Adair between 13 September and 10 October 1978 (Koski and Davis 1979). We note with interest that according to Kemp (1976) the people of Clyde hunted walruses, mainly in fall, in five main areas during 1923-54: 1. the mouth of Alexander Bay and associated fiords; 2. central Isabella Bay and haulout sites off Henry Kater Peninsula; 3. Clyde Inlet and the mouth of Inugsuin Fiord; 4. the south side of Eglinton Fiord; 5. Scott Inlet.

From the dates when walruses appeared at various locations, Dunbar (1956) suggested that the

Hudson Bay, Hudson Strait and Frobisher Bay groups might comprise one large population. He suggested that the population moves into Hudson Strait in spring and out again in late fall, wintering perhaps in the neighborhood of the ice edge in Davis Strait, where they may well join the walruses occurring off Central West Greenland, as also suggested by Freuchen and Salomonsen (1961) and Mansfield (1973). It is still not clear, however, whether walruses from eastern Hudson Strait mix with walruses in Hudson Bay (Orr and Rebizant 1987).

Born *et al.*(1982) found indications of a northward movement in spring along the west coast of Disko Island. However, scattered observations of walruses in May-July in the middle of Davis Strait suggest that some walruses cross Davis Strait from Greenland to southeastern Baffin Island.

The finding of six haplotypes in analyses of mitochondrial-DNA from 10 walruses sampled during spring off Attu-Sisimiut in Central West Greenland (Cronin *et al.*1994) may reflect a mixing in this area during winter of walruses from different areas – for example northern Baffin Bay and southeastern Baffin Island.

Indications that walruses no longer migrate in any significant number southward in the fall along either the northeast coast of Baffin Island or the northwest coast of Greenland can be interpreted to mean that walruses occur in more sedentary groups nowadays, and that their numbers have decreased substantially.

Population Size

There are no historical estimates of abundance of walruses in western Greenland. Apparently several hundred used the uglit during fall. On 21 September 1897, about 300 animals were estimated to be present at the islands of Taseralik. In 1919 an estimated 600-800 walruses hauled out on the promontory of Illorssuit. In the fall of 1929, 600-700 animals were present on the islands south of Attu.

Catches during several decades of many hundreds of animals indicate, however, that several thousand walruses wintered in Central West Greenland at the beginning of this century.

The estimates of abundance based on aerial surveys between 66°N and 70°30' N from 1981-1982 and 1990-1991 revealed no trend since 1981 (Born *et al.*1994a). The line transect estimates in 1990 and 1991 produced a point estimate of the visible population wintering in Central West Greenland, between approximately 66°15' N and 70° 30' W, of about 500 animals (95% CI: 204-1512). Aerial surveys during late winter in 1993 and 1994 confirmed that the number of walruses wintering in Central West Greenland is in the low hundreds. These estimates are not corrected for animals which could have been submerged during the surveys. There were indications of a decline during the 1980s and early 1990s in numbers in the southern wintering area (Attu-Sisimiut) (Heide-Jørgensen and Born 1995).

Exploitation

Hunting methods – Central West Greenland (65° 30' N to 70° 30' N): The walruses were caught for their hide, blubber and tusks. In Greenland the meat was also used for human food and as food for sled dogs. Salted walrus hides, blubber and tusks were exported by the Greenland Trade Company (Vibe 1967, Born *et al.*1994a).

Traditionally, walruses were hunted from kayak, and often the skin-covered boats – umiat – were used for transportation. Some, presumably few, walruses were also taken during winter at their breathing holes in new ice – for example along the west coast of Disko Island, along ice edges, or when they hauled out on the shorefast ice.

However, of most significance were the walrus hunts by Greenlanders at the uglit in fall, and from 1932 the catch offshore during spring and early summer. Foreign whalers and sealers also caught walruses along the coast of western Greenland. These three types of hunting operations are described briefly in the following.

Traditionally, Greenlanders conducted co-operative walrus hunts during fall at the uglit at the entrance to Nassuttooq. Skin-covered boats and kayaks were used for transportation. However, in 1911 the Greenland Administration provided a motorized schooner which served as an auxiliary vessel during the walrus hunts at the uglit. This initiated an era of increased catches. For the period 1911-1937, a total catch of 1737 walruses was recorded for these hunts at the haul-out sites. This represents a minimum for the catches in these areas. Although these hunts were organized to some extent, many severely wounded walruses escaped into the sea, and losses could be high in some cases. Furthermore, in some years many walruses were killed but not reported. The annual catches were highly variable. For example, in 1898, 44 walruses were caught, and in this area more than 200 animals were killed in 1905. Despite the use of a larger vessels after 1911, the annual catch was still very variable due to the adverse weather conditions prevailing during fall.

Fig. 22. Greenlanders hunting walruses in the "West Ice" off the coast of Central West Greenland, presumably in the late 1930s. Photo: Archives of Arktisk Institut, Copenhagen. Photographer unknown.

A rapid increase in the population of Greenlanders led to an increased demand for hunting products and cash income. During the period 1911 to 1945, the human population in western Greenland almost doubled. During the same period the hunting technology changed dramatically. The number of motorized boats in western Greenland increased from one in 1925 to 390 in 1951. In 1939, 42% of the privately owned motorized vessels were registered in Sisimiut and Aasiaat, two of the most important walrus hunting communities. In 1949 this figure was 57.5%. A major reason for the relatively large number of motorized boats in these towns was that in these areas hunting, particularly of walruses, could be combined with fishing.

The Greenlanders began to use motorized vessels to take walruses offshore in 1932. In the beginning the Greenland Administration supplied the hunters with the vessels free of charge, but soon both vessels owned by the Greenland Administration and privately owned motorized vessels participated in the catch.

During cold winters the edge of the West Ice lies close to the coast (Vibe 1967). Apparently, the mild weather after about 1920 made ice conditions at the edge of this ice less severe during spring, thereby facilitating access by the vessels to walrus habitat. Hence, the combination of increased size of the fleet of motorized fishing vessels and lighter ice conditions during spring may have had a synergistic effect, causing the catch of walruses in Central West Greenland to increase rapidly during the 1920s.

Both British and Norwegian whalers and sealers caught walruses in the Davis Strait and Baffin Bay regions. Many of these walruses were taken along the coast of western Greenland off Sisimiut and Disko Island (Ross and MacIver 1982, Born *et al.* 1994a).

The British whaling operations in these areas ceased around 1910 (Ross and MacIver 1982). However, by that time Norwegian sealers and whalers commenced their walrus hunt in the West Ice between Sisimiut and Disko (*e.g.* Isachsen 1922, Isachsen and Isachsen 1932, Vollan 1951). The Norwegian offshore operations in western Greenland continued until World War I, and were resumed for the period 1919-1923 (Isachsen and Isachsen 1932, Vollan 1951). Prices of walrus hides dropped in 1921 and the Norwegian sealers discontinued

Fig. 23. Greenlanders butchering walruses in the "West Ice", presumably in the late 1930s. Photo: Archives of Arktisk Institut, Copenhagen. Photographer unknown.

their walrus hunt in Davis Strait until 1931, when two vessels again took walruses there (*Ibid.*).

The fact that foreign sealers made large catches of walruses close to the west coast of Greenland was used in Greenland as an argument for commencing the "rational" exploitation of walruses by Greenlanders, involving the use of motorized vessels (*e.g.* Müller 1906).

Northwestern Greenland (70°30' N to 76° N): In the Uummannaq and Upernavik areas walruses are either caught when they winter in the shear zone between the fast ice and the Baffin Bay pack ice, or when they move along the ice edge in spring. The seasonal distribution of the catch indicates that relatively many "late stragglers" are taken in the Uummannaq area. Walrus hunting practices in the Uummannaq and Upernavik area differ appreciably from those in the more southern districts. In the Uummannaq and Upernavik area, walruses were and are still caught by boat during fall, and from the ice edge during winter and spring; larger vessels are not used for walrus hunting.

Catch levels – Catches by Greenlanders in Central West Greenland: According to Rink (1877), the annual walrus catch in western Greenland hardly exceeded 200 animals in the first half of the 19th century. The catch in South Greenland (*i.e.* south of Maniitsoq) was estimated to be 10-20 per year at the beginning of this century (Müller 1906).

During the 1930s the offshore catch of walruses was intensified. According to the Hunters' Lists of Game (HLG) the highest landed catches were reported for 1938 (625 walruses) and 1940 (621 walruses), whereafter the catches decreased by an aver-

Fig. 24. A 20 ton fishing vessel during a walrus hunt in the "West Ice" off Sisimiut/-Holsteinsborg, Greenland, in April 1982. Photo: R. Dietz.

age of 3% per year until about 1965. According to the HLG, a total of 12306 walruses were landed by Greenlanders in western Greenland (Avanersuaq-Thule area not included) between 1900 and 1987 (last year of reporting). Due to loss of mortally wounded and killed walruses, and under-reporting of the landed catch, this figure represents an absolute minimum of the total removals of walruses during the period. Furthermore, the catch taken by foreign sealers and whalers should be added to these figures.

About 89% of the total catch was reported from the communities between Sisimiut and Nuussuaq in Central West Greenland (between 67°N and 70° 30' N); 74% were reported from Aasiaat, Attu and Sisimiut alone. About 7% of the total catch was reported from the Uummannaq and Upernavik areas, and only about 4% from areas south of Sisimiut.

Since about 1965 the reported catches of walruses have remained low. For the period 1965-1987 the annual catch in western Greenland, according to the HLG, averaged 56 animals (SD= 19.7, range: 19-101, n=23 annual reports). However, about 1975, the numbers of hunters reporting catches decreased. To compensate for this development, the catch figures reported for 1979-1985 in the published HLGs include estimates of unreported catches. Hence catch figures since about 1975 are not reliable. The numbers of reports received from Sisimiut – traditionally an important walrus hunting community – have been particularly insufficient in recent years. For example, in 1983 and 1984, when in each year an estimated 10 walruses were caught in Sisimiut according to the HLG, 40 and 74 walruses were taken, respectively, according to information obtained from residents in Sisimiut (Born *et al.* 1994a).

During the period of intensified exploitation in the 1930s and 1940s reproductive females were hunted selectively. The adult females occurred closer to land than males and were considered more valuable economically. The yield of blubber was relatively high in adult females and the ivory from their tusks was good for making tools and artifacts (Born *et al.* 1994a).

Catches by Greenlanders in northwestern Greenland: According to the HLG the annual catch of walruses in the Uummannaq and Upernavik areas decreased between 1940 and 1987. The average annual catch in the period 1940-1959 in the Upernavik and Uummannaq areas combined was around 22 walruses; between 1960 and 1987 the catch averaged 11 walruses per year. Over the entire period, the catch in the Uummannaq area amounted to about 20 % of the total catch of walruses in these two municipalities.

Catches by foreign whalers and sealers: Between 1859 and 1910, a minimum of 3734 walruses were taken in the Davis Strait and Baffin Bay regions by British whalers. The actual catch of walruses by British whalers probably was much higher. A substantial portion of these catches was taken off Central West Greenland during spring (Ross and MacIver 1982). In some years catches were high. For example, in 1906 a whaler took 300-400 walruses in the West Ice (Müller 1911).

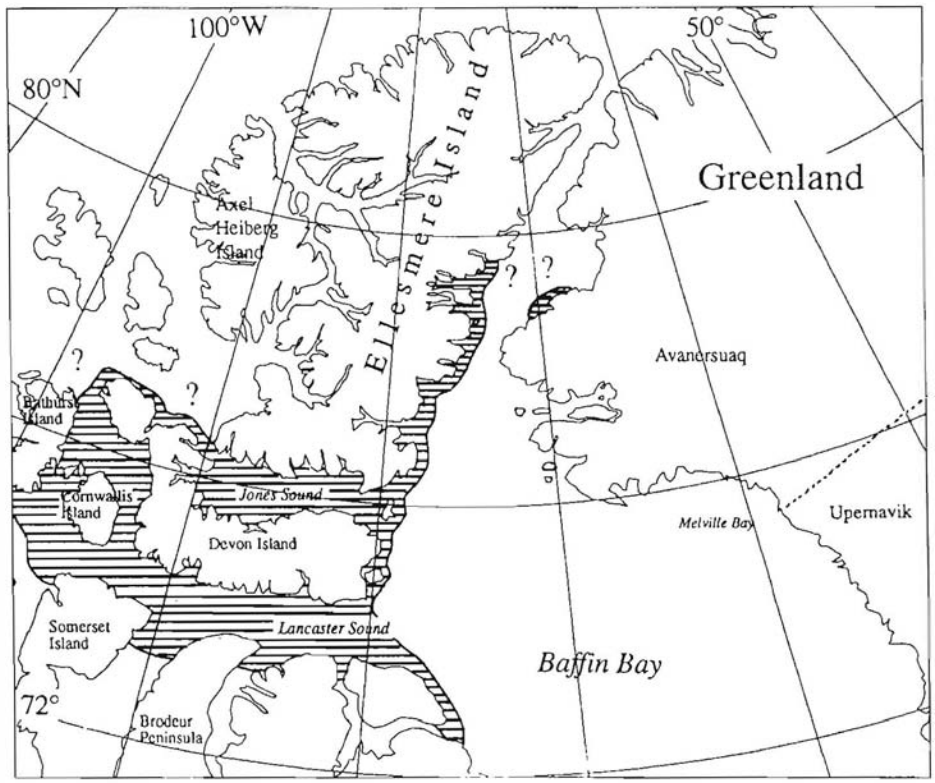

Fig. 25. Approximate summer distribution of walruses belonging to the North Water stock.

Information on the positions and the magnitude of the Norwegian catches of walruses at the beginning of this century is generally incomplete. However, in some years the Norwegian catch of walruses off western Greenland was high, sometimes several hundred animals (Born *et al.*1994a).

Hunting loss: No quantifiable data on hunting loss are available for western Greenland. An eyewitness account from 1937 from the hunt in the West Ice indicated that losses could be considerable. During those days the hunting practice was similar on board other vessels, and often the walruses were not harpooned before being shot (Born *et al.*1994a).

Due to the similarity in hunting practice between Greenland and Canada where losses from 20 to 50% have been reported (Mansfield 1973, Smith and Taylor 1977, Orr *et al.*1986), an overall loss rate (proportion of all animals killed or mortally wounded that are not retrieved) of 30 % is suggested for the kill in western Greenland.

Catch composition: A sample (n=26) taken offshore in the Sisimiut-Attu area (1982-1989) indicates that at present old and large walruses are hunted selectively. Sexually mature females (here, 5 years and older) constituted about 58% of the sample (Born *et al.*1994a).

5. North Water (Baffin Bay – Eastern Canadian Arctic)

The North Water (NOW) situated in northern Baffin Bay is the largest recurring polynya (*i.e.* area of open water surrounded by ice; Stirling and Cleator 1981) in the Canadian and West Greenland Arctic (*e.g.* Smith and Rigby 1981). Smaller persistent open (or semi-open) water areas exist at the entrance to Jones Sound off Coburg Island, in Hell Gate-Cardigan Strait in western Jones Sound and in Lancaster Sound off the southeast coast of Devon Island (*e.g.* Sverdrup 1903, Vibe 1950, Kiliaan and Stirling 1978, Smith and Rigby 1981, Fig. 26). Such open water areas are found in Greenland around Northumberland Island, and between Saunders Island and Wolstenholme Island (Vibe 1950).

For this report we include under the NOW area the entire eastern Canadian high Arctic, encompassing the Lancaster and Jones sound regions and their adjoining inlets and fiords.

Distribution and Stock Identity

Approximate summer and winter distributions of walruses in the NOW area are presented in Figs 25 and 26, respectively. Names of places mentioned in the text and terrestrial haul-out sites, are shown in Fig. 27.

Walruses winter in the NOW, in the polynyas connected with it, and in leads and holes in the

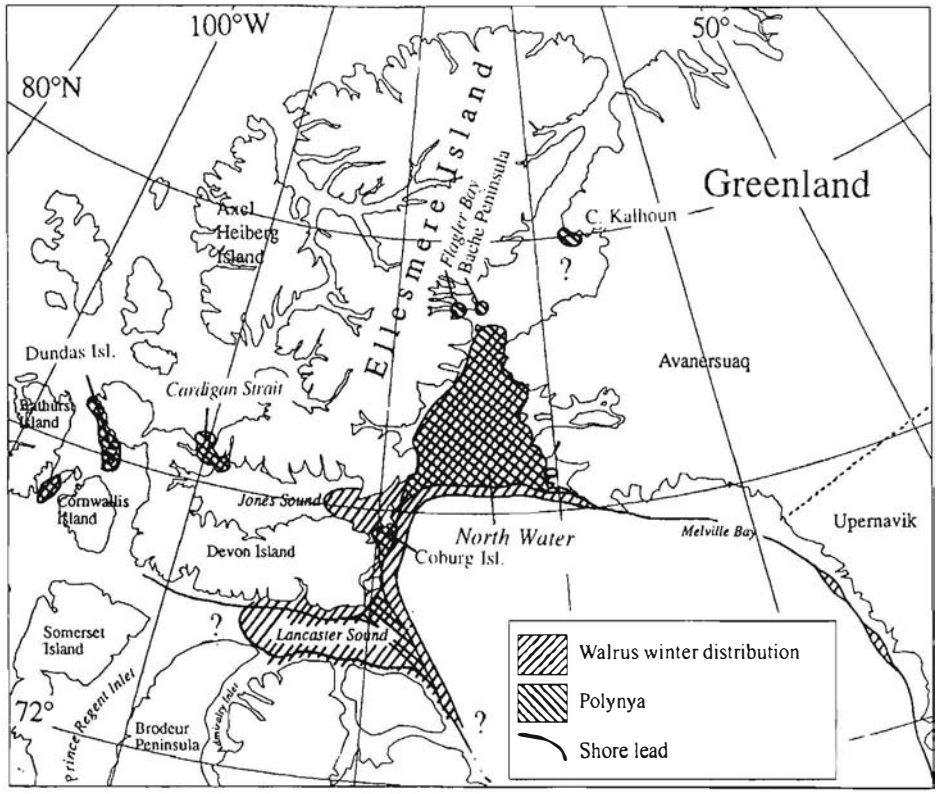

Fig. 26. Approximate winter distribution of walruses belonging to the North Water stock.

consolidated ice of adjacent areas (*e.g.* Kane 1892, Vibe 1950). It has been suggested that walruses might also winter in small polynyas in the Kane Basin region, for example in Flagler Bay (Schledermann 1980), off the tip of Bache Peninsula, and near Cape Kalhoun on Washington Land (Vibe 1950).

The following description of the distribution and movements of walruses in the NOW area proceeds from winter through fall.

In the eastern parts of the NOW area walruses winter in the Avanersuaq (Thule) area between Qeqertarsuaq (Wolstenholme Island) and Cape Inglefield (*e.g.* Kane 1856, Hayes 1867, Peary 1898, Freuchen 1921, Vibe 1950, Born 1987). The thin ice

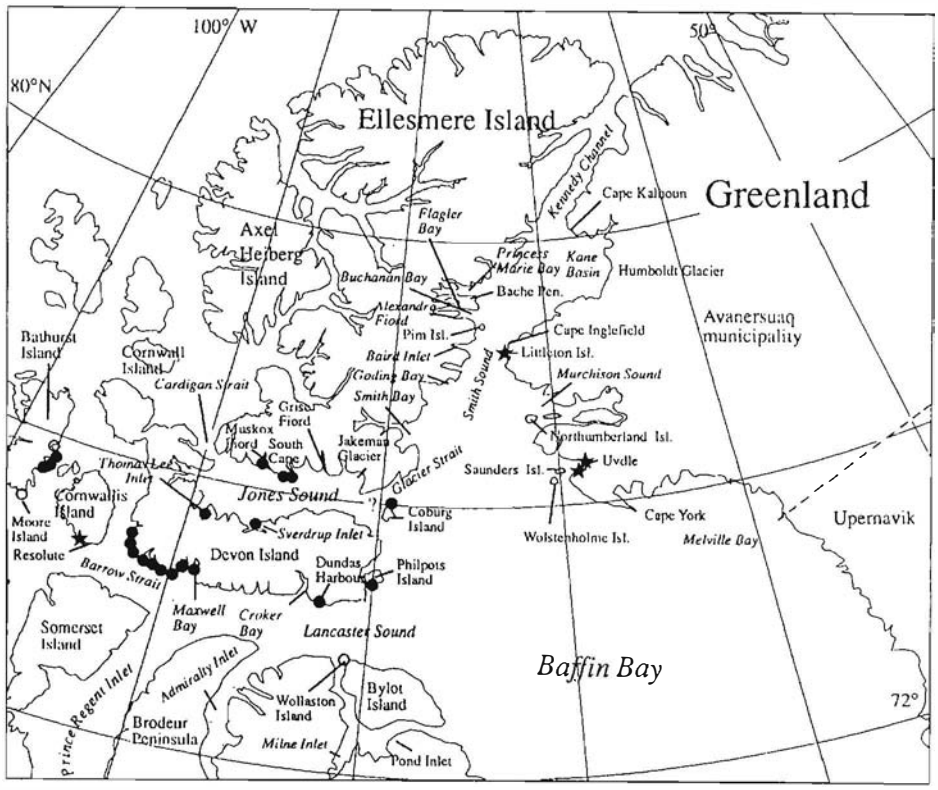

Fig. 27. Terrestrial haul-out sites used by the North Water stock of walruses. Legend: Black dots = haul-outs still used by walruses. Open circles = historical haul-outs; present status unknown. Stars = Abandoned haul-outs.

Fig. 28. In the Penny Strait-Queens Channel area (Canadian High Arctic), some walruses overwinter in heavy consolidated pack ice. They keep breathing holes open or surface in cracks and leads. Photo: E.W. Born.

there is frequently broken up by storms, giving the walruses access to shallow feeding banks (Vibe 1950, Born and Kristensen 1981). During winter walruses are hunted on the thin ice or from the edge of the fast ice. Walruses in the Avanersuaq area are segregated on the basis of sex and age class, with females and subadults generally occurring farther north than adult males (*e.g.* Peary 1917, Freuchen 1921, Vibe 1950, Born unpubl. data).

Walruses also winter in the outer half of Jones Sound (Freuchen 1921, Vibe 1950, Loughrey 1959, Riewe 1976, 1977), including Glacier Strait (Riewe 1992:180). Occasionally some individuals become stranded in Jones Sound by a quick freeze-up and are forced to maintain aglus in the ice throughout the winter (Riewe 1976, 1977, Riewe and Amsden 1979, Kiliaan and Stirling 1978). In May 1972 a hundred walruses were reported to be present in the Hell Gate-Cardigan Strait polynya in western Jones Sound (Kiliaan and Stirling 1978), where walruses are known to winter (Sverdrup 1903, Riewe and Amsden 1979, Stirling *et al.*1983). Walruses winter in the Cardigan Strait-Fram Sound and Penny Strait-Queens Channel areas (Stirling *et al.* 1983).

In connection with polar bear studies the Flagler Bay polynya and the open water at the eastern tip of Bache Peninsula were surveyed

Fig. 29. Hot-iron branding of a male walrus at the Dundas Island polynya (Canadian High Arctic) in April 1988. The animal, which was immobilized with Zoletil ® (Stirling and Sjare 1988), was unconscious during the branding. In the late 1980s a total of nine male walruses were branded and tagged in the Dundas Island polynya – Kerr Island area by Canadian Wildlife Service scientists. These animals have not been resighted outside the tagging area (I. Stirling ***in litt.*** 1995). Photo: E.W. Born.

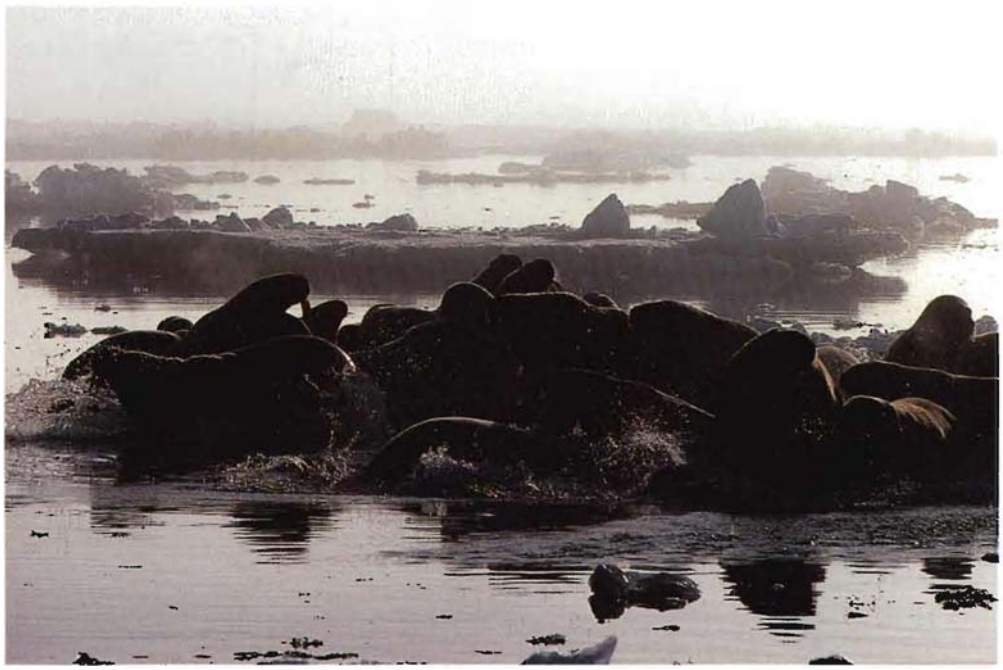

Fig. 30. A mixed herd of walruses hauled out on the pack ice in northern Smith Sound in July 1977 (see text). Photo: T. Kristensen.

between 29 April and 2 May 1994. No signs of walruses were detected in these areas. This was also true of the polynya off Cape Kalhoun (at southwestern Washington Land, *cf.* Vibe 1950) where open water was found at 80°08' N-67°30' W on 1 May 1994 (Born unpubl. data). It thus appears that walruses usually do not winter in these polynyas, which were separated during late April and early May 1994 by consolidated pack ice from the suitable walrus habitats farther south in the Smith Sound region.

In the past, walruses arrived in Avanersuaq (Thule) from the south during spring (Freuchen 1921, Vibe 1950). These migrants joined the animals that had overwintered there. Although information from local people indicates that some walruses still do come from the south during spring (Born unpubl. data), it appears that the pronounced influx during June and July, described by Freuchen (1921) and Vibe (1950), no longer takes place. During aerial surveys conducted in the periods 2 to 18 May 1992 and 4 to 8 May 1993 in the Melville Bay area (including the shore lead between 74° 30' N and 76°N) only two walruses were observed (Born *et al.*1992, Rosing-Asvid 1993). This supports the conclusion that there is no longer any substantial northbound spring migration of walruses along the west coast of Greenland.

Walruses are present at the floe edges of Pond Inlet and Lancaster Sound in spring (Riewe 1992); there is no strong evidence to suggest that these animals are from wintering areas along the east coast of Baffin Island. Aerial surveys during spring 1978 and 1979 revealed no major movement of walruses towards the NOW area from the south along the east Baffin coast (Koski and Davis 1979, Koski 1980). The westward movement of walruses as the ice breaks up makes them available to hunters all along the south side of Lancaster Sound and up to 15 km offshore (Schwartz 1982). According to Schwartz (1982), much of whose data came from interviews with hunters, walruses also penetrate well inside Pond Inlet, Milne Inlet and Admiralty Inlet during late spring and summer.

From April until sometime in June the walruses that wintered in Avanersuaq migrate north along the edge of the shore-fast ice (Freuchen 1921, Vibe 1950, Born 1987). Until about mid-July the ice dam in northern Smith Sound between Pim Island and Cape Inglefield prevents them from migrating farther north into the Kane Basin region. In June and July concentrations of walruses can occur along the edge of the pack ice in northern Smith Sound (*e.g.* Born 1987, Born and Knutsen 1988, Born and Knutsen 1990a) and along eastern Ellesmere Island south of Pim Island (Vibe 1950, Koski and Davis 1979). When the boat hunting is allowed to commence in Avanersuaq on 15 May, after which date thin ice usually does not form, the walruses retreat to the eastern coasts of Ellesmere Island, apparently as a reaction to the hunting (Born unpubl. data).

During aerial surveys conducted over the NOW area in 1978 walruses were observed in May-June along the edge of the shorefast ice off Ellesmere Island, the Lancaster Sound ice edge and the southeast coast of Devon Island. However, small numbers were also consistently sighted along eastern Devon Island, east of Coburg Island, and in Jones Sound (Koski and Davis 1979). During aerial surveys flown over the NOW area during the period 9 May-

2 July 1979 walruses were found in or north of Lancaster Sound. Other areas of importance to walruses were: 1. Coburg Island, 2. the Jones Sound ice edge, 3. southeastern Devon Island, and 4. the Navy Board Inlet ice edge (Koski 1980).

During summer (mid-June to mid-September) the central parts of the Avanersuaq area is devoid of walruses, except for a few stragglers (Born unpubl. data).

When cracks form in the consolidated pack ice in the Kane Basin – Nares Strait region walruses moved northward from Smith Sound; some were reported to penetrate the Kennedy Channel region (*e.g.* Kane 1856, Greely 1888, Rasmussen 1921, Freuchen 1921, Vibe 1950). According to the Inuit of the Avanersuaq area some walruses, predominantly males, still migrate via cracks and leads in the pack ice north along the coast of Inglefield Land to summer off the Humboldt Glacier (Born and Knutsen 1988). Presumably the number of walruses summering in the Kane Basin area varies a great deal from year to year, depending on ice conditions. However, there are no indications that in any year significant numbers summer there.

Officers stationed at an RCMP post in Alexandra Fiord during the 1950s and 1960s regularly reported large numbers of walruses, including a large proportion of females and calves, hauled out on the pack ice in Buchanan Bay and Hayes and Flagler fiords (RCMP game reports). The animals generally arrived in July or early August and left the area by mid September when new ice began forming in the embayments and along the coast. The occurrence of walruses in these areas and in Princess Marie Bay appears to be fairly regular (Freuchen 1921, Vibe 1950, Burton 1980, Schledermann 1980, Born and Knutsen 1988). A small recurring polynya in the Flagler Bay area is thought to attract walruses (Schledermann, 1980). Walruses reach this area in late June or early July (Schledermann 1978), following leads in the ice from the NOW (K. McCullough *in litt.* 1988).

Freuchen (1921) stated that according to Inuit, walruses migrate south along the east coast of Ellesmere Island, where they could meet those that spend the summer in or near Jones Sound (Vibe 1950). According to Greely (1888) Baird Inlet was a favorite feeding ground for walruses. On 7 August 1894 Ohlin (1895) found walruses in great numbers in Talbot Inlet west of Cape Faraday. At the end of July 1987 considerable numbers of walruses were seen at Cape Clarence Head; many females accompanied by calves were observed in Goding Bay (J. Schneller, pers. comm. 1989).

Walruses summer in Jones Sound, entering mainly from the east as the fast ice begins to break up in June or July (Riewe 1992:75,131,185,238). Females and young congregate along the lip of Jakeman Glacier, while males reportedly travel farther west towards the Hell Gate area (Riewe 1976, 1977, Riewe and Amsden 1979). This influx of walruses in late June and early July to Jones Sound was observed during aerial surveys of the NOW area. On 13-15 September relatively small congregations (<15) of walruses were observed along the coasts of Jones Sound west of South Cape, in Baad and Muskox fiords, along the ice edge at Hourglass Bay and off Viiks Fiord (Koski and Davis 1979). Riewe (1976) stated that walruses often haul out during the open-water season on the lowland west of South Cape and in Muskox Fiord. During this period mixed groups that are feeding are regularly observed off the settlement of Grise Fiord (D. Akeagok pers. comm. 1994 and 1995).

The walruses that congregate along the Lancaster Sound ice edge in May and June migrate westward following the receding ice edge (*e.g.* Degerbøl and Freuchen 1935, Bissett 1968, Johnson *et al.* 1976, Greendale and Brousseau-Greendale 1976, Davis *et al.* 1978). The main migration into Lancaster Sound apparently occurs between mid-June and mid-July from the northeast. During the open-water season walruses remain in considerable numbers along the south and southeast coasts of Devon Island (Koski and Davis 1979, Koski 1980, Renewable Resources Consulting Services Ltd. 1976). Along this coast, which has several terrestrial haul-out sites, they prefer Croker Bay, Dundas Harbour and the shallows north of Cape Sherard. The north and east coasts of Bylot Island seem to function primarily as a migration route (Renewable Resources Consulting Services Ltd. 1976). A few walruses may still haul out on the Wollaston Islands in the mouth of Navy Board Inlet, where they are hunted by the Inuit of Pond Inlet (Schwartz 1982).

Walruses were observed regularly from late September until early November off Dundas Harbour in the 1930s (Hudson's Bay Company Archives, Dundas post journals, unpubl. data). They were also present near the post in mid February and between Cape Warrender and Maxwell Bay from early March through July. In 1935 they were described as "exceptionally abundant" at the floe edge of this area on the first of May. They were hunted between Croker Bay and the southwest corner of Devon Island throughout July (*Ibid.*).

Resolute hunters report that walruses winter in the loose ice of Lancaster Sound, arriving at Resolute in late spring as the ice breaks up. In the past, westward migrating walruses entered Barrow

Strait through Resolute Passage, then moved into McDougall Sound, Queen Channel, and Penny Strait. They supposedly stopped going through Resolute Passage because of ship traffic, pollution, and other human disturbances associated with the development of Resolute. The walruses now migrate south of Griffin Island to reach the areas farther north. McDougall Sound, Queens Channel and Penny Strait were still considered walrus summering areas in the mid 1970s (Riewe 1976).

In years when the ice in Barrow Strait fails to clear, large numbers of walruses are said to move into Prince Regent and Admiralty inlets or into Wellington Channel. They are hunted relatively intensively in the vicinity of Cape Clarence and along the north coast of Somerset Island (Schwartz 1982). There was (and may still be) an ugli at Rapid Point on Bathurst Island. In the 1950s there were small uglit on one or two islands on the west side of Allen Bay, southwestern Cornwallis Island, where the Inuit from Resolute regularly hunted walruses (Manning and Macpherson 1961). These were no longer occupied by walruses in the 1960s "because of human disturbance" (Riewe 1976:178).

Manning and Macpherson (1961) reported that in August 1954 small groups of walruses, including calves, were present in western Barrow Strait around the western entrance of Baring Channel. They also claimed that walruses were killed occasionally in northern Peel Sound (Browne Bay). In fact, these authors surmised that the "scattered records" of walruses all the way west to Coronation Gulf and Amundsen Gulf probably involved mainly Atlantic walruses that had strayed westward, perhaps through Peel Sound or Bellot Strait (also see Bethune 1934, Harington 1966, Finley *et al.* 1974, Stewart and Burt 1994 for other "extralimital" records and interpretations).

Walruses have apparently always been rare in the waters near Pelly Bay (southwestern Gulf of Boothia) and Spence Bay (James Ross Strait) (Villiers 1970, Brice-Bennett 1976, Lyall 1979). Those that reach these areas are most likely wanderers from the Lancaster Sound/Barrow Strait region. The Pelly Bay people reportedly caught individual walruses in the 1960s or early 1970s at the mouth of the Kellett River and the southern end of St. Peter Bay (Brice-Bennett 1976).

Judging by the sparseness of records and the fact that walruses are not mentioned among the resources used by Inuit in Prince Regent Inlet and Gulf of Boothia (*cf.* Schwartz 1982), it can be assumed that these areas are unimportant as walrus habitat.

During fall walruses migrate eastward through Lancaster Sound to their wintering grounds in the northern Baffin Bay region. This migration is less conspicuous than the spring migration into Lancaster Sound. For example the eastward migration of walruses through Lancaster and Jones sounds was not even detected during studies in 1978. A southward migration from Lancaster Sound along northeastern Baffin Island was not observed during coastal watches until 10 October 1978 (Koski and Davis 1979). Neither were movements of walruses along the coast of northeastern Baffin Island observed in 1979 (Koski 1980).

Substantial numbers of walruses were present in Jones Sound in late summer and fall 1979 (Koski 1980). Prior to freeze-up walruses congregate in hundreds in the vicinity of Cape Sparbo in Jones Sound (Riewe 1977). Some migrate eastward (Schwartz 1982) and a few overwinter in cracks and aglus (Riewe 1977, Kiliaan and Stirling 1978). Walruses winter in leads and cracks in the eastern Canadian High Arctic as far west as Penny Strait (approx. 98° W; Kiliaan and Stirling 1978). They also winter near small areas of open water in Baird Fiord and Copes Bay as well as in the more extensive open water of Hell Gate (Riewe 1976). In October and November (the actual timing apparently being related to the formation of new shorefast ice) walruses of both sexes and all age groups reappear in the Avanersuaq area where they are hunted along the coast between Etah (Foulke Fiord) and Appat (Saunders Island; Born 1987).

There is no indication of any substantial southward migration along the west coast of Greenland from Avanersuaq to the Upernavik area. Some walruses are reportedly seen, however, migrating south in the Upernavik area during fall (Born *et al.* 1994a).

There are indications that the walruses occurring in the NOW area belong to a different group than those that occur along southeastern Baffin Island and on the southern wintering ground (Attu-Sisimiut) in western Greenland. A uniform haplotype was found in analyses of mt-DNA in a sample of 10 walruses from Avanersuaq (Cronin *et al.*1994). Using protein electrophoresis, walruses (n=93) from this area were also found to have low levels of genetic variation (Simonsen *et al.* 1982). An adult male walrus which was tagged on 18 June 1989 at Cape Inglefield was killed by a hunter on 17 May 1991 about 70 km south of the tagging site (Born 1991). The fact that walruses in Avanersuaq grow to a larger body length than walruses in Hudson Bay (Knutsen and Born 1994) indicates that there is no connection between walruses in these two areas.

Some connections exist, however, between the

Fig. 31. A walrus wearing a satellite-linked radio transmitter is given an additional drug dose by hand injection on Brooman Point, Bathurst Island (Canadian High Arctic), August 1993. One of the walruses tagged at this site was later shot at the entrance to Lancaster Sound (see text). Photo: E.W. Born

walruses in the NOW area and those that winter farther west in the eastern Canadian Arctic (*e.g.* Davis *et al.* 1978) and off the west coast of Disko Island, Central West Greenland (see section: Western Greenland). Walruses appear to winter annually in polynyas of the Cardigan Strait-Fram Sound and Penny Strait-Queens Channel areas (*e.g.* Stirling *et al.*1983). It cannot be excluded that walruses that move westward through Jones Sound and Lancaster Sound during late spring mix with this group of walruses, which probably hauls out on Bathurst Island during summer. This assumption was supported by the fact that one of ten walruses tagged in August 1993 at Bathurst Island was killed by Inuit off Bylot Island in June 1994 (R.E.A. Stewart information in NAMMCO 1995).

There are indications that some walruses move from Avanersuaq south along the coast of western Greenland as far south as Disko Island (Born *et al.* 1982, 1994a).

Uglit: Uglit identified in recent times in the NOW region are shown in Fig. 27. Terrestrial haul-out sites on the Greenland side of the NOW area are no longer used by walruses. Hence the walruses in this region now rely entirely upon access to uglit in Canada or haul out on floating ice. Until some time in the beginning of this century walruses hauled out on Littleton Island and on the Greenland coast opposite this island (Hayes 1867, Peary 1917, Freuchen 1921). According to information given by the Inuit in Avanersuaq to Vibe in 1939-40 (Vibe 1950), walruses also hauled out on land in two other places in the Avanersuaq area in the past (Fig. 27).

The available information indicates that there are no uglit along the east coast of Ellesmere island north of Jones Sound. However, this coast has not been visited frequently during summer, and the hunters from Grise Fiord do not go this far north during the open-water season (L. Audlaluk pers. comm. 1995).

Hundreds of walruses are said to haul out on Coburg Island in the entrance of Jones Sound (Riewe 1992:131,238). Along the north shore of Jones Sound, there are two uglit at and just west of South Cape, another (up to 50 animals) on the east side of Muskox Fiord, and one with "hundreds" of walruses at the base of Jakeman Glacier (Riewe 1992:71,180).

Information obtained from residents of the settlement of Grise Fiord (D. Akeagok and L. Audlaluk pers. comm. 1994, 1995) confirmed that walruses – primarily males – haul out west of South Cape at approximately 76°35' N, 85°15' W at a place called "Sannialuit" (*i.e.* the place with bones). After walruses had been killed on land at Sannialuit they abandoned this ugli. However, recently it has been re-occupied by a group of 50 to perhaps 100 walruses. Walruses still haul out on land in Muskox Fiord (76° 55' N, 87° 25' W). During the open-water season many walruses – primarily females with calves – congregate in the Anstead Point – Jakeman Glacier area east of Grise Fiord, but information conveyed to us (*Ibid.*) did not support the statements by Riewe (1992) that walruses haul out on land in this area, or on Coburg Island.

According to Koski and Davis (1979) there are uglit in Thomas Lee and Sverdrup inlets on the south coast of Jones Sound (*i.e.* north coast of Devon Island). During summer the Grise Fiord hunters usually do not go as far as to the southwest

Fig. 32. On 10 August 1993, 43 walruses were hauled out on Brooman Point. Eight others, including females with newborn calves, were in the water. Photo: E.W. Born

coast of Jones Sound and therefore less is known about uglit in this area. In connection with fishing for Arctic char (*Salvelinus alpinus*) walruses have, however, been seen hauling out on a small island at Cape Newman Smith (Sverdrup Inlet) on the south coast of Jones Sound (L. Audlaluk pers. comm. 1995).

Riewe (1992) identified several uglit along southern Devon Island – on the east side of the entrance to Dundas Harbour, at the southwest corner of Philpots Island, and along the southwestern part of Devon Island at Innes Point, Kearney Cove, Beechey Island, Cape Ricketts, and Cape Hurd and near the head of Maxwell Bay (<100 at each site). In the Queens Channel and McDougall Sound areas there are uglit at Brooman Point, Markham Point and occasionally Milne Island (Riewe 1992:157). Salter (1979) studied walrus behavior at the Brooman Point ugli on southeastern Bathurst Island that is occupied in July-August by as many as 194 walruses (Johnson *et al.* 1976).

Uglit on the Wollaston Islands in northern Navy Board Inlet and on the south coast of Devon Island were traditionally the main sites for walrus hunting by Inuit of the Pond Inlet region during the open-water season (Miller 1955, Ellis 1957, Brody 1976). According to Koski and Davis (1979), who cited Miller (1955) and Bisset (1968), the Inuit from Pond Inlet reported that the Wollaston Island haul-out was used by 200-300 walruses. During aerial surveys conducted in 1976 and 1978 walruses were not seen on the Wollaston uglit although small groups (30 animals) were present on ice pans near the site in late July 1976 (Johnson *et al.* 1976, Koski and Davis 1979).

Systematic surveys of all uglit used by walruses in the Canadian section of the NOW area have not been carried out. Information about the quantitative importance of the various uglit is fragmentary, but evidently the numbers using the different sites vary between years depending, among other things, on variable ice conditions (Koski and Davis 1979). Together, the uglit in Union Bay, Maxwell Bay, Thomas Lee Inlet and Sverdrup Inlet were used by at least 250 walruses in August 1977 (Davis *et al.* 1978). These four uglit were not occupied by walruses in mid September 1978 when they were surrounded by fast ice (Koski and Davis 1979).

Change in distribution: The absence of walruses from the Avanersuaq area during summer is in contrast to the situation earlier when walruses apparently were abundant in, for example, Murchison Sound during the open-water season (*e.g.* Sverdrup 1903, Peary 1917, Vibe 1950).

Apart from this decrease in the length of the period that walruses occur in the Avanersuaq area, their geographical range during summer has also decreased. They previously occurred farther east in Wolstenholme Sound and also penetrated McCormick Fiord (Vibe 1950).

Most likely, these changes have been caused by increased hunting. Between the mid 1950s and the mid 1970s the human population in Avanersuaq more than doubled to about 700 Inuit. This population increase was accompanied by an increased demand for hunting products and cash income. Since the 1960s there has been a substantial change in hunting technology, with an increased use of motorized boats with increased motor power (Born 1987, Born unpubl. data).

Fig. 33. A harpooned walrus surfaces in a lead near Dalrymple Rock/Iganaq, May 1975. Photo: T. Kristensen.

Population Size

Information about numbers of walruses in the NOW and adjacent areas has been collected at different seasons and in different years. Both aerial surveys and ship-borne surveys have been used and the entire range has not always been covered. Hence any numbers must be treated with caution.

Aerial surveys of the NOW during late winter 1978, 1979 and 1993 were intended to sample the entire wintering stock of walruses (Finley and Renaud 1980, Richard *et al.*1993). During the March-April 1978 survey only a few walruses were observed, but during the March 1979 survey approximately 700 were counted along the ice edge between Jones Sound and Talbot Inlet (Finley and Renaud 1980). A comparable aerial survey during 20-26 March 1993 resulted in a total count of only 10 walruses in the Glacier Strait-Cape Norton Shaw area (Richard *et al.* 1993).

Summer concentrations of walruses have been observed in several parts of the NOW area. On 12 July 1978 a minimum of 700 walruses of both sexes and all age classes were seen on the pack ice about 4 to 10 km west of Cape Inglefield (northern Smith Sound) (Born and Kristensen 1981). Between 18 June and 8 July 1989 a minimum of about 170 animals were observed along the ice edge across Smith Sound. Females, calves and subadults were found in the vicinity of Pim Island, while the only adult males observed were in the pack ice close to Cape Inglefield on the Greenland coast (Born and Knutsen 1990a).

Riewe (1992:39,154) indicated that "thousands" of walruses were found along the east coast of Bache Peninsula and also that the population scattered along the east coast of Ellesmere Island in summer represents the third greatest concentration of walruses in Canada (after the Southampton Island and northern Foxe Basin areas). The basis, however, for the statements by Riewe (1992) is not clear. RCMP game reports from Alexandra Fiord refer to a herd of 500-800 in Flagler Bay in summer 1956 and a group of 400, mainly females with calves, near Cape Sabine in early September 1962 (RCMP game reports). In July 1978 Schledermann (1978, 1980) saw about 300 walruses in the Flagler Bay polynya in western Buchanan Bay. The timing indicates that these animals were probably the same group as seen by Born and Kristensen (1981) in Smith Sound. In 1979 at least 250 walruses were observed in the Buchanan Bay area (Schledermann 1980). These estimates of numbers in Buchanan Bay were considered to be conservative (K. McCullough *in litt.* 1988). During an aerial reconnaissance on 31 August 1985 an estimated 300 walruses were observed in Buchanan Bay (Born unpubl. data) where on 21 August 1988 a minimum of 171 walruses were present (Born and Knutsen 1988).

The population estimate obtained from aerial surveys in July 1976 for Lancaster Sound was 309 walruses, the majority of which were along the south coast of Devon Island (Renewable Resources Consulting Services Ltd. 1976). Based on densities of walruses recorded between 9 and 15 July 1979 on coastal, nearshore and offshore transects, 468 walruses were estimated to have been present in parts of eastern Lancaster Sound (*i.e.* all non fast-ice

Fig. 34. A boat approaches a group of walruses in dense fog at Avanersuaq/Thule in June 1977. The hunters attempt to kill the hauled-out walruses instantly by firing a bullet at the head. Wounded animals that escape into the water are harpooned and shot. Photo: E.W. Born.

areas between 79° 30' W and 83° 30' W; Koski 1980).

Davis *et al.* (1978) estimated that 300-500 walruses move westward in the Canadian High Arctic via Lancaster Sound and an estimated 200-300 animals via Jones Sound. They concluded that a minimum of 1000 walruses summer between Devon Island and Bathurst Island. Riewe (1992:185) suggested that less than a thousand walruses remain in Lancaster Sound for the winter.

Based on these fragments of information we tentatively suggest that during summer the numbers of walruses in the NOW area are: 1) Avanersuaq (from Cape York to Cape Inglefield): 0; 2) Kane Basin region: 100; 3) Buchanan Bay and Princess Marie Bay: 300; 4) eastern Ellesmere Island south of Pim Island, and Jones Sound: 300-600; 5) southern Devon Island and Lancaster Sound: 1000.

Hence we conclude that approximately 1700-2000 (perhaps as many as 3000) walruses are present in the entire NOW area during the open-water season.

Exploitation

Hunting methods: The walrus hunt is very important in the subsistence harvest of the Inuit in Avanersuaq. On an annual basis walruses provide an estimated 25% of the meat and other edible products obtained from hunting (Born 1987). The majority of the tusks are sold to the Greenland Trade Company; some are sold directly to tourists.

During the first half of this century walruses were primarily taken from kayaks and on thin ice (Vibe 1950). According to Freuchen (1921) a few were taken during summer from a small schooner that operated from the trade station at Dundas in North Star Bay. Since the mid-1960s there has been an increased use of boats with outboard engines and small "Peterhead"-type boats.

There are two major hunting seasons: 1) The winter hunt takes place from November to mid May (peak March-April) on the walrus feeding banks. The animals are harpooned as they surface, then shot, in thin ice or at the ice edge. 2) The open-water season commences on 15 May when, according to a local rule, motorized vessels are allowed to be launched from the ice edge. This hunt has peaks in June-July and in fall, usually in October. It ends when the formation of new ice prevents navigation (Born 1987). Most of the walrus catch is made during the open-water season. Walruses are first hunted from boats until about mid-July, when the majority of animals have retreated to the east coast of Ellesmere Island, apparently as a reaction to the hunt. In the period September to November, with some variation from year to year, walruses reappear in the Avanersuaq area and are again hunted from boats.

According to local regulations, walruses must be harpooned before being shot (see section: Regulations). This only happens, however, during the thin-ice hunt. In order to secure a walrus during the open-water hunt, the hunter first wounds it with a body shot, sometimes from a long range. This makes it possible to approach the animal closely enough to harpoon it. After the harpoon is secure, the hunter dispatches the animal with head shots. When walruses are hauled out on ice floes, the hunters try to kill them instantly with head shots.

The harpoon is used afterwards to secure mortally wounded animals that have escaped into the water (Born pers. obs.).

We have little information about contemporary hunting methods in the Canadian parts of the NOW area. The Grise Fiord Inuit typically hunt walruses from motorized freighter canoes during summer and fall, approaching individuals and small groups that are either swimming or hauled out on ice floes (Riewe 1976, 1977, Riewe and Amsden 1979). The harpooning and killing methods appear to be similar to those described for Avanersuaq. In some cases walruses hauled out at aglus are stalked. In the past the Inuit used the entire carcass for various purposes. However today walruses are killed primarily for their ivory, and only a small portion of meat is brought back to the village for consumption by people and dogs. Since 1967, when snowmobiles were adopted by hunters, the walrus harvest has diminished at Grise Fiord (*Ibid.*). In recent years, however, there has been an increased interest in hunting walruses, partly because the demand for dog food has increased after the re-introduction of dog teams in Grise Fiord (D. Akeagok pers. comm. 1995).

Inuit of the Pond Inlet region traditionally made expeditions to the Wollaston Islands with the explicit purpose of hunting walruses (Bissett 1968, Brody 1976, RCMP game reports). However according to Treude (1977), whose field work was in 1972-73, "special walrus hunts" no longer occurred at Pond Inlet by the time of his visit. Walruses were, and still are, hunted by the people of Pond Inlet and Admiralty Inlet mainly at the floe edge during spring and early summer, and opportunistically during the open-water hunting directed primarily at phocid seals and monodontid whales (Brody 1976:164, Schwartz 1982, Reeves pers. obs.). This is at least partially due to the fact that large herds of walruses are not available. Hunting methods are presumably similar to those mentioned above for Grise Fiord.

The Resolute hunters hunt walruses in conjunction with seal and whale hunting just outside Resolute Bay in the spring, and also around Cunningham Inlet in the spring and fall (Riewe 1976). Other walrus hunting areas for the Resolute people are in Penny Strait, around Baring and Crozier islands, and along the south coast of Bathurst Island. According to Riewe (1976) the kill of walruses at Resolute declined sharply after the mid 1960s because of the reduced number of sled dogs needing food.

Catch levels – Catches by foreign whalers: In the late 19th century and until 1910 British whalers took numerous walruses in the NOW area. Particularly large kills were recorded for Smith Sound, around Coburg Island, at the entrances of Prince Regent Inlet and Navy Board Inlet, and in Croker and Maxwell bays (Ross and MacIver 1982). Walruses were killed on uglit at the Wollaston Islands at the entrance of Navy Board Inlet, and the large kills in Croker and Maxwell bays may also have been made on uglit. At around the turn of the century large catches of walruses were also sometimes made, by members of exploratory and scientific expeditions (*e.g.* Sverdrup 1903, Peary 1917; see summaries from Allen 1880 etc. in Reeves 1978). In 1949 and 1951, a Norwegian sealing vessel caught 623 and 1175 walruses, respectively,

Fig. 35. A pile of walrus skin, blubber and meat brought back to the settlement of Siorapaluk from a hunt in northern Smith Sound, July 1978. The small "Peterhead"- type boat can bring back the products of 5 to 10 walruses, depending on their size. Photo: E.W. Born.

Fig. 36. Walrus skulls are cleaned before they are sold to the Greenland Trade Company in Avanersuaq/Thule. Photo: T. Kristensen.

in the Davis Strait and Baffin Bay areas. Another vessel took some hundred walruses in 1951. Although the exact positions of the high catches in 1949 and 1951 are not well documented, there are indications that they were taken in the northern Baffin Bay region (Born *et al.*1994a). These latter catches led to a Norwegian hunting regulation in 1952 (Anon. 1952, Rasmussen 1952) which totally banned the hunting of walruses by Norwegians anywhere.

Catches by Greenlanders: The annual catch of walruses in the Thule area around 1940 was estimated at 200 (Vibe 1946, 1950). Bruemmer (1971) estimated the annual catch in the Thule area to range between 100 and 130 animals, to which figures an estimated 30 to 40 animals lost should be added (*i.e.* estimated loss 20-30%). According to Mansfield (1973) an annual average catch of 132 walruses was reported in the HLG for the period 1948 to 1965. Based on information obtained from the walrus hunters in the Thule area, Born and Kristensen (1981) estimated an annual catch of about 215 walruses for the late 1970s. Generally, the reporting in the HLG has been insufficient, and for some years is lacking entirely. The average annual catch during the 1970s and early 1980s was estimated at 250 animals (loss not included) by Born (1987), who pointed out that the walrus catch showed great annual fluctuations, determined mainly by variable ice conditions. In 1988 samples were obtained from 114 walruses, and according to a local informant a minimum of 150 walruses were taken that year (Born unpubl.). According to a new system of collecting catch statistics (introduced in 1993), a total of 217 walruses were landed in Avanersuaq in 1993 (Department of Fisheries, Nuuk).

In some years catches are high. According to the HLG, 290 and 440 walruses were reported for the years 1957/58 and 1961/62, respectively.

As stated earlier, walrus hunting was an important activity at the Hudson's Bay Company trading post at Dundas Harbour during 1934-36, when a total of at least 115 kills were recorded in the post journal (Hudson's Bay Company Archives unpubl. data).

Walruses were killed for dogfood by the RCMP stationed at Alexandra Fiord, Buchanan Bay, during the 1950s and 1960s. Smith and Taylor (1977:26) indicated that a total of 70 was taken in two years with records after 1962. From 1953 to 1962 the annual catch averaged about 16, of which less than 20% were females (7 years with records, RCMP game reports unpubl.).

Loughrey (1959:appendix II) estimated that Pond Inlet, Arctic Bay and Clyde accounted for about 42 walruses per year during the mid 1950s and that an additional 76 were taken each year in the areas of Resolute, Dundas Harbour, Craig Harbour and Alexandra Fiord, combined, during this same period. These totals certainly declined by the late 1960s as the need for dogfood diminished.

Recent reported catches in the Canadian parts of the NOW area (defined as including Resolute, Arctic Bay, Pond Inlet and Grise Fiord) averaged about 23 per year during the period 1972-1985 (Richard and Campbell 1988) and 21 for 1988-1993 (5 years; range: 13-30) (Anon. 1991...94, R.E.A. Stewart *in litt.* 1995).

We estimate that annual removals (including loss) from the NOW walrus population average approximately 375 animals. This estimate is derived in the following manner: annual landed catch in Avanersuaq = 250 walruses to which a loss rate of 25% is applied (see: Hunting Loss); Upernavik = about 10 walruses per year plus a loss rate of 25%; reported catches from the same population in Canada have averaged about 20 walruses per year,

subject to an overall loss rate of 30%. To these catches from the NOW walrus stock another 10 walruses landed in the Ummannaq municipality and in the Disko Island area may be added.

Hunting loss: In the Avanersuaq area losses during the open-water season ranged between 15% and 25% (based on 34 hunting trips, in which 112 animals were retrieved in 1977 and 1978). The highest figure includes animals that escaped during the hunt (newborn young and wounded animals) and whose fate was unknown (Born and Kristensen 1981). Presumably the majority of the injured animals eventually die from their wounds (Fay *et al.*1994). Although adoption in walruses may occur (Fay 1982:204) we consider it likely that many of the orphaned calves die. Hence, the loss rate tends to be closer to the upper end of the range. Hunting loss undoubtedly occurs in the Canadian sector of the NOW area even though there has been no systematic effort to estimate the loss rate from field observations. We assume that the rate is similar to those in other parts of Canada (*e.g.* Orr *et al.*1986) - about 30%.

Catch composition: Information on the age and sex composition of catches in Avanersuaq are available for a full hunting cycle ("a year") during 1977-78 and for two full hunting cycles during 1987-90. In all cases the samples presumably represent more than 50% of the actual take and can be considered representative for the total catch in the area (Born unpubl. data). Young and subadult animals are under-represented in the catch. Females are usually not recruited to the catch until 5-7 years of age, and males not until 7-9 years of age (*i.e.* age at sexual maturity). Similar age compositions showing that hunters select for larger animals with more yield of meat and larger tusks have been reported from Foxe Basin (Orr *et al.* 1986) and the Bering Strait region (*e.g.* Fay and Bowlby 1994).

Sexually mature females (5 years and older) represented 35% (1977-78), 37% (1988-89) and 48% (1989-90) of the Avanersuaq catch. Overall, 40 % of the catch consisted of females five years and older (Born unpubl. data).

We have no information about the catch composition in the Canadian parts of the NOW area. It would be reasonable to expect some selection of larger individuals, considering that the numbers of walruses that can be taken are restricted by quota and that ivory is a relatively valuable product of the hunting.

6. Eastern Greenland

Information about the occurrence of walruses in eastern Greenland was summarized by Dietz *et al.* (1985) and Born (1990). The following review is based mainly on these sources. When relevant, the original source is cited. Some additional recent information is also presented.

Distribution and Stock Identity

Summer and winter distributions of walruses in eastern Greenland are shown in Fig. 37-38 respectively. Places mentioned in the text and uglit are shown in Fig. 41.

The few historical observations of walruses along the coast of southeastern Greenland, between the Tasiilaq area (Ammassalik) and the entrance to Kangertiittivaq (Scoresby Sound), are concentrated around the fjord of Kangerlussuaq and at the shallow banks along the northern parts of the Blosseville Coast, just south of the entrance to Scoresby Sound. Walrus food items were reported by Thorson (1934) from the Kangerlussuaq area.

When the Inuit community at the entrance to Scoresby Sound was founded in 1924/25, walruses were common there; they also hauled out on land in this area (Rasmussen 1925, Pedersen 1926). They occurred only rarely in the inner parts of Scoresby Sound. Walruses wintered in the polynya at the entrance to this fjord system (Pedersen 1926). Walrus food items have been reported from the north coast of the entrance to Scoresby Sound and from Hurry Inlet.

In August 1924 about 30 walruses were observed in Hvalrosbugten close to where the settlement of Ittoqqortoormiit/Scoresbysund was founded. On 7 August 1924 a Norwegian sealer took "quite a few" walruses at the entrance to Scoresby Sound (Isachsen 1925). During 1925/26, 70 walruses were caught by the Inuit in this area, whereas during the following years only 10, 6 and 2 animals were secured (Pedersen 1931, Mikkelsen and Sveistrup 1944). After that time walruses were scarce in Scoresby Sound, and only old males were observed occasionally during summer hauled out on floes (Pedersen 1931). This indicates that a resident group of walruses probably had been exterminated.

Historical observations of walruses between Scoresby Sound and Clavering Island are few, presumably because there is little or no suitable walrus habitat in this area. The waters are deep in the fjords along this stretch of coast.

Walruses were common and used several uglit in

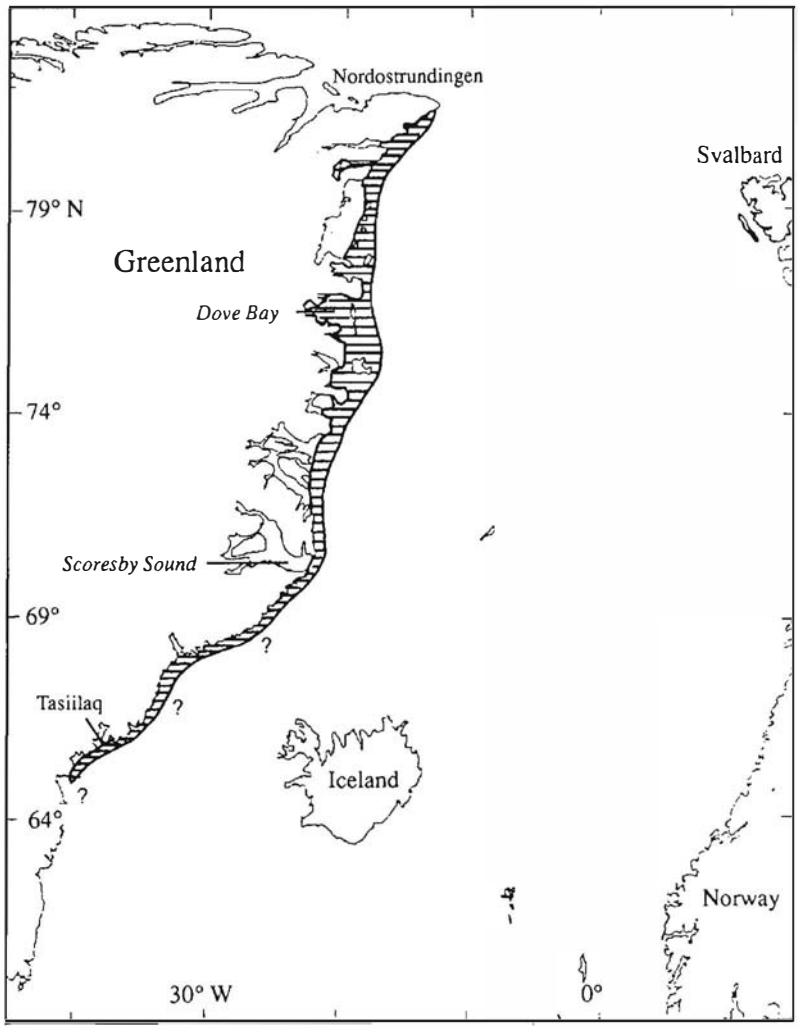

Fig. 37. Approximate summer distribution of walruses in eastern Greenland. Stragglers may occur south of the main concentration area.

the Clavering Island – Hochstetter Bay areas (Knudsen 1890, Giæver 1937). Sizeable concentrations were seen occasionally. For example, on 26 May 1932, 26 walruses were shot from a herd of about 200 at Cape Herschell according to Jennov (1945), who stated that the number of walruses around Clavering Island had decreased around 1940.

Several observations of walruses have been reported at Cape Borlase Warren, Cape Wynn, Sabine Island, Hvalros Island and Lille Pendulum Island at the promontory of Wollaston Forland. They also occurred in the Kuhn Island area and along the south coast of Shannon Island. In these areas there can be open water during winter, and a polynya is present along the south coast of Shannon Island (*e.g.* Koch 1945, Mikkelsen 1994).

Walruses were common in the Dove Bay area where they also hauled out on land (Friis 1909, 1925, Johansen 1910, Jennov 1945). Observations reported by Trolle (1908) and Johansen (1910) showed that walruses occurred along the coast from Dove Bay north to 81°10' N at Nordostrundingen (*i.e.* the northeastern cape of Greenland).

Recent observations indicate that the distribution of walruses in eastern Greenland is essentially similar to that described above.

A few walruses are occasionally caught in the Tasiilaq area (Dietz *et al.* 1985, Born 1990), and they are observed from time to time at the entrance to Kangerlussuaq (Glahder 1992). The seasonal distribution of catches for the period 1950-1983 indicates that walruses can occur in southeastern Greenland at all seasons (Dietz *et al.*1985, Born 1990). Stragglers that reach Iceland are likely to be from eastern Greenland (Born 1988).

At all times of the year, but particularly from February until late June, single walruses or groups of 2-3 animals of both sexes and all age groups (except newborn) may occur at the entrance to Scoresby Sound, where they feed along the north coast (Born 1983, Sandell and Sandell 1991). According to inhabitants of the area, the number of walruses frequenting this area has increased in recent years. The people ascribe this increase to the fact that walruses have been protected since the 1950s in the areas north of Scoresby Sound (Born 1983).

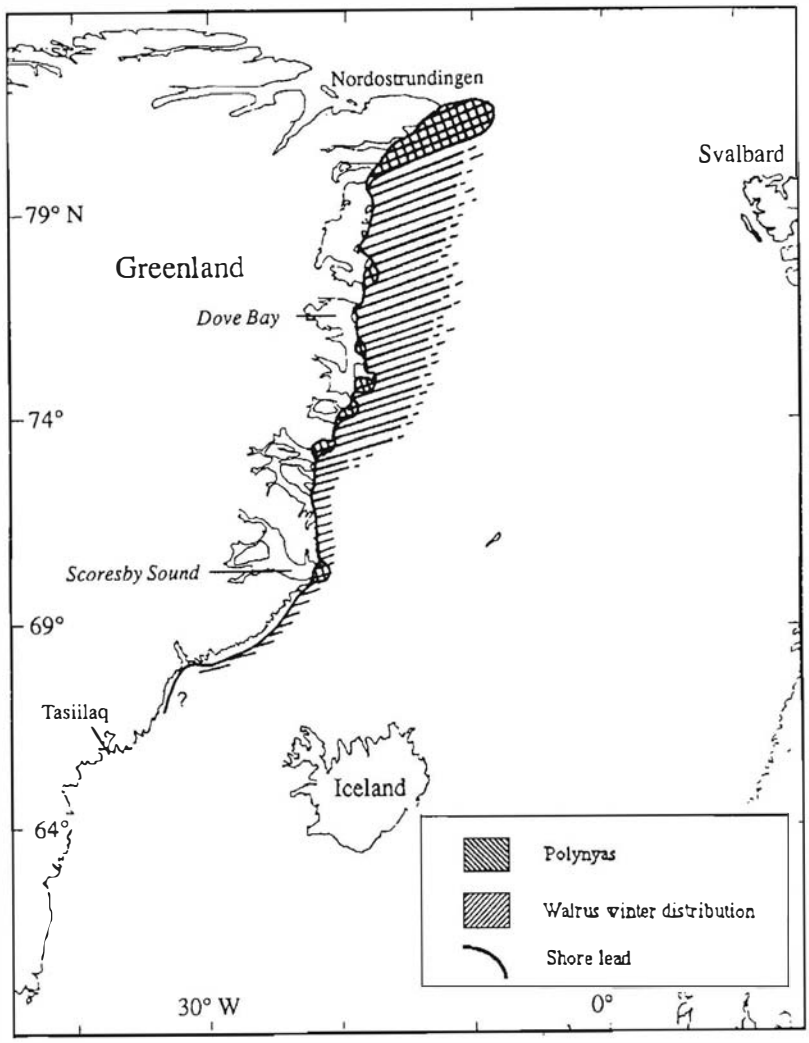

Fig. 38. Approximate winter distribution of walruses in eastern Greenland. Walruses can winter offshore in the moving pack ice over deep waters.

Small groups of walruses are observed along the coast between Hold with Hope and Dove Bay, and in the Dove Bay area. In these areas, regularly used uglit are found only on Sandøen (Young Sund) and Lille Snenæs (Dove Bay), although a few individuals have been observed while hauled out on land in other places.

North of Dove Bay walruses have been observed in several places along the coast between Skærfjorden (approx. 77°30' N) and Kilen (approx. 81° 14' N). Apparently they prefer the coastal areas between Dijmpha Sound (approx. 80° N) and Kilen (approx. 81°10' N) where the water is shallow. During aerial surveys of the coastal areas between Norske Islands and Nordostrundingen 26 May-18 June 1993 walruses were observed several times (Born and Thomassen 1994). Most notably, a total of 108 walruses were observed close to the coast between Kilen and Henrik Krøyer Holme on 3 June 1993 (Born *et al.*1994b). During a survey of the same area on 25 July, 93 walruses were seen, of which 17 were recorded as small calves (Tahon and Vens 1994).

Various sources indicate that walruses winter in the following areas of eastern Greenland: the entrance to Scoresby Sound, the Gael Hamkes Bay area, along Wollaston Forland and at Sabine Island, at Shannon Island and the southern tip of Store Koldewey Island, and farther north off Amdrup Land in the Eskimonæs and Antarctic Bay area. In these areas there are recurring polynyas with shallow water. Tracking of walruses instrumented with satellite-linked radios revealed that they can winter in the pack ice up to about 200 km offshore, between about 78°N and 81°N (Born and Knutsen 1992). The presence of polynyas at Île de France and at Hold with Hope (Pedersen 1942, Koch 1945) suggests that walruses may also winter there.

Observations of walruses between eastern Greenland and Svalbard suggest that some animals swim all the way across the Greenland Sea and Fram Strait (Dietz *et al.*1985, Born and Knutsen 1991). Such a connection was proven by the observation at Svalbard in 1992 of a walrus that had been tagged in eastern Greenland (77°N) in 1989 (Born and Gjertz 1993). Studies of the variation in mitochondrial DNA in a limited number of walruses showed the haplotype of those from the Scoresby

Fig. 39. Walruses at the ugli on Sandøen, Young Sound on 26 August 1994. Photo: E.W. Born.

Sund area to be different from that of walruses from Avanersuaq (Thule) in northwestern Greenland. However, three walruses in a sample of ten from Central West Greenland had a haplotype also found in walruses from eastern Greenland (Cronin *et al.* 1994). This indicates that some genetic mixing has occurred between eastern Greenland and Central West Greenland. In southwestern Greenland walruses are sporadically caught in the period January to August (Born 1990). These could be stragglers from either eastern Greenland or Central West Greenland.

Uglit: We are not aware of reports of uglit south of the entrance to Scoresby Sound. North of Scoresby Sound only two uglit are used regularly at present: Sandøen and Lille Snenæs (Figs 39, 40, 41). Both are used by males.

Around the mid-1920s walruses hauled out on Fame Islands in Hurry Inlet (Rasmussen 1925) and on the beach in Hvalrosbugten near the settlement of Scoresbysund (Pedersen 1926 Fig. 4). These uglit were soon abandoned due to hunting. Before the turn of the century other uglit were used by walruses in the Young Sound and Kuhn Island areas. For example, in 1889 more than 100 animals were killed on land at Cape Berghaus in Young Sound. Large kills were also made at an ugli situated somewhere in the Kuhn Ø area (Knudsen 1890, Giæver 1937, Jennov 1945). Due to hunting, these uglit were abandoned at the beginning of this century.

Fig. 40. The haul-out Lille Snenæs in northern Dove Bay in August 1990. Photo: E.W. Born.

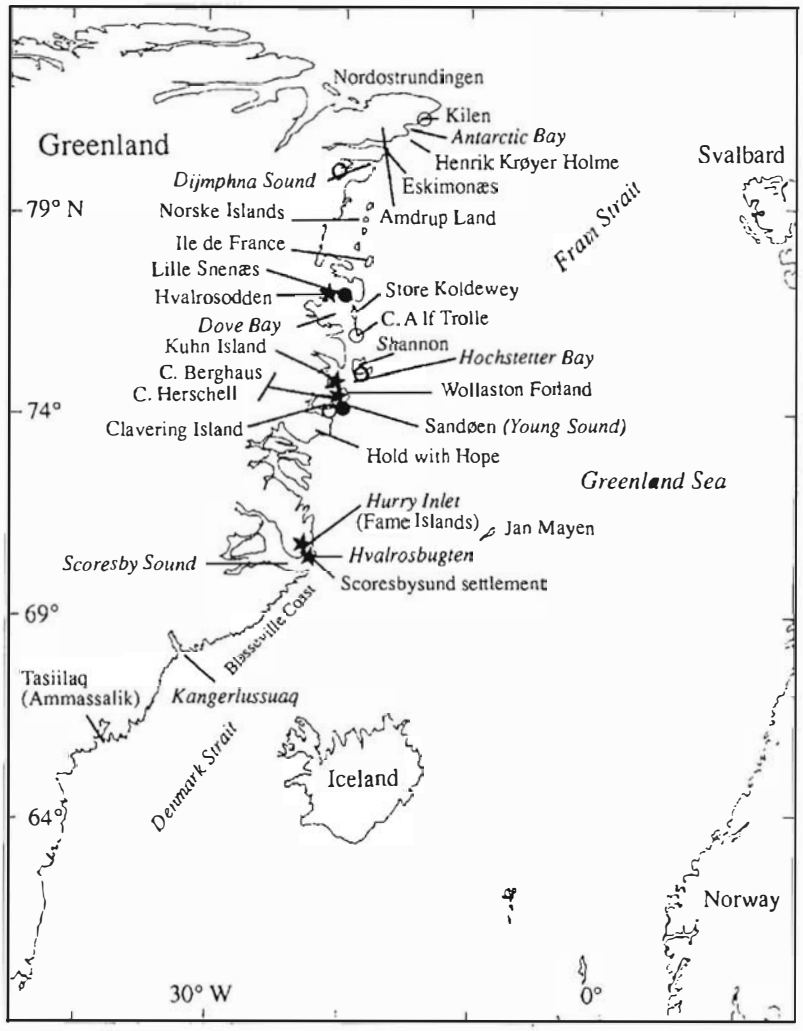

Fig. 41. Terrestrial haul-out sites used by walruses in eastern Greenland. Legend : Black dots = haul-outs still used by walruses. Open circles = places where walruses have been observed on land; present status unknown. Stars = Abandoned haul-outs.

Fig. 42. Walruses at the haul-out in Hvalrosbugten ("Walrus Bay") at the entrance to Scoresby Sound, East Greenland, in August 1924. It is apparent from the photo (bottom) that adult males, females and calves used this haul-out which was soon abandoned due to hunting (see text). Photo: A. Pedersen.

At present the Sandøen ugli is used regularly by a group of 20-30 up to perhaps as many as 50 walruses, primarily males. Walruses have also recently been observed on land at Cape Berghaus, on the southern coast of Clavering Island and on Shannon Island (Dietz *et al.* 1985, Born unpubl.).

Walruses formerly hauled out on land at Hvalrosodden ("walrus point") in northwestern Dove Bay. During the "Danmark Expedition" (1906-1908) about 30 walruses were shot in the northern Dove Bay area. Several of these were killed on the beach at Hvalrosodden. After this the walruses tended to avoid this ugli (Friis 1909, 1925, Johansen 1910, Jennov 1945, Dietz *et al.*1985). However, in 1933 they were observed on a new ugli at Lille Snenæs, about 10 km east of Hvalrosodden (Pedersen 1934). In July and August 1933 about 50 walruses were seen on this beach (Pedersen 1942, Jennov 1945).

Observations during the last decades have confirmed that Lille Snenæs is used as a haul-out site for adult males from late July until late September - early October (Dietz *et al.* 1985, Born and Knutsen 1992). A Petersen-estimate obtained from resightings of individually recognized walruses suggests that about 50 males used this haul-out site in 1989 and 1990 (Born and Knutsen 1990c).

Walruses have also been observed on land at Cape Alf Trolle (southern tip of the island of Store Koldewey) (Dietz *et al.*1985). Farther north, they have been observed on land in the Dijmphna Sound and Hanseraq Fiord areas (Dietz *et al.* 1985, Born unpubl. data).

Population Size

Andersen (1984), who was traveling along the coast in a kayak, recorded a total of 329 walruses between Nordostrundingen and Scoresby Sound. About 240 of these were observed between Kilen and Norske Islands. Based on aerial surveys in June 1993, Born *et al.* (1994b) tentatively concluded that not more than about 200 walruses were present between Eskimonæs and Nordostrundingen. This crude estimate is similar to that of Andersen (1984) and refers to those parts of the areas covered by Andersen (1984) where he found the highest concentrations of walruses. Various observations indicate that each of the two summering areas for males, Dove Bay (Lille Snenæs) and Young Sound (Sandøen), has about 50 adult males during the open-water season. Hence, about a hundred animals may tentatively be added to the 329 recorded by Andersen (1984). Consequently, a highly conservative estimate of the total population of walruses in eastern Greenland would be about 400. As this estimate is not corrected for walruses which may have been present in areas not covered by the surveys or for animals submerged and out of sight during the surveys, a rough estimate of 500 to 1000 animals in the eastern Greenland stock is tentatively suggested.

Exploitation

Hunting methods: Some, presumably few, walruses were traditionally taken by the Inuit of eastern Greenland (*e.g.* Sandell and Sandell 1991). Due to a general scarcity of walruses in southeastern Greenland, the catch in this region has been very small. Since 1966 walruses have been shot sporadically in Kangerlussuaq in the northern part of the municipality of Ammassalik (Siegstad 1989, Glahder 1992). The limited records available indicate that walruses may be caught in the Ammassalik area at any season, with a peak in August-Septem-

Fig. 43. Danish trappers ready to flense adult male walruses at Hvalrosodden (Dove Bay) in the summer of 1934 (year uncertain). Usually the walruses were towed into shallow water to be butchered at low tide. Photo: presumably P. Poulsen.

ber. We have no details about hunting methods but assume that they are similar to those described below for Scoresby Sund.

In the Scoresby Sound area walruses are usually taken between April and August at the entrance to the fjord complex (Born 1983, Sandell and Sandell 1991). According to Sølberg (1975) they are shot either from land or from the ice edge when they are observed during the hunt for ringed seals. Sometimes when walruses haul out on ice they are shot from dinghies powered by outboard engines. Rifles with calibres of 7.62 or larger are used to shoot the walruses either in the head, neck or spine (*Ibid.*). A harpoon is usually not used. Walruses that sink in shallow water are retrieved with a hook (J. Thygesen pers. comm. 1988).

Catch levels – Catches by foreign sealers etc.: During a period of 40 to 50 years beginning in 1889, more than 1000 walruses were killed by foreigners primarily Norwegian and Danish sealers and trappers mainly in the areas around Clavering Island and the island of Shannon and in Dove Bay. The majority were taken during the first half of this period (*e.g.* Jennov 1945; Fig. 43). Jennov (1945) believed that walruses had decreased in northeastern Greenland as a result of overexploitation. An unknown presumably limited number of walruses were also taken between the 1940s and 1960 by Danish and Norwegian trappers (Mikkelsen 1994).

Catches by Greenlanders: During the late 1920s an average of one walrus per year was taken in southeastern Greenland (Pedersen 1931). According to the Hunters' List of Game (HLG), the catch of walruses in the municipality of Ammassalik averaged 3.5 walruses per year (SD=4.4, range:1-10, four years of reporting) between 1980 and 1987 - the last year for which there was a record.

In the period 1980-1987 the catch in the Scoresby Sound area averaged 12.1 walruses (SD=7.0, range: 2-22, six years of reporting) according to the HLG.

The reporting in the HLG in eastern Greenland generally has been insufficient. We estimate that the annual landed catch of walruses in eastern Greenland ranges between 15 and 25 animals. With an overall loss rate of 23% (see below), the total annual kill would be approximately 20 to 30 walruses.

Hunting loss: Losses are not well documented. Dietz (pers. comm. 1986), who witnessed the kill of three walruses during the spring hunt, suggested that an overall loss rate of about 30% appeared likely. Three of nine walruses killed during April 1983 at Cape Swainson (entrance to Scoresby Sound) sank and were lost (Born 1983). Information about the fate of 23 walruses killed during the spring hunt in 1986-1988 (J. Thygesen pers. comm. 1988) indicates a loss rate of about 17% (four lost of 23 killed). Hence these observations, combined, indicate that the overall loss rate is about 23 %.

Catch composition: We have no information about the composition of the catch south of Scoresby Sund. The majority of the catch in the Scoresby Sund area consists of old males (J. Thygesen pers. comm. 1988, Born unpubl. data; but see Fig. 44). This catch composition presumably reflects the general distribution of walruses in

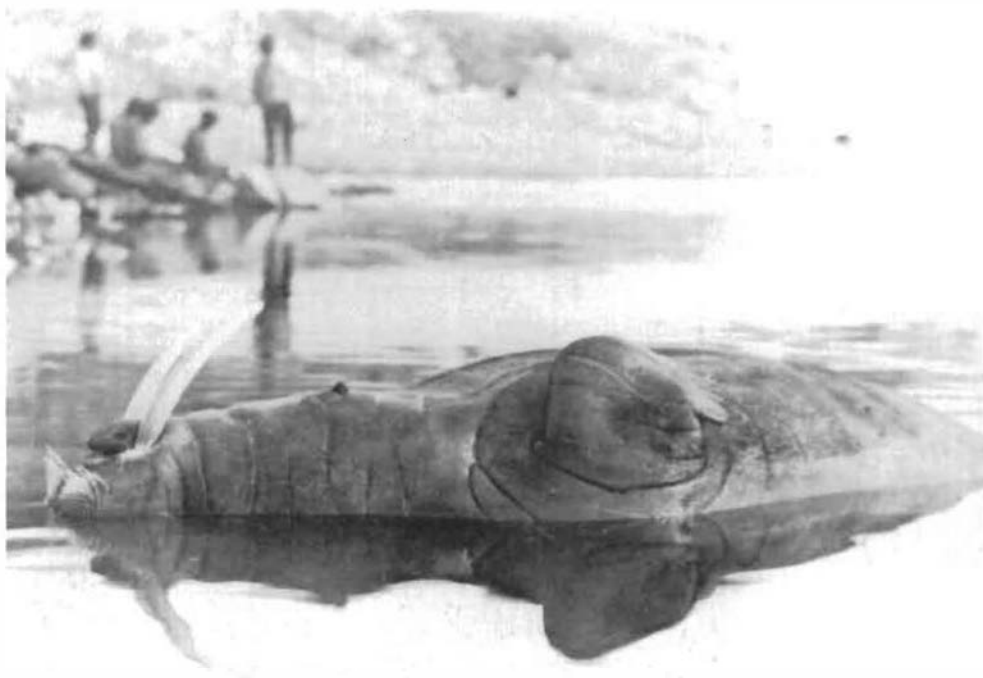

Fig. 44. Greenlanders waiting for low tide so that they can butcher an adult female walrus killed near the settlement of Scoresbysund in the mid-1920s. Note the plug in the throat. After the walruses were killed the Greenlanders would often inflate the carcasses, through a hole in to the lungs, to make them float. Thereafter the hole was plugged to prevent the air from escaping. Photo: A. Pedersen

northeastern Greenland, with the males occurring farther south than the females.

7. Svalbard – Franz Joseph Land

Little is known about the walruses of the western European Arctic. Recent studies have been undertaken in Svalbard, and in parts of Franz Joseph Land, but recent scientific information on walruses from the Russian Arctic is largely non-existent. However it is clear that walruses in all areas of their European Arctic range were over-harvested up to the mid 1950s. The result was that they were virtually exterminated in several of these areas. In Svalbard they were more or less exterminated, but there were apparently still a few hundred left in Franz Joseph Land (Norderhaug 1969). The largest remaining groups were probably in the Franz Joseph Land – Kara Sea area. Today there are signs, at least in Svalbard and the White Sea area, that walruses are recolonizing their former distribution area.

Distribution and Stock Identity

Places mentioned in the text are shown in Fig. 45. Summer and winter distributions are shown in Figs 46-47, respectively. Locations of uglit are depicted in Figs. 48-49.

Walruses were once very abundant in the Svalbard archipelago. However three and a half centuries of commercial exploitation had caused the

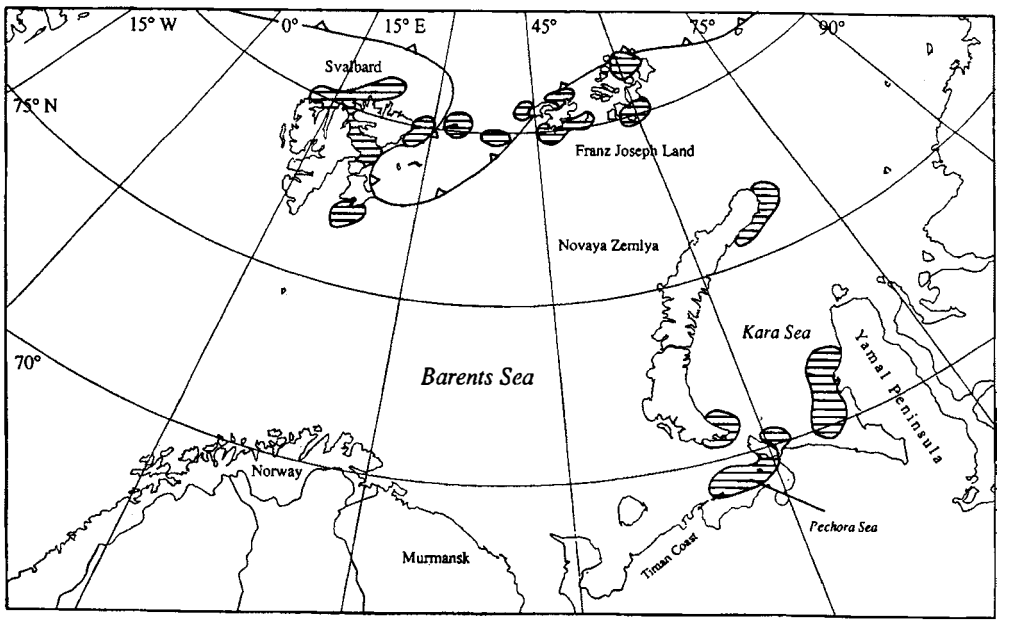

Fig.46. Approximate summer distribution of walruses in the Norwegian High Arctic and western Russian Arctic. A generalized picture of the extent of the polar pack ice is indicated.

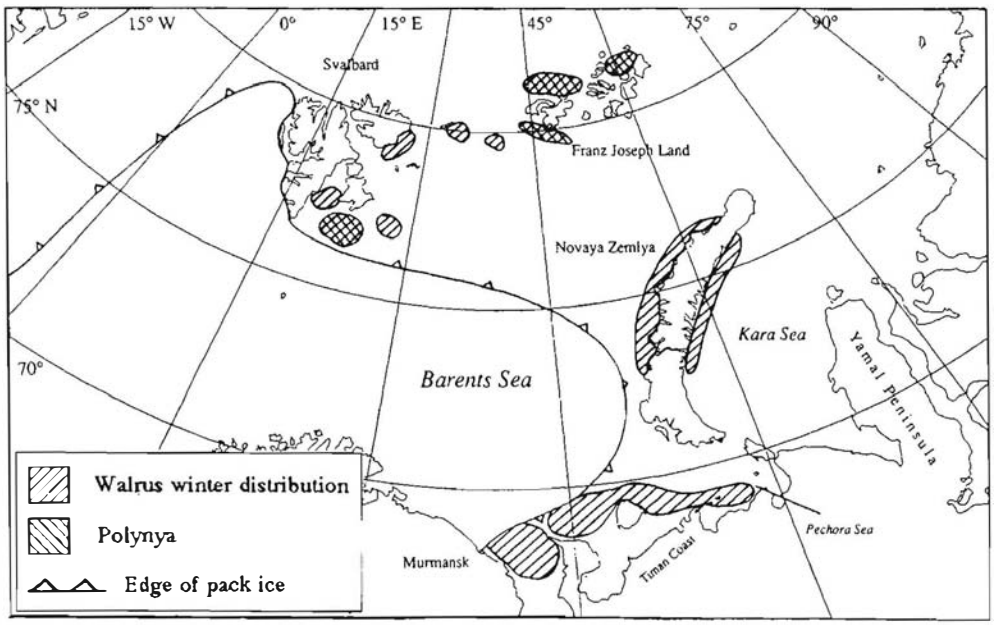

Fig. 47. Approximate winter distribution of walruses in the Norwegian High Arctic and western Russian Arctic. Several wind-driven polynyas exist in these parts of the Arctic. The walrus wintering areas are not well known, but walruses are thought to winter in these polynyas. The approximate position of the pack ice edge during winter is indicated.

walrus to be on the verge of extinction in this region when it finally was totally protected in 1952 (Norderhaug 1969). The hunting started in the most accessible parts of the archipelago, but as catches declined the hunters pushed further and further into the more remote parts of Svalbard (Lønø 1972). Lønø (1972) postulated, based on catch statistics, that the Svalbard stock must have consisted of partially stationary groups that had some contact with each other. This would explain why walruses still could be found in the more remote parts of the archipelago after they had been exterminated along the western coasts. Lønø (1972) found no indication of an annual migration between the northeastern parts of Svalbard and Franz Joseph Land.

In the 1970s walruses started reappearing in Svalbard. Born (1984) concluded, based on opportunistic observations and surveys between 1954 and 1982, that about 100 walruses, primarily bulls, summered in Svalbard. He suggested that the observations indicated that Svalbard was in the process of being repopulated by dispersal of the popul-

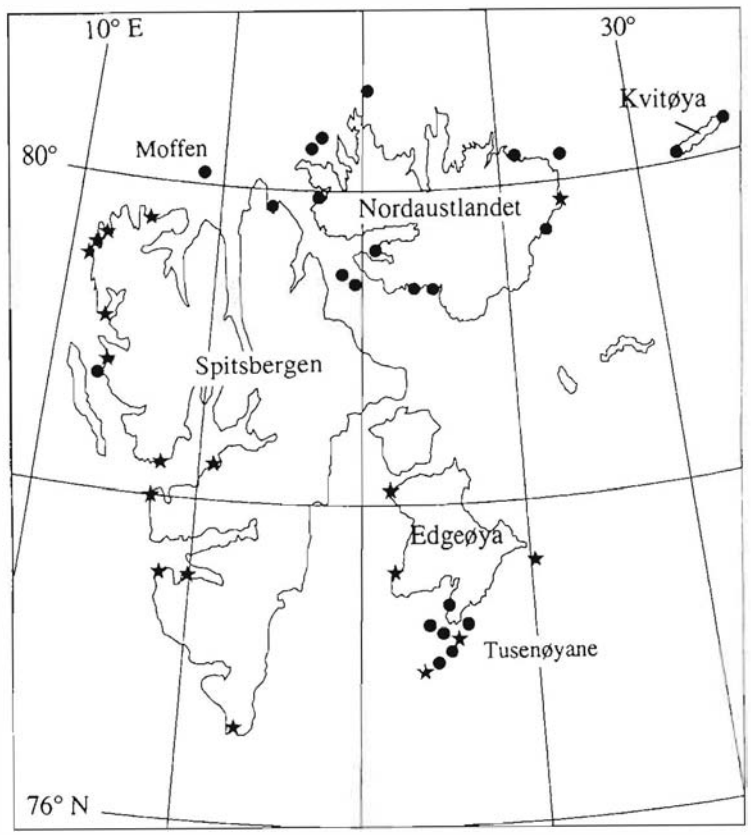

Fig. 48. Locations on Svalbard of walrus haul-outs still and formerly used. Little information was available to the authors concerning haul-outs in the Russian sector of the Atlantic walrus's range. Legend: Black dots = haul-outs still used by walruses. Stars = Abandoned.

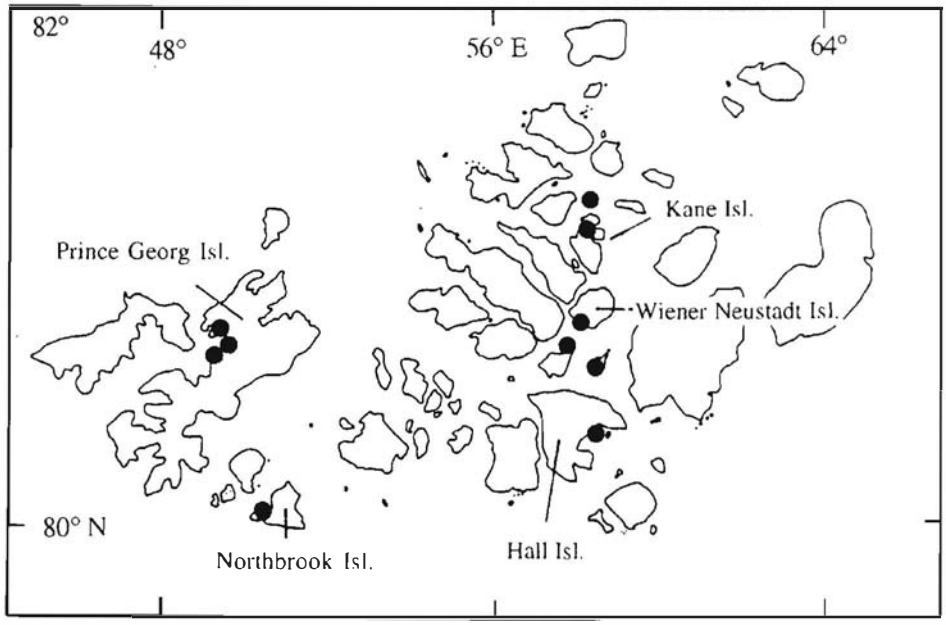

Fig. 49. Locations of haul-outs presently used by walruses on Franz Joseph Land.

ation centered at Franz Joseph Land.

Franz Joseph Land had a large walrus population when the archipelago was discovered in 1873. Because ice conditions were much more severe at Franz Joseph Land this group of islands was much less accessible than Svalbard. At Franz Joseph Land walrus hunting therefore first became significant around the turn of the century and it lasted until the early 1930s (Gjertz *et al.*1992). Harvests of walruses in Franz Joseph Land continued on a limited basis until 1953 (Lønø 1972). Atlantic walruses were totally protected in Russian waters in 1956 (Beloborodov and Timoshenko 1974). The distribution of walruses in Franz Joseph Land was described and mapped by Gjertz *et al.*(1992).

Based on ground and aerial surveys Gjertz and Wiig (1994) showed that walruses in Svalbard today are predominantly males (Fig. 50), although some females and calves are present in the northeasternmost part of the archipelago. Cows and calves were found to be abundant in the western part of Franz Joseph Land (*Ibid.*). It was therefore concluded, in concordance with Born (1984), that the majority of walruses in Svalbard in summer are males that probably belong to a common Svalbard – Franz Joseph Land stock.

In the period 1990 to 1993 thirty-four walruses (28 at Svalbard and six at Franz Joseph Land) were fitted with satellite-linked radio transmitters in order to study their movements. All of the instrumented animals were adult males except for one adult female caught at Franz Joseph Land (Gjertz

Fig. 50. In some parts of Svalbard, like here at Kalvøya, male walruses haul out as much as several hundred meters from shore.
Photo: I. Gjertz.

Fig. 51. More than 500 walruses hauled out on Kræmerpynten (Kvitøya, Svalbard) on 23 July 1984. Photo: L. Åby.

and Wiig 1993, Knutsen 1993, Wiig *et al.* in press). The results of the satellite trackings showed that male walruses move among most of the walrus areas in Svalbard and Franz Joseph Land. In particular, it seems that movement by males from southern Edgeøya to Kvitøya (Fig. 51), Victoria Island and Franz Joseph Land (Fig. 52) is common. The walruses winter in the southern parts of Svalbard as well as within the pack ice off north-eastern Svalbard. The only walrus at Franz Joseph Land that was followed until mid winter stayed in the same area. This observation supports the view that walruses also winter there. The results of the telemetry support the hypothesis of Born (1984) that the majority of walruses in Svalbard are males from a common Svalbard-Franz Joseph Land stock (Wiig *et al.* in press).

It is important to bear in mind, however, that walruses in both archipelagos, but especially in Svalbard, constitute a recovering population. The current distribution and behavior therefore very likely differ from that found in former times when walruses were abundant in these areas.

Population Size

The pre-exploitation size of the walrus population in the Barents and Kara seas is not known, but Fedoseev (1976) concluded that it could not have numbered less than 70 to 80 thousand animals.

Fig. 52. Walruses hauled out on the ice off the ugli on Appolonoff Island (Franz Joseph Land) in August 1992. Photo: L.Ø. Knutsen.

During the period 1989-1993 walrus haul-out sites in Svalbard were mapped, and age and sex composition at the haul-outs was determined (Gjertz and Wiig 1995). Aerial surveys were conducted in 1992 and 1993. The results of the surveys indicate that at least 723 males are present in Svalbard during summer. The bulk of the females and calves associated with these males are believed to be in Franz Joseph Land. Assuming a 1:1 sex ratio in the population, the Svalbard – Franz Joseph Land stock of walruses is therefore thought to number 2000 individuals. This is a conservative estimate, and the actual number is believed to be considerably higher. This is because undoubtedly some walruses in Svalbard were not counted, and because no survey has been conducted in Franz Joseph Land, where males, in addition to those counted in Svalbard, may be found.

In Svalbard three possible threats to the walrus population can be identified: conflicts with fishing interests, especially scallopers, disturbances by tourists, and planned petroleum development.

Exploitation

See under stock 8.

8. Kara Sea – Southern Barents Sea – Novaya Zemlya

Distribution and Stock Identity

Walruses are believed to have been more or less resident along parts of Finnmark (northern Norway) in former times (Lund 1954), but they were exterminated there. Today only stray individuals are encountered along the Norwegian coast and farther south in Europe, and these are believed to come from Russia or Svalbard (Lund 1954, Brun *et al.* 1968, Born 1988, Gjertz *et al.*1993).

Historically there was a large trade in walrus ivory between northern Russia and both Europe and the Muslim world. This ivory came predominantly from the White and Pechora seas (Chapskii 1939, Storå 1987).

Popov *et al.* (1990) reviewed information on the former distribution areas in the White Sea. Timoshenko and Popov (1990) indicated when and where walruses have been observed in the White Sea in recent years. Most observations have been in the Funnel, *i.e.* the northernmost part of the sea. Belkovich and Khuzin (1960) claimed that these animals usually have been young, with tusks of 20 cm length or longer (*sic!*). Popov *et al.* (1990) stated that the animals usually are encountered in pairs or as single individuals. They believed that the regular occurrence of walruses in the White Sea, though small in numbers, reflected the inclination of animals to return to their former habitat. Thus according to these authors there is good reason to believe that the Funnel of the White Sea is now a normal part of the walrus's range. Born (1988) suggested that an increase since about 1970 in the number of walrus stragglers appearing along the western coasts of Norway and the European continent perhaps reflected an expansion of the range of the population(s) in the western Russian Arctic.

According to Popov *et al.* (1990) walruses occur in the southeastern part of the Barents Sea throughout the year, though numbers are small. The most frequent occurrences are off the Timan coast near Gulyaevskie Koshki and near Kolguev and Matveev islands.

Beloborodov and Timoshenko (1974) mentioned several observations of herds of walruses in this area, also in mid winter. One of the herds (55 individuals) consisted of adults, subadults and calves. Lukin (1978) observed walruses on 4 January 1977 near Gulyaevskie Koshki islands in northern Pechora Bay. Quite remarkable was the observation of six adults with what were thought to be newborns. Lukin (1978) suggested that the period of birth in this area was late December-early January. The total number of walruses wintering in the southeastern Barents Sea was estimated not to exceed 100-120 animals. Haug and Nilssen (1995) reported observations between 5 and 17 February 1993 of a total of 138 walruses (including 21 mother-calf pairs) along the northeastern coasts of the Kanin Peninsula and in the western Pechora Sea. These observations suggest that the Pechora Sea is a wintering area for walruses from the Barents and Kara seas.

Walruses in the Kara Sea and Novaya Zemlya region are believed to belong to a stock that is distributed over a larger area; the animals presumably migrate into and out of the Kara Sea.

Arsenev (1976), based on Chapskii (1936), described in detail the supposed seasonal migrations of walruses in the Kara Sea as follows: Atlantic walruses inhabiting Russian waters in winter and spring are situated mainly in the southeastern part of the Barents Sea. In October they haul out on the coast in the vicinity of the Kara Entrance. With the formation of ice, the animals move onto the ice. Possibly in June the walruses abandon this area. They enter the Kara Sea via two routes – through the Kara Entrance and around the north end of Novaya Zemlya. The animals that pass through the Kara Entrance are found in the second half of July

and in August inhabiting the ice along the west coast of Yamal Peninsula. Under the influence of easterly winds in August, the ice goes out from there, and the walruses withdraw with it. In October these animals appear on the southern coast of Novaya Zemlya, near the Kara Entrance. There they congregate on coastal haul-out sites until freeze-up. The other walruses, which migrate northward with the ice, around the end of Novaya Zemlya, are found on the floating ice in nearshore waters in July and August. Toward September, when the drifting ice breaks away from the coast of Novaya Zemlya, these animals begin to concentrate very close to shore, usually at the northeast end of the island. There they form herds on shore in the area from Oransk Islands to Cape Sporyi Navolok. Probably new ice begins to form on the north coast of Novaya Zemlya by October. At this time the walruses vacate the nearshore waters, transfer to the drifting ice, and pass with it into the Barents Sea. There they proceed along the west coast of Novaya Zemlya, and by the end of the month reach their winter habitat in the southeastern Barents Sea.

Other authors have suggested that walruses in the Kara Sea – Novaya Zemlya area also migrate to other areas. Tsalkin (1937) suggested, based on differences in the sexual composition of groups of walruses in Franz Joseph Land and Novaya Zemlya, that they belong to a widely distributed population inhabiting the waters of the European Arctic. On the other hand Popov *et al.* (1990) suggested that walruses from the Pechora Sea move into the Kara Sea in summer.

The eastern distribution of walruses in the Kara Sea is somewhat unclear. According to Ivashin *et al.* (1972) walruses are observed on the drift ice in the region of the small arctic islands lying south and southeast of Franz Joseph Land (Vize, Ushakova and Schmidt islands). Further east at Severnaya Zemlya they are more rarely seen (*Ibid.*). Bychkov (1975) claimed that these were Atlantic walruses. According to Arsenev (1976) walruses at Severnaya Zemlya are mostly found on the east side of the archipelago; and in the Laptev Sea walruses are principally found in the western parts along the eastern Taimyr coast and near the Lena Delta. According to Chapskii (1936) walruses in the Laptev Sea form a subspecies (*O. r. laptevi*) which morphologically is intermediate between the Atlantic and Pacific subspecies. The taxonomy of the walruses in the Laptev Sea is, however, still disputed (see Fay 1981, 1982, 1985). Chapskii (1936) believed that the ranges of the Laptev and Atlantic walruses met at Severnaya Zemlya and western Taimyr, but that the animals near Vilkitski Strait (between Severnaya Zemlya and the mainland coast) were predominantly Laptev walruses. S. Belikov (pers. comm. 1994) confirmed that walruses in western Severnaya Zemlya are Atlantic walruses whereas those found in the eastern part of the archipelago and southward past Vilkitski Strait are Laptev walruses. Presently available information is, however, insufficient to determine whether these walruses have separate geographical distributions or are morphologically distinct.

Population Size

According to Lukin (1978) the total number of Atlantic walruses wintering in 1977 in the south-eastern Barents Sea apparently did not exceed 100-120. The number of walruses observed in the southern Barents Sea has increased in recent years (Popov *et al.* 1990, Haug and Nilssen 1995), and Lukin's (1978) figure is probably too low. Popov *et al.* (1990) referred to an observation of a herd of 100 animals, which can be interpreted as confirming that there are well over 120 walruses in the Barents and Pechora seas.

No new population figures are available for the Kara Sea – Novaya Zemlya region and all estimates are outdated. Chapskii (1936) estimated that there were no more than 1200-1300 walruses in the Barents and Kara seas in the mid-1930s. Popov (1960) estimated the stock to be 2000-2500 off the northern extremity of Novaya Zemlya and in Franz Joseph Land in 1952-55. According to Bychkov (1975) the Novaya Zemlya stock consisted of no more than 400 animals in 1969-1970. According to Popov *et al.* (1990) there are 1500-1700 walruses in the northern Novaya Zemlya – Franz Joseph Land area. This, however, is the same figure that has been presented previously (Nazarenko and Timoshenko 1983, Timoshenko 1984).

Bychkov (1975) and Popov *et al.* (1990) suggested that predation by polar bears may be one reason for the decrease in numbers and poor recovery of the walrus population in the western Russian Arctic. They also cited anthropogenic factors, such as industrial development in the haul-out areas, year-round shipping, petroleum and gas development and poaching as possibly contributing to the situation. One additional threat to the walrus population is the large amount of nuclear waste that has been dumped into the Kara Sea and west of Novaya Zemlya.

Exploitation (Stocks 7 and 8)

Walruses in Norwegian waters, including Svalbard, became totally protected in 1952 (Anon. 1952; see

Fig. 53. Numerous skulls and bones on the beach at Kapp Lee (Edgeøya, Svalbard) in 1982 bear witness to the massive slaughter of walruses by European hunters in former days. Photo: E.W. Born.

also section Regulations; Fig. 53). In Norwegian waters poaching is not very likely to occur since walruses are relatively scarce and are mostly found in inaccessible and uninhabited parts of the Svalbard archipelago. Moreover well-equipped law enforcement authorities patrol the main areas of walrus distribution on a regular basis. Walruses were given complete protection in the Northeast Atlantic Arctic in 1958 (see section: Regulations). Poaching may, however, be somewhat of a problem in Russia. Since the collapse of the Soviet Union law enforcement has been slack in the arctic areas, and Russian scientists admit that poaching, especially for polar bears and walruses, takes place. Frantzen (1992) documented one case of poaching in Franz Joseph Land, but other cases are also known. The size of this illegal hunt in Russia is not known.

One of the authors (Gjertz) has been contacted both by private persons and by foreign governmental agencies regarding offers from Russian sources in the Murmansk Region, Russia, to provide walrus calves for the international market. No such sales are known to have taken place, but the fact that offers have been made suggests that certain parties can and will provide illegally caught walruses. This can be viewed as a part of the large illegal trade in protected wildlife which has flourished in Russia since the collapse of the Soviet Union.

REGULATIONS

Uncontrolled hunting led to the depletion of Atlantic walruses in nearly all areas of their range. Regulations were introduced, belatedly, to control the hunting and to protect the walruses from extermination.

In Canada regulations intended to conserve the stocks of walruses have been in force since 1928 and have been amended numerous times (see Mansfield 1973, Reeves 1978, Richard and Campbell 1988). The regulations limit hunting mainly to indigenous people. Under the Marine Mammal Regulations only licensed hunting is permitted, but Indians and Inuit are allowed to take up to 4 walruses (per person per year) without a license "for food, social or ceremonial purposes" (Government of Canada 1993). In addition there is an annual quota system for four settlements: Coral Harbour, Sanikiluaq, Arctic Bay and Clyde River. These communities have annual quotas of 60, 10, 10 and 20, respectively (Government of Canada 1993).

As mentioned by Richard (1993) the Nunavut Land Claim agreement has changed some aspects of walrus management in Canada. The Nunavut Wildlife Management Board and its constituent Regional Wildlife Organizations, which consist of representatives of local Hunters and Trappers Associations, "will have considerable influence in shaping every aspect of management and conservation of Canadian walrus populations" (Richard 1993:18).

The Marine Mammal Regulations include a reporting requirement stating that a hunter must keep a record of his catch for two years and report this to a fishery officer "when requested to do so." The record is supposed to include the date and location of the catch, the animal's sex and its colour (!) (Government of Canada 1993). Catch data for settlements in northern Québec are supplied to the Department of Fisheries and Oceans through a contract with Makivik Corporation (S. Olpinski pers. comm. 1995).

Regulations for walrus hunting in Greenland were reviewed by Born (1990) and Born *et al.* (1994a). The latest amendments to the regulations were made in 1994 (Anon. 1994b).

The walrus hunt in the Avanersuaq (Thule) area has been regulated since the late 1920s (Rasmussen 1929). The present hunting regulations are essentially unchanged. It is permissible to hunt walruses at any time. While there is ice cover, shooting at walruses is not permitted before they have been harpooned. It is permitted, however, to shoot at walruses that appear in small leads or cracks in the ice, where they can then be harpooned. During the open-water season, it is not permitted to shoot more walruses than can be transported back to the hunter's home. Walruses are not allowed to be shot in the head before they have been harpooned. Hunters are permitted, however, to shoot at walruses before harpooning if the walruses are swimming along the ice edge, where they can be dangerous.

In Central West Greenland, changes in walrus hunting practices, and in particular the high catches in 1937, led to a discussion in the Local Political Council (Landsrådet) where it was proposed to regulate the walrus hunt. However, hunting regulations were not introduced until 1949 when walruses in the West Ice were protected between 20 May and 31 December. New hunting regulations came into force in 1956. Originally walruses were not allowed to be hunted at the uglit of Kitsissut and Aarfiit in Kangaatsiaq municipality between 15 October and 31 January. This paragraph was, however, canceled in 1959. The regulations were amended in 1978 and 1994 (see Born 1990 and Born *et al.* 1994a for reviews of regulations before 1994). According to the 1978 amendments, there was no quota for boats smaller than 40 tons, but after 1978 boats larger than 40 tons were permitted to catch five walruses per year. By the 1994 amendments boats above 40 tons are no longer allowed to catch walruses (Anon. 1994b). According to the latest regulations (*Ibid.*) the hunting of walruses in Greenland is only permitted to licensed persons resident in Greenland. Between 1 June and 31 December the take of walruses between 66°N and 75°N is prohibited. Between 1 April and 31 December females and young are protected in the same areas. All walruses are protected in western Greenland south of 66°N. Only vessels less than 40 tons and dog sleds can be used for hunting walruses. There are restrictions concerning the types of weapons and bullet types that can be used. It is stated explicitly that wounded walruses must be harpooned before they are killed. Municipal councils can, if they desire, place further restrictions on walrus hunting. It is now mandatory that hunters report the catch (number, sex, age, date etc.) (Anon. 1994b). According to a special regulation (Anon. 1990d) the hunting of walruses is allowed in the municipality of Kangaatsiaq between 1 February and 14 October. This regulation was not included in the recent amendment.

In 1938 hunting regulations were made for the Danish trappers working for the company "Nanok" in Northeast Greenland primarily north of 73°30' N. According to these regulations, the hunting of walruses at uglit or within 1 km of such sites was not allowed. Care was to be taken to ensure that

only walrus bulls were hunted. Females with calves were to be fully protected. All walruses became completely protected in 1956 in all areas of East Greenland north of the Scoresby Sound area (*i.e.* north of approx. 72° N; Anon. 1938, Born 1990).

In 1952 the walrus was given complete protection within Norwegian territory and walrus hunting by Norwegian citizens in other areas was prohibited (Anon. 1952, 1959, Øritsland 1973). In 1973 about half of Svalbard was included in nature reserves and national parks (*e.g.* Mehlum 1989). These areas include a major part of the walrus habitat.

Since 1921 various steps have been taken to regulate and minimize the harvest of Atlantic walruses in Russian territory (Bychkov 1973). In 1935 the harvest from sealing vessels run by the Soviet State ceased and in 1949 the killing of walruses by the fishing and sealing industry was prohibited. From 1956 hunting for Atlantic walruses was banned for all Soviet citizens, excluding a limited harvest by native peoples for subsistence purposes and by expeditions.

The Norwegian-Soviet Sealing Agreement of 1958 (Anon. 1959), which applies to northeast Atlantic waters east of Cape Farewell (*i.e.* southern tip of Greenland), also includes provision that the catching of walruses is forbidden throughout the year. This agreement thus confirms both the Soviet total prohibition of walrus hunting in the western Russian Arctic since 1956 and ship-borne hunting of Atlantic and Laptev walruses in 1935, and the Norwegian total protection since 1952 (Øritsland 1973).

In 1971 the Novaya Zemlya population of Atlantic walruses was included in the list of Rare Animals of the USSR (Bychkov 1971, 1973). In 1994 Franz Joseph Land became a national park (zapovednik), and most of the walrus habitat in this archipelago is therefore officially protected.

At Canada's request the walrus was included in Appendix III of the Convention on International Trade in Endangered Species of Fauna and Flora (CITES), beginning in 1975. The walrus is included in Appendix II of the Convention on the Conservation of European Wildlife and Natural Habitats of 1979 (the Bern Convention; Born 1992).

ANTHROPOGENIC EFFECTS APART FROM THOSE DUE TO HUNTING

Like other wildlife, walruses are affected by many human activities other than those involving their deliberate killing. In this section we identify the human activities, apart from hunting, that are known or suspected to have negative impacts on walruses, and we review the available evidence concerning the nature and degree of these impacts on populations.

Disturbance from different sources of noise

Various sources of disturbance that might affect walruses and the potential consequences of such disturbance have been listed previously (*e.g.* Mansfield 1983, Anon. 1990c, 1993b, U.S. Fish and Wildlife Service 1993). In the present review we consider only the potential effects on walruses of in-air and underwater noise from aircraft, ships, off-shore drill-sites and seismic activities. Potential negative effects of noise on walruses include: 1) trampling of calves during stampedes, 2) insufficient rest, increased stress and energy expenditure, 3) insufficient suckling of calves, 4) interference with feeding, 5) masking of communication and 6) impaired thermoregulation in calves that spend too much time in water. Few studies have actually addressed questions about disturbance of walruses.

Walruses react to man-made disturbance by an escape response, presumably triggered by visual, auditory and olfactory cues (Loughrey 1959). The walrus's senses of smell and hearing are keen, whereas its vision is not particularly good (Loughrey 1959, Fay *et al.* 1984, Kastelein *et al.* 1993a, b). Walruses are highly vocal both in air and underwater (*e.g.* Ray and Watkins 1975, Miller and Bonness 1983). During the mating season in late winter and early spring, walruses use a complex array of vocalizations underwater. Displaying bulls produce sounds such as rasps, clicks, bell tones, strums etc. to attract females in estrous (*e.g.* Stirling *et al.* 1987). Most calls are within a frequency range of 50 Hz to 4 kHz. These sounds are transmitted underwater up to at least 10 km (*e.g.* Stirling *et al.* 1987, Anon. 1991). Underwater acoustic studies off Round Island (Alaska) indicate that walrus vocalizations can raise calm-water ambient noise levels by 11 dB (USFWS 1991 unpubl. data *fide* Anon. 1991). A study of the hearing ability of walruses in the wild indicated that they are sensitive to sounds between 250 Hz and 4 kHz. (Kastelein *et al.* 1993b).

The intensity of a walrus's reaction to human-made noise can be highly variable, and in some cases walruses may even be attracted by human presence (Fay *et al.* 1984, Anon. 1993b). Factors such as sex and age of the animal, the size and location of its group (on ice, in water, on land), distance from the disturbance, the type and intensity of the disturbing factor, the animal's previous experience with disturbance, the weather and the animal's behavioral state (*e.g.* hauled out in sunny weather and drowsy) can all affect its responsiveness. On ice or on shore, male walruses tend to be less shy than females, and solitary individuals tend to be less shy than groups. Females with calves appear to be most sensitive to disturbance (*e.g.* Salter 1979, Miller 1982, Fay *et al.* 1984).

Aircraft traffic: Richardson *et al.*(1989) and Davis *et al.*(1990) summarized information about marine mammal reactions to noise and concluded that seals and walruses were probably the most susceptible to disturbance by aircraft.

The sound and sight of an aircraft moving rapidly overhead appear to be particularly disturbing to walruses (*e.g.* Fay *et al.* 1984). Studies of walrus reactions to aircraft noise (Salter 1978, 1979, Fay 1981, Fay *et al.* 1984, Born and Knutsen 1990 c) have shown that the response varies with aircraft type, range, flight pattern, altitude and environmental factors such as, for example, wind speed and wind direction. The reactions of the walruses also depend on age and sex, group size and behavior (*e.g.* Salter 1978, 1979, Fay 1981, Orr *et al.*1986). Usually walruses that are hauled out react by lifting the head when the noise from a helicopter or other aircraft becomes audible to humans. An acute escape response, with animals fleeing into the water, is usually not observed until the aircraft is within 1-2 km of a group. However, there are exceptions to this, and in certain cases walruses can be scared by helicopter noise and escape into the water when the helicopter is even further away (Gjertz, unpubl. observation). Adult females, calves and subadults are more likely than adult males to enter the water during disturbance. This can result in a stampede, sometimes causing calves to be crushed to death. Tomilin and Kibal'chich (1975 *fide* Fay 1981) reported how an aircraft overflight caused Pacific walruses to stampede, leading to the trampling to death of some calves and the abortion of some fetuses. The passing of an aircraft at 800 m altitude over an ugli on Wrangel Island caused a stampede in which 102 walruses of all age and sex classes died. Many traumatized animals that were able to leave the ugli died later (Ovsyanikov *et al.*

1994). To reduce disturbance, overflights of most walrus haul-out sites in Russia are prohibited within 50 km except by special permit (U.S. Fish and Wildlife Service 1993).

Smith *et al.* (1979) noted that direct observations of walrus responses to aircraft flying over haul-out areas, disturbance by boats, and chronic disturbance by the construction of DEW (distant early warning) line sites and associated activities near haul-out areas all point to the sensitivity of walruses to any change in their environment. Chronic disturbance may lead to permanent abandonment of an ugli (Gol'tsev 1968, 1975 *fide* Fay *et al.* 1984). Richardson *et al.* (1989), however, stated that some walruses that were exposed to repeated aircraft disturbance at haul-out sites close to airstrips, *e.g.* at Cape Lisburne (Alaska), seemed to become more tolerant of the aircraft noise, *i.e.* they became partially habituated.

Vessel traffic: Walruses usually do not react to small boats with outboard engines before these are less than about 400 m away (Salter 1979, Fay 1981). However, drowsy walruses can sometimes be approached slowly to within about 10-20 m in small skiffs with outboard engines. In such cases the escape reaction often appears to be triggered by the sense of smell or sight. The reaction of the walruses is clearly related to their previous experience with skiffs. In hunted populations, *e.g.* that in Avanersuaq (Thule) in northwestern Greenland, walruses are much more skittish than they are in unhunted populations, *e.g.* at Svalbard (Born, unpubl. observations). According to Fay *et al.*(1984), Pacific walruses reacted to the icebreaking activities of a ship, starting when the ship was as much as 2 km away. These authors believed that the walruses reacted more to the sound of the ice breaking than to the sounds of the ship's engine. When the ship was 100-300 m away, male walruses on ice went into the water. Females with young usually went into the water when the ship was 500-1000 m away, apparently as a response to both the sight and the sound of the ship. Low-frequency diesel engines appear to cause less disturbance than high-frequency outboard engines (Fay *et al.* 1984). However, the opposite sometimes might be the case (Anon. 1991).

Haul-outs in Russia have been protected by regulations limiting access; the distance varies with the site but is usually 20 km (U.S. Fish and Wildlife Service 1993). It is, however, not clear from this source whether these regulations apply to all areas of Russia.

The reactions of walruses to drilling operations involving icebreaker activity were studied in the Chukchi Sea between late June and early October 1989 (Brueggeman *et al.* 1990, 1993). Walruses moved 20-25 km away from the ice-breaking operations deeper into the pack ice where noise levels approached ambient. Once the ice-breaking activities stopped or became more focused at the drill site, the walruses began returning to previously occupied areas. Under these circumstances, walruses displayed some behavioral responses which rapidly decreased at distances beyond 0.46 km from the ice breaker. They showed little response to other drilling operations. These studies demonstrated that walruses react to icebreaker activities, but responses varied according to the intensity of the ice management. According to Brueggeman *et al.*(1993) the variability of walrus responses to different activities offers opportunities to minimize disturbance to walruses during drilling and other industrial operations.

Intensive year-round ship traffic, including the use of large ice breakers in winter, reportedly has had a negative impact on walruses in the western Russian Arctic, particularly in the southern Barents Sea (Timoshenko 1984). In recent years, hunters from several villages along the northwest coast of Alaska have commented to the United States Fish and Wildlife Service that the abundance of walruses in the retreating spring pack ice declined at about the time when large ocean-going tugs arrived in the area, pulling barges of supplies destined for more northerly villages and industrial sites (U.S. Fish and Wildlife Service 1993).

See also section: Interactions with fisheries and changes in walrus food resources.

Offshore hydrocarbon exploration and operational activities: Sources of man-made underwater noise considered here include: 1) offshore drilling and production, 2) underwater "explosions" (high explosives, airguns, gas exploders and vibrators) associated with seismic activity (Davis *et al.* 1990). Seismic exploration usually involves the production of sounds with high source levels, making them audible many kilometers away. Vibroseis (use of vibration vehicles on the ice to project sounds into the water) creates low-frequency sounds with source levels greater than 185 dB (*Ibid.*).

In a study of the effects on walruses of offshore drilling, the animals were found to exhibit only weak short-term behavioral responses to the drilling activities *per se* (Brueggeman *et al.* 1990). According to Davis *et al.*(1990), detailed studies of how pinnipeds react to noise from seismic exploration have not been published, and there is little information on how they react to impulsive sounds generally. The available information is not conclusive, but

what there is suggests that, in some cases at least, seals will tolerate intense impulsive sounds, *e.g.* if they are strongly attracted to an area for feeding or reproduction.

Underwater noise could interfere with walrus mating activities in the wintering areas and thereby reduce their reproductive capacity. Fay *et al.* (1984) assumed that some inhibition of communication through garbling or "drowning out" of underwater vocalizations could take place if the noise level was high enough. Underwater noise might affect walruses in three ways: 1) by "masking" ordinary communication and thus preventing individuals from locating one another, 2) by "masking" vocalizations of displaying bulls and thereby preventing them from attracting females in estrus, and 3) by scaring walruses away from critical habitats, *e.g.* feeding banks (Anon. 1990 b,c).

Military activity : We are not able to evaluate to what extent military activity (rocket launching, explosions) in different areas (*e.g.* southern Barents Sea) may have adversely affected walruses.

Pollution

Oil spills etc.: Oil and gas exploration and development pose several potential risks to walruses and their habitat: 1) harassment, such as stampede induced by noise etc. from ships, seismic activities and installations, or crushing from direct contact with ships, 2) negative effects of noise (for example masking of communication), 3) contact with or ingestion of oil from oil spills etc., 4) damage or destruction of essential habitats, such as haul-out sites and feeding banks, from oil spills.

Potential risks associated with items 1 and 2 are discussed elsewhere in this report, and only items 3 and 4 are considered here.

Documented and hypothetical effects of oil spills on marine mammals have been reviewed by, for example, Griffiths *et al.* (1987), Richardson *et al.* (1989), and Boertmann *et al.* (1994). However, as far as we know, no studies have specifically addressed the direct or indirect effects of oil on walruses, and little specific information is available. Speculations and hypotheses about the potential impact of oil spills on walruses were given in Anon. (1990c).

Studies of seals have shown that surface contact with oil causes stress, and temporarily irritates the eyes and skin. Some studies have indicated that ingestion of oil leads to physiological and chemical changes, but most evidence of internal organ and tissue damage from oil ingestion by seals is inconclusive (see review by Richardson *et al.* 1989). Inhalation of aromatic hydrocarbons from an oil spill caused mental debilitation in harbor seals – *Phoca vitulina richardsi* (Frost and Lowry 1993). Walruses exposed to an oil spill are likely to show some of these reactions. However, walruses depend almost entirely on blubber to minimize heat loss. Their sparse pelage presumably is of little value as insulation, and their skin is thick and very tough (Fay 1982). It is therefore unlikely that exposure of the skin to oil would have any appreciable thermal effect except in newborn walruses. Perhaps the oiling of newborns that have not yet accumulated a thick insulating blubber layer would affect their ability to keep warm. Consequently, oil spills during the walrus calving season (May-June) in areas where females and young are present could, theoretically, have a greater adverse impact than spills at other times and in other areas.

Richardson *et al.* (1989) stated that hair seals (Phocidae) often do not actively avoid spilled oil, but Burns and Frost (1979 *fide* Richardson *et al.* 1989) mentioned circumstantial evidence that some bearded seals (*Erignathus barbatus*), ringed seals and walruses avoid waters that have been contaminated by fuel.

We believe that some features in the ecology of walruses make them more vulnerable to the harmful effects of spilled oil than are many other marine mammals:

1) Due to the high level of gregariousness in walruses, an oil spill that affects one would be likely to affect at least several individuals.
2) Their pronounced thigmotactic behavior on ice and on land makes it likely that oil-fouled walruses will rub oil onto the skin or into the eyes of other individuals.
3) Walruses tend to inhabit coastal areas and areas of relatively loose pack ice. Spilled oil is likely to accumulate in just such areas (Griffiths *et al.* 1987). Walruses therefore have a high risk of being fouled not only in the water but also when they haul out on land.
4) Because they are benthic feeders, walruses may be more likely to ingest petroleum hydrocarbons than are most other pinnipeds. Benthic invertebrates are known to accumulate petroleum hydrocarbons from food, sediments and the surrounding water (see Richardson *et al.* 1989, Anon. 1990c). Mortality of several species of benthic invertebrate, including bivalve mollusks, has been observed as a direct effect of oil spills (North 1967, Percy and Mullin 1975, both *fide* U.S. Fish and Wildlife Service 1993). Furthermore, sub-lethal effects on the behavior,

Fig. 54. A walrus devouring a ringed seal on the ice at Kong Karls Land (Svalbard) on 24 July 1991. It is suspected that the high levels of chlorinated hydrocarbons found in some walruses are related to their seal-eating habits. Photo: M. Forsberg.

physiology, and productivity of benthic mollusks may result from exposure to petroleum products (Clark and Finley 1977). The implications for walruses may be serious since contaminants in their food are certain to build up in their own tissue. Also, if oil contamination were to reduce the biomass or productivity of the invertebrate communities that sustain walruses, there would obviously be some secondary impact on the walruses themselves. However, information about population dynamics of marine mammals and the effects of oil on prey species is generally too incomplete to allow a meaningful assessment of the potential indirect long-term effects of oil spills (for a review see also Richardson *et al.* 1989).

5) Walruses are stenophagous (*i.e.* narrow feeding niche) and depend on access to mollusk banks in shallow water. Oil spills in certain feeding areas could force walruses to seek alternative food or relocate to other feeding areas. It cannot be assumed that alternative types of food or feeding areas are actually available, however, so such a scenario could prove detrimental to the walruses.

Activities associated with oil and gas exploration are now occurring in many areas inhabited by Atlantic walruses. In some areas these activities are large-scale. For example, around Svalbard there has been extensive offshore exploration for oil since the early 1980s (Moe 1994), and exploratory drilling is presently underway a little south of Bjørnøya. The feasibility of exploitation on the Spitsbergen Banke between Bjørnøya and the island of Hopen is being evaluated, and exploitation is expected to begin before the end of this century. One of the world's largest fields of liquified natural gas, the Stockmann Felt, is in the Barents Sea (Gjertz, unpubl. information).

In the western Russian Arctic there are large oil and gas fields in the southern Barents Sea from the White Sea northeast to southern Novaya Zemlya, and along the west coast of Novaya Zemlya. Furthermore, large fields in the Kara Sea stretch eastward to the Yamal Peninsula (Anon. 1992, Moe 1994). Seismic surveys started in 1971, and exploratory drilling in 1981. There are several drilling platforms along western Novaya Zemlya and in the Kara and Pechora seas, and oil is now produced on Kolgujev Island (*Ibid.*). These oil fields overlap the summer and winter distribution of walruses and therefore large-scale petroleum activities pose a potential threat to walruses in these areas.

Problems of oil spills or leaks on land in northwestern Russia are of concern for many reasons, among them the possibility that massive contamination will eventually reach marine waters and affect marine organisms. Of special interest in this regard are the walruses in outer Pechora Bay and the nearshore southern areas of the Pechora Sea (*cf.* Haug and Nilssen 1995).

At present, there is no exploitation of nonrenewable resources in Greenland. Since 1991, however, there has been marine seismic activity related to oil exploration along the coasts north to 79°N in eastern Greenland and 77°N in western Greenland (for a review see Born 1995).

We are not aware of any offshore petroleum development activity that is occurring in the eastern Canadian Arctic in areas presently occupied by walruses.

Heavy metals and chlorinated hydrocarbons (CHCs): Two classes of pollutants have given particular cause for concern in marine mammals: heavy metals and chlorinated hydrocarbons (CHCs) (for a review see Reijnders *et al.* 1993). Few studies have been made of heavy metals, PCBs and other CHCs in walruses.

Heavy metals: The three metals which give greatest cause for concern are mercury (Hg), cadmium (Cd) and lead (Pb) (Reijnders *et al.* 1993).

Concentrations, on a wet weight basis, of Hg in Atlantic walruses from northwestern Greenland, males and females combined, were 1.78 μg/g (SD = 1.54) for liver and 0.08 μg/g (SD = 0.05) for muscle (Born *et al.* 1981).

Wagemann *et al.*(1993) reported regional differences in heavy metal burdens in Atlantic walruses sampled between 1982 and 1990 in southeastern Hudson Bay, Foxe Basin and southeastern Baffin Island. Concentrations of Pb and Hg in Hudson Bay animals (8.0 and 0.58 μg/g dry weight Pb and Hg in the liver, respectively) were approximately twice as high as those in animals from Foxe Basin. Metal concentrations, except Cd, in walrus tissues appeared to parallel those found in clam tissues. Cd levels were relatively high in liver and kidney of walruses, and the spatial trend was opposite that for Hg and Pb, decreasing toward the south. The Cd concentration in liver of walruses from Foxe Basin (on average 38 μg/g dry weight) was twice as high as that in animals from southeastern Hudson Bay. Cd concentrations in tissues of walruses from Foxe Basin were also high compared with those in other marine mammals. The concentrations of Pb and Hg in animals from southeastern Hudson Bay were unexpectedly high compared with animals from the other locations.

Mean concentrations of mercury in liver of Pacific walruses (1981-1984) were as high as 1.85 μg/g (SD=2.59) in males and 4.00 (SD=8.41) in females. Cadmium in kidney reached 66.25 μg/g in males (SD=14.78) and 44.29 μg/g in females (SD=18.80) (Taylor *et al.* 1989). Further results of this study (1986-1989), which involved only adult animals, were presented in Warburton and Seagars (1991, 1993). Analyses were completed for 23 elements. All tissues had Pb, Cd, Ar, Zn and Hg in detectable quantities. Mean Cd concentrations were 27.6 μg/g (1.0-86.7 μg/g) in liver and 166.5 μg/g (3.6-457.6 μg/g) in kidney. In kidney and liver tissues, mean Hg concentrations were four times higher and Cd concentrations three times higher than reported previously. Mean Cd concentrations exceeded levels (13μg/g) considered by the EPA (Environmental Protection Agency) to interfere with organ function in some animals. Mean Hg concentration in liver exceeded the EPA standard (1 μg/g) considered safe for human consumption. Male and female tissues differed significantly in mean concentrations of Ar (liver and kidney) and Se (liver). Warburton and Seagars (1993) were unable to assess, conclusively, the meaning of their results with respect to the health of walruses.

CHCs, chlorinated hydrocarbons: PCBs are anthropogenic chemicals. They accumulate mainly in blubber and are of concern because of their potentially harmful effects on walrus reproduction, the walrus immune system, and human health through consumption of contaminated walrus tissue (Anon. 1993b). Norstrom and Muir (1994) identified 45 PCB congeners in walruses from the Canadian Arctic, but walruses typically contain low levels of CHCs (Anon. 1993b). These generally low burdens in walruses are likely explained by their diet. Walruses appear to be more efficient than ringed seals in metabolizing PCBs, but the difference could be diet-related (Norstrom and Muir 1994). It has been suggested that the comparatively high levels of PCBs found in some individual walruses in Canada were due to these walruses' seal-eating habit (Wagemann *et al.* 1993).

Concentrations of DDT in blubber from walruses in northwestern Greenland were 0.09 μg/g (wet weight; SD = 0.13) in males and 0.05 μg/g (SD = 0.05) in females (Born *et al.* 1981). Concentrations of total-PCB in blubber were 0.36 μg/g (SD = 0.31) and 0.18 μg/g (SD = 0.12) for males and females, respectively (Born *et al.* 1981). These values are relatively low compared with those reported for Pacific walruses (Norstrom and Muir 1994) and Atlantic walruses in eastern Hudson Bay (Segstro *et al.* 1993).

Blubber from walruses in eastern Hudson Bay, Foxe Basin and SE Baffin Island was analyzed for PCB congeners and other persistent CHCs (DDT, toxaphene, chlordanes, dieldrin, mirex) by Segstro *et al.* (1993) and Wagemann *et al.* (1993). Samples from 17 of 58 individuals had concentrations of total-PCB ranging from 1 to 20 μg/g; the remaining individuals had much lower concentrations (0.05-0.6 μg/g). Especially high concentrations were found in the sample from eastern Hudson Bay. Compared with previous studies from Greenland and Alaska these levels were unexpectedly high. Local contamination was ruled out, and Segstro *et al.* (1993) suggested that the high levels of the different CHCs found in some individuals in their study might have been caused by the fact that these animals had consumed ringed seals as a significant proportion of their diet (Fig. 54).

Compared with some other marine mammals, walruses have generally low concentrations of heavy metals in their tissues, and their concentrations generally are not significantly different from those reported for other pinnipeds (Wagemann and Muir 1984). This is also the case for CHCs (chlorinated hydrocarbons). The effect of CHCs on walrus physiology and reproduction is not known, but the comparatively high concentrations of these substances reported from some individuals give cause for concern. The contamination of walruses with CHCs warrants further study.

Radioactivity and nuclear activity: Only a few studies on radioactive elements in walruses have been made. In 1968 a USAF B-52 bomber crashed in the Avanersuaq area (Thule area, northwestern Greenland). In connection with this accident plutonium was released from the nuclear bombs to the surroundings (Anon. 1970a, b). Analyses of plutonium in sediment, bivalves (including walrus food items) and other benthic organisms collected at the crash site showed values elevated from background levels (Aarkrog 1970, 1971). Therefore, there is a risk that some walruses have become, and more will continue to become, contaminated with radioactive waste through their food. Aarkrog (1970) concluded that the animals at higher trophic levels such as birds, seals, and walruses showed plutonium levels hardly significantly different from the fall-out background.

In analyses of plutonium in liver and jaw tissues of 15 and five walruses sampled in northwestern Greenland (1977-78, 1989) and Central East Greenland (1989), respectively, very low values were detected in two jaws and seven livers. In the remainder of samples, values were below detection limit (Aarkrog, Nielsen and Born, unpubl. data). However, in this study, and in that reported by Aarkrog (1970, 1971), it was unclear to what extent the walruses analyzed had actually been feeding close to areas potentially contaminated by nuclear waste.

In general, nuclear weapon tests in different parts of the world caused widespread fall-out of plutonium. However, the levels of this element and other radionucleides, such as ^{137}Cs, reported so far from marine mammals are not considered high enough to pose a health risk to the animals (A. Aarkrog pers. comm. 1995).

No information is available about the effect on walruses of the nuclear activities in the Novaya Zemlya region. Thus we have no basis for determining if these large-scale activities, some of which were within or close to walrus habitat (see Stokke 1994: 147), have affected the walrus population by contaminating the walruses or their prey. If there has been an effect, it would most likely be in the form of direct killing by the shock waves, killing by acute nuclear "poisoning", or noise disturbance.

Second-hand information from Russian sources indicates that certain walrus haul-out sites in Novaya Zemlya were deserted in the 1960s due to the nuclear testing on this island. These walruses supposedly moved to Franz Joseph Land and have not returned (Gjertz, unpubl. information). This information may be connected to Bychkov's (1975) assumption that only 400 walruses remained of the Novaya Zemlya stock , and that their numbers were declining despite total protection. Although walrus population estimates in the Novaya Zemlya region are not very reliable, there are indications that both the population in this region, and the number of terrestrial haul-outs, have decreased since the 1950s (Bychkov 1975, Timoshenko 1984, Popov *et al.* 1990).

Interactions with fisheries and changes in walrus food resources

Walruses typically feed on bivalve mollusks in shallow continental shelf waters (*e.g.* Vibe 1950, Fay 1985). They have a narrow feeding niche and are therefore forced to inhabit specific areas for a major part of the year. Fishing activities in such areas may have direct or indirect negative effects on walrus populations.

Fishing activities may affect walrus populations in the following ways: 1) a fishery can compete directly with walruses for a food resource or damage their food supply by disturbing the ocean floor, 2) fishing activities produce noise and other forms of disturbance that can cause stress to walruses.

In none of the areas occupied by Atlantic walruses are the effects of interactions with fisheries understood, although major commercial fisheries have been developed during the present century in walrus habitats off western Greenland, around Svalbard and in the Barents Sea region. Sufficient information is available only for Svalbard and western Greenland to allow us to consider potential conflicts between fisheries and walruses.

In the Svalbard area concentrations of Icelandic scallops (*Chlamys islandica*) are found between 20 and 70 meters depth. From the mid-1980s there has been an intensive fishery for Icelandic scallops on the continental slope around Svalbard (J. Sundet pers comm. 1990). In 1986, 26 trawlers (all about 2000 GRT) took scallops (*Ibid.*); in 1987, 15-20 trawlers participated in the fishery (Anon 1990b). In

the period 1985-1990, the largest trawlers took 10-50 tons of living scallops per day, and during the operations the large ships had three dredges, each up to 5 m width, in operation at the same time (J. Sundet pers. comm. 1990). This fishery peaked in 1986 and 1987 when about 720 and 4000 tons, respectively, of scallop meat (adductor muscles) was processed. Thereafter the fishery collapsed (*Ibid.*). In Svalbard most of the important walrus habitat lies within protected areas (*i.e.* nature reserves and national parks). Apart from shrimp trawling at depths greater than 100 m, trawling and dredging in these areas are prohibited. One of the best-known terrestrial haul-outs for walruses in Svalbard, the island of Moffen, is located at the center of the richest scallop banks in Svalbard. In the mid-1980s this led to a siege of Moffen by a fleet of trawlers that, whenever given a chance, violated the protected area. This activity occurred in spite of increased surveillance by the coastguard and police (I. Gjertz unpubl. information).

It is not known to what extent walruses feed on scallops. In the Canadian Arctic, Mansfield (1958) found remains of scallops (*Pecten* sp.) in four walruses; scallops were the dominant prey in two of these animals. Scallop eating by walruses in the Svalbard area, has not been documented, but Gjertz and Wiig (1992) found some indications that Svalbard walruses do eat scallops. Walruses also feed on a large variety of other benthic organisms (*e.g.* Fay 1982). According to Anon. (1990c:133) the non-selective dredging technique that was used at Svalbard radically altered the sea floor. It is therefore reasonable to assume that the large-scale dredging in and around important walrus feeding grounds in Svalbard damaged benthic communities and reduced their biological diversity. Thus walruses presumably have been affected regardless of whether they feed on scallops.

In West Greenland a small-scale commercial fishery for Icelandic scallops began in 1983. Catches have ranged from 410 tons in 1984 to 1966 tons in 1991 (Pedersen 1994). The main fishing area is between Nuuk and Disko Island. The scallop beds are located close to the coast, and the fishery is confined to summer and autumn. Icelandic scallops are usually found on hard substrate (shell gravel, gravel, stones, rocks, sand and less frequently mud) in areas associated with strong tidal currents. These are not areas where typical walrus food items are found. The relatively small size of this fishery and its spatial and temporal location indicate that it probably has had no major effect on the stock of walruses wintering off western Greenland.

In contrast, the noise caused by another intensive fishery in walrus habitat off West Greenland may have had a negative impact on walruses. Since about 1920 fishing activities have increased in western Greenland, and the development of commercial fisheries has been especially rapid since the 1960s (*e.g.* Born *et al.* 1994a). At the beginning of the 1970s trawling for shrimp was initiated in offshore areas, including parts of Store Hellefiske Banke in the Sisimiut-Aasiaat area. Walruses occur in winter and spring on this bank in areas where water depths are less than 100 m. In spring 20-25 large trawlers and some smaller vessels operate close to the edge of the West Ice (Born 1990). As soon as ice conditions permit, the fishery commences on Store Hellefiske Banke. This may be as early as March, and during April and May fishing activity increases in this area. Similarly, the large trawlers operate along the west coast of Disko in or close to walrus habitat as early as May (P. Kanneworff pers. comm. 1995).

Most underwater sounds associated with fishing vessels are generated from propeller cavitation and are in relatively low frequencies (40 Hz-4 kHz). Measurements of a medium-sized trawler's underwater sounds showed source levels of 169 dB when transiting (at 10 knots) and 157 dB when trawling (at 5 knots) (Urick 1983). Small to medium sized ships operating at full power produce sound source levels of 165-175 dB (Malme *et al.* 1989). Underwater sounds produced by vessels are within the frequency range of those produced by walruses. It is therefore possible that intense vessel noise could mask the calls of walruses and impair the efficiency of signaling between individuals (Anon. 1991). In addition to the underwater sounds, airborne sounds of various kinds are associated with fishing activities (engines, generators, deck activities etc.)

Compelling circumstantial evidence indicated that yellowfin sole (*Limanda aspera*) fishery operations were causing airborne and submerged acoustic disturbance responsible for a significant decline (up to 60%) in the number of Pacific walruses reported hauling out at Round Island, the Twins, and Cape Pierce in Alaska. Many walruses from Round Island may have moved to other haul-out areas in Bristol Bay (U.S. Fish and Wildlife Service 1993). In order to reduce the negative impact of this fishery on the walruses, a 12-nautical-mile buffer zone has been established around the Walrus Island State Game Sanctuary and Cape Pierce (Anon. 1991, U.S. Fish and Wildlife Service 1993).

LIFE HISTORY AND VITAL PARAMETERS

In order to give the reader a background for evaluating the information presented in this report about the status of Atlantic walrus populations, the life history of walruses is briefly described. We emphasize aspects that are important for evaluating information about distribution, survey results, population recruitment and trends. Fay (1981, 1982) and Born (1992) gave more thorough reviews of the biology of walruses.

Taxonomy: The walrus genus, *Odobenus*, has only one species: *rosmarus*. Two subspecies are recognized (*e.g.* Heptner *et al.* 1976, Reeves 1978, Fay 1985): Atlantic walrus, *O. r. rosmarus* (Linnaeus 1758) and Pacific walrus, *O. r. divergens* (Illiger, 1815). On the basis of morphological variation and geographical isolation the existence of a third subspecies, *O. r. laptevi* , confined to the Laptev Sea, was suggested by Chapskii (1940). This taxon has generally been accepted by Russian scientists (*e.g.* Heptner *et al.* 1976, Belikov *et al.* 1984, Vishnevskaia and Bychov 1985), but was considered questionable by Fay (1981, 1982, 1985).

Only the Atlantic subspecies occurs in the northwestern and northeastern Atlantic Arctic.

Distribution: Today the walrus has a disjunct circumpolar distribution between the latitudes of approx. 55°N and 81°N (Heptner *et. al.* 1976, Reeves 1978, Fay 1985). The Atlantic walrus ranges from the eastern Canadian Arctic eastward to the Kara Sea (Reeves 1978). Several more or less well-defined subpopulations or stocks exist within this range (Fig. 3).

Body size: Walruses are the largest pinnipeds of the Arctic. Male Atlantic walruses reach a standard body length of about 300 cm and can weigh about 1200 -1500 kg. Females reach a body length of about 250 cm and a total body weight of 600-700 kg (Loughrey 1959, Mansfield 1958, Knutsen and Born 1994). Wiig and Gjertz (in press) have recently found that male walruses at Svalbard can reach a standard body length of about 380 cm corresponding to an estimated total body weight of nearly 2000 kg (Fig. 55). There are indications of differences in total body length in different stocks in the western Atlantic Arctic (Mansfield 1958, Knutsen and Born 1994). Chapskii (1936) reported body lengths of Atlantic walruses from the Kara Sea. However, in his study the methods of age determination and measuring differed from those of the authors cited above and his data are therefore not comparable.

Reproduction: On the basis of body and tusk size Chapskii (1936) estimated that male Atlantic walruses in the Kara Sea became sexually mature at 5 or 6 years of age. With more accurate methods of determining ages but on a relatively small sample, Mansfield (1958) judged that males in the eastern Canadian Arctic reached sexual maturity at 6 or 7 years of age. In *O.r.divergens* spermiogenesis commences between 7 and 10 years of age. The capa-

Fig. 55. Weighing an immobilized adult male walrus in Svalbard, where large males may weigh close to 2000 kg (Wiig and Gjertz in press). Photo: I. Gjertz

Fig. 56. Adult female with 1-year-old calf at Svalbard. Walruses give birth to a single calf at intervals of 2 or more years. Photo: I. Gjertz.

bility of fertilizing females is usually not achieved until later, when social or full physical maturity has been reached. Physical maturity is accompanied by a secondary growth spurt in males of *O. r. divergens* (Fay 1982); this growth pattern has not been observed in *O. r. rosmarus* (Mansfield 1958, Knutsen and Born 1994).

The majority of *O. r. rosmarus* females experience their first ovulation at 7 years of age (range: 5 to 10 years). According to Mansfield (1958) ovulations in 5-year-olds presumably usually do not result in successful pregnancies. However, Garlich-Miller and Stewart (1993) found one pregnant six-year-old in a sample of 71 females from Foxe Basin. In northwestern Greenland first ovulation occurs at five years of age. About 50% of the females experience their first ovulation at around the age of six and all have ovulated before the age of 10 (Born 1990). In *O. r. divergens* about 10% of females ovulate at 4 years, the majority of 6-year-olds have ovulated at least once and all have ovulated by the age of 10. The rates of reproductive failure in walruses appear to be high, and in any given year about 20% of the sexually mature females are resting. Females may experience reproductive senility. In *O. r. divergens* an onset of decline in productivity of females by age 16-18 has been observed (Fay 1982, Anon. 1990a).

In *O. r. rosmarus* potent bulls have been found between November and late May (Mansfield 1958) and the mating season is believed to be between late January and March-April (Mansfield 1966, Born 1990). In *O. r. divergens* spermiogenesis peaks in December-January for mature males and about 2 months later for adolescents (Fay 1982, 1985). Like in other pinnipeds, implantation is delayed in the walrus for 4-5 months (Fay 1982, Born 1990). Although unseasonal births have been reported (Vibe 1950, Lukin 1978), the main period of birth in *O. r. rosmarus* lasts about two months with a peak between mid-May and early June (Vibe 1950, Mansfield 1966, 1973). According to Fay (1985) calves of *O. r. divergens* are born mainly from mid-April to mid-June. Hence, pregnancy lasts about 15 to 16 months (Mansfield 1973, Fay 1985) and individual walruses therefore give birth to a calf at intervals of 2 or more years (Mansfield 1958, Fay 1982, 1985, Born 1990; Fig. 56).

Vital parameters: The segregation of different sex and age classes for most of the year, and the selective hunting pattern of the Inuit, make it very difficult to obtain unbiased samples for determining vital biological parameters (*e.g.* Fedoseev and Gol'tsev 1969, Fay 1982, DeMaster 1984). Sex ratio at birth is 1:1 with a slightly higher, but not significantly higher, proportion of males (Fay 1982, Fay *et al.* 1984). The sex ratio in the population is not well known. On the assumption that walruses are polygynous, an adult sex ratio of 1 male to 3 females has been suggested (Fay 1982, Fay *et al.* 1984, Sease and Chapman 1988). Generally, the low rate of reproduction (between 35 and 40% of fecund females give birth to a single calf in any given year; Mansfield 1958, Fay 1982, Born 1990) is believed to be balanced by a low rate of natural mortality, mainly secured by a prolonged period of parental care, and a higher recruitment to breeding age than in other pinnipeds (Fay 1982). Low reproductive capacity is probably also counterbalanced by the highly developed sociality

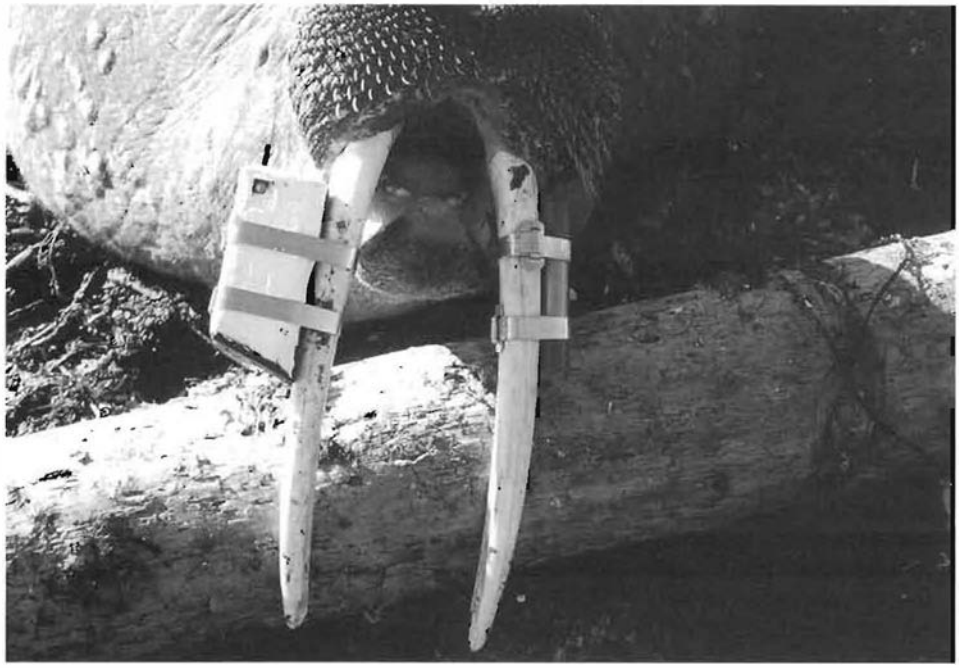

Fig. 57. A satellite-linked radio transmitter (the larger unit) and a time-depth recorder (TDR) attached to the tusks of an adult male walrus at Svalbard. The satellite-radios have been used for studies of movements (Born and Knutsen 1992, Wiig *et al.* in press). The TDR demonstrated a mean dive duration of 5.2 min (SD = 2.8 min, range = 0.2-12.7 min.) of which 81% of the time was spent at the bottom (Wiig *et al.* 1993). Photo: I. Gjertz

of walruses at all seasons (Fay 1985) and their long lifespan (up to about 40 years; Fedoseev and Gol'tsev 1969). The population birth rate (fraction of neonates in the total population) has been estimated at 0.07 (Mansfield 1966) or 0.11 (Mansfield 1973) in *O. r. rosmarus* and between 0.12 and 0.17 in *O. r. divergens* (Fedoseev and Gol'tsev 1969, Fay 1982). The differences in these estimates likely reflect sample variance rather than actual differences at the subspecies level. In *O. r. divergens* total annual mortality (A) for adult males has been estimated at 13% (Burns 1965). DeMaster (1984) suggested an A of about 9% for adult males and considered it likely that total annual mortality of adult females was much lower. Fedoseev and Gol'tsev (1969) estimated A for the entire population of *O. r. divergens* at 8-10%. The natural mortality rate is not known but has been estimated to be 3 to 5 % for the entire population of *O. r. divergens* (DeMaster 1984, Fay *et al.* 1989). An annual hunting mortality of 5 to 7% of the total population is therefore believed to be sustainable (Fay 1985). DeMaster (1984) estimated that maximum sustainable yield of adult females (4 years and older) would be 5.1% of the total population of females. He suggested that an adult female harvest of 1 to 5% could be sustained. Based on a variety of assumptions, maximum sustainable yield of a hypothetical walrus population has been estimated at 3 to 5% for a population between 59 and 91% of carrying capacity (*Ibid.*).

Instantaneous net growth rate of the population of Pacific walruses during the late 1950s to mid-1970s was estimated at 0.067 (Tavrovski 1971, Sease and Chapman 1988), indicating a finite growth rate of about 7% per year for a population in a phase of growth under favorable environmental conditions with no food limitations.

Estimates of abundance: Attainment of abundance estimates is hampered by the fact that the population usually occupies a very large area and has a clumped distribution. Furthermore the fraction of the population which is hauled out and visible at any given time is highly variable. In addition, walruses are "cryptically" colored and can be difficult to see in water (Estes and Gilbert 1978, Estes and Gol'tsev 1984, Gilbert 1989). During feeding, walruses are submerged and hence are not detectable for 80-85% of the time. (Fay 1982, Born and Knutsen 1992, Wiig *et al.* 1993; Fig. 57).

Ecology: As they feed mainly on bottom-dwelling bivalve mollusks, walruses are largely confined to continental shelves, where water depths are not greater than 80 to 100 m (Fay 1982, Wiig *et al.* 1993). Walruses are able to break through ice up to about 20 cm thick, but when the ice grows thicker than this walruses are forced to retreat to areas with drift ice. Hence, in winter walruses inhabit those regions of the drifting ice where leads and polynyas are numerous and where the ice is thick enough to support their weight (Burns *et al.* 1981, Fay 1982). They show a strong preference for hauling out on floes of first-year ice with a surface area between 50 m^2 and 400 m^2 (Wartzok and Ray 1980, 1981). Some walruses winter at high latitudes in polynyas (Vibe 1950, Finley and Renaud 1980, Stirling *et al.* 1981, Born 1984, Born and Knutsen 1992). In summer, males rest and molt while hauled out on land on traditional sites (uglit) often situated close to their feeding grounds (Tsalkin 1937, Mansfield

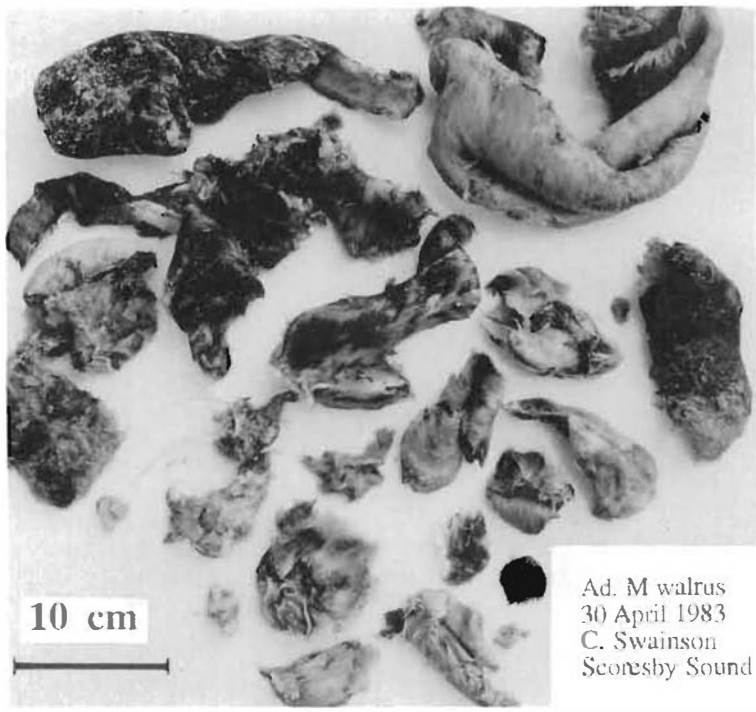

Fig. 58. Contents of the stomach of an adult male walrus killed at the entrance to Scoresby Sound (East Greenland) on 30 April 1983. The walrus had sucked out pieces of ringed seal skin and blubber. (See also Fig. 54). Photo: E.W. Born.

1958, Loughrey 1959, Fay 1982). Females and calves tend to occur farther off shore in association with the drifting ice (Fay 1982, 1985), although in some areas they also haul out on land (Miller 1982, Miller and Boness 1983).

Food and feeding: Walruses are stenophagous and depend on the soft parts (mainly feet and siphons) of bivalve mollusks for about 95% in numbers and weight of their food (Fay *et al.* 1977, Fay and Stoker 1982). This food is taken at water depths of less than about 80 m (Vibe 1950, Fay 1982). The principal food items are the bivalves *Mya truncata*, *Astarte borealis*, *Serripes groenlandicus* and *Hiatella arctica* (Vibe 1950, Heptner *et al.* 1976, Fay 1982, Gjertz and Wiig 1992). Other benthic invertebrates are also ingested to a varying extent (Fay 1982). Although reports of fish in walrus stomachs are rare (Fay 1982), piscivory may play a role in periods when other food is not available. Atlantic walruses have also been reported to prey on birds (Gjertz 1990). Walrus predation on seals is well documented (*e.g.* Johansen 1910, Fay 1982, Lowry and Fay 1984, Smith *et al.* 1979; Fig. 58). Apparently, the habit of seal-eating occurs in both sexes but apparently is confined largely to older subadults and adult walruses (Lowry and Fay 1984). In seasons and areas where the distribution of seals and walruses overlap considerably or when ice conditions make the mollusk feeding-banks inaccessible to walruses, seals may well be an important food source. This could be the case, for example, in northeastern Greenland. There is indirect evidence (trace metal and chlorinated hydrocarbon contaminant levels, ^{13}C analysis of tissues) that walruses in eastern Hudson Bay regularly prey on seals (Wagemann *et al.* 1993).

Natural enemies: Apart from man, the main predators of walruses are killer whales (Fig. 59) (*Orcinus orca*) and polar bears (*Ursus maritimus*) (Fay 1982). Interactions between killer whales and walruses occur in spring, summer and autumn, when the range of the two species may overlap (Fay 1982). Several instances of killer whales attacking and killing walruses, primarily young and calves, are summarized in Fay (1982). Several reports exist of polar bears attacking walruses. Apparently mainly calves and subadults are vulnerable to predation from bears (*e.g.* Parovschikov 1967, Fay *et al.* 1984, Calvert and Stirling 1990, Rugh 1993), although also adults are taken (Parovschikov 1967). A variety of other causes of natural mortality other than aging can be listed: adverse weather, freeze-out, disease, intraspecific interactions such as aggression during the breeding season, crushing of calves, and stampedes (Anon. 1990a). Although predation by bears and killer whales cannot be ruled out as a primary cause of natural mortality in regions where those predators are concentrated or seasonally abundant, the relative importance of the different causes of natural mortality is difficult to assess.

Behavior: Walruses are highly gregarious. They almost invariably occur in small groups and sometimes haul out on land in herds numbering thousands of individuals (Fay 1982, Miller and Boness 1983). The number of walruses hauled out at a given ugli can vary enormously from day to day (Salter 1979,

Fig. 59. An encounter in the ice near Svalbard between a polar bear and an adult walrus. Polar bears occasionally attack walruses but usually show respect toward adults (see text). Photo: L. Åby.

Miller 1982, Miller and Boness 1983). Walruses are polygynous; the sex ratio of adults in the breeding area is about one male per ten females. In the mating season, adult males fight intensively in the water, evidently in competition for display sites near females (Fay *et al.* 1984). During courtship displays the male walrus emits a stereotyped sequence of underwater sounds consisting of taps, knocks, pulses and "bells" (Schevill *et al.* 1966, Ray and Watkins 1975, Stirling *et al.* 1983, 1987, Fay *et al.* 1984). Probably, this acoustical display serves as an advertisement to females and as a warning to other males (Fay *et al.* 1984). Females choose a mate from among the displaying males and copulation occurs in the water. Hence, the mating system of the walruses is unique among pinnipeds. It resembles a lek in that: 1) dominant males display for females while congregated in a traditional location, 2) subdominant males take peripheral positions, and 3) the female appears to take the active role in consorting with the male of her choice within the "arena" (*e.g.* Fay *et al.* 1984, Le Boeuf 1986). However, Sjare (*e.g.* 1989, 1993), who studied the Atlantic walrus in the Canadian High Arctic, found no obvious indications that female choice was an important factor in determining which male was dominant. The mating behavior of Atlantic walruses may be more similar to female defense polygyny than to a mobile lek as described for the Pacific walrus.

ACKNOWLEDGMENTS

Publication of this report was funded by the North Atlantic Marine Mammal Commission (NAMMCO), Norwegian Polar Institute, and the Greenland Institute of Natural Resources. We are indebted to Pia Barner Neve, Cathleen Knötsch and René Søder for the great help that they provided during the preparation of this report. We also wish to thank Rob Stewart (DFO, Winnipeg) who provided us with, and helped us interpret, Canadian catch statistics. Thanks are due to the photographers who allowed us to use their photos in this publication. Finally we wish to thank all those who gave us information on walruses.

Responses of male sperm whales (*Physeter macrocephalus*) to killer whale sounds: implications for anti-predator strategies

Charlotte Curé[1], Ricardo Antunes[1], Ana Catarina Alves[1], Fleur Visser[2,3], Petter H. Kvadsheim[4] & Patrick J. O. Miller[1]

[1]Sea Mammal Research Unit, School of Biology, University of St. Andrews, Fife KY16 8LB, St. Andrews, UK, [2]Netherlands Organization for Applied Scientific Research (TNO), 2592 AK, The Hague, The Netherlands, [3]Kelp Marine Research, 1624 CJ, Hoorn, The Netherlands, [4]Norwegian Defence Research Establishment (FFI), N-3191, Horten, Norway.

Interactions between individuals of different cetacean species are often observed in the wild. Killer whales (*Orcinus orca*) can be potential predators of many other cetaceans, and the interception of their vocalizations by unintended cetacean receivers may trigger anti-predator behavior that could mediate predator-prey interactions. We explored the anti-predator behaviour of five typically-solitary male sperm whales (*Physeter macrocephalus*) in the Norwegian Sea by playing sounds of mammal-feeding killer whales and monitoring behavioural responses using multi-sensor tags. Our results suggest that, rather than taking advantage of their large aerobic capacities to dive away from the perceived predator, sperm whales responded to killer whale playbacks by interrupting their foraging or resting dives and returning to the surface, changing their vocal production, and initiating a surprising degree of social behaviour in these mostly solitary animals. Thus, the interception of predator vocalizations by male sperm whales disrupted functional behaviours and mediated previously unrecognized anti-predator responses.

Interspecific interactions across multiple scales (species, population, individual) remain a central question in understanding the organization of animal communities[1–3]. In predator-prey interactions, the importance of predation over evolutionary time (e.g. regulating prey population) has long been clear, but the influence of predation on phenotype (e.g. body size) and behaviour of prey has seen a growing recognition in the last decade. In fact, prey can be affected by predators in other ways than direct (lethal) predation, in the form of stress[4], changes in behaviour and anti-predator strategies[5]. Prey must search for food and reproduce while maintaining the capability to detect and avoid predators. There is thus a constant trade-off for prey between avoiding predation and continuing fitness-enhancing activities such as foraging or mating[5,6].

Cetaceans spend most of their time underwater and thus the effect of predator-prey interactions on the animals' behaviour is difficult to observe and rarely studied, especially in comparison to terrestrial animals[7]. However, the advanced multi-sensor tag developed by Johnson and Tyack (2003) contributed to a major advance in cetacean behavioural studies, enabling reliable monitoring and quantification of the animals' behaviour, even below the sea surface[8]. Using such technology, it becomes possible to study the effects of predation risk on cetaceans' behaviour.

The two main potential predators of cetaceans are killer whales and sharks[9]. Both of these predator types are widespread in the world's oceans and have been observed to feed on a large number of prey items including fishes, cephalopods, seabirds, seals and cetaceans. In general, small cetaceans such as dolphins and porpoises are likely more vulnerable to predation than larger cetaceans. Sharks seem not to pose a significant risk to large whales, though small calves of some species may be vulnerable to attacks occasionally[9]. Killer whales, however, clearly prey on large cetacean species including mysticetes and some odontocetes such as adult female and juvenile sperm whales[10–13]. In the last decade, there has been a growing interest in the role of killer whale predation in shaping marine ecosystems and regulating prey population[14,15]. However, the effect of predation pressure on behaviour and social organization of prey and especially of cetacean prey, remains to be experimentally tested[16]. Although various observations have reported interspecific predatory or non-predatory encounters between killer whale and

other cetaceans, there is a lack of consistency in these observations[10,13] and thus no prediction on how cetaceans' behaviour is altered by killer whale presence and how these interactions are mediated.

The sperm whale is the largest toothed whale. A considerable number of observations of lethal and non lethal attacks by killer whale on calves and adult female sperm whales have been reported[10,11]. Male and female sperm whales are geographically segregated outside of the breeding grounds. Females stay in tropical and subtropical areas in warm surface waters where they live in cohesive groups including adult females and immature males and females. Males leave their family unit at approximately 10 years of age and gradually move to higher latitudes into colder surface waters where they are usually seen solitary[17]. In their late twenties, males start to return periodically to the breeding grounds inhabited by females to mate[18]. In female sperm whales, grouping behaviour to defend themselves and their calves has been observed in response to killer whale attacks[10,15] and may be the primary function of their sociality[11,17,18].

Killer whales are a highly vocal species and their vocalizations can be heard underwater over long distances[19]. Specific avoidance responses to killer whale sounds have been demonstrated experimentally in fish[20,21], pinnipeds[22] and few cetacean species[23–25]. As sperm whales hear well at the frequencies of killer whale vocalizations[26], the unintended interception of killer whale sounds may inform the eavesdroppers about the presence of predators, enabling them to make adjustments of their behavior[27,28].

To our knowledge, no reports exist on how high-latitude male adult sperm whales might respond to predation risk, suggesting that male sperm whales are rarely attacked by killer whales. It's possible that anti-predator strategies exhibited by male sperm whales would be sufficiently powerful to actually discourage killer whales to attack such low benefit prey.

In natural conditions, sperm whales spend 80% of their time foraging and 20% of their time resting[29–31]. To meet their energy requirements, they predate mainly upon cephalopods and have developed a sophisticated and efficient foraging strategy, performing almost continuously long deep foraging dives and producing loud echolocation clicks to localize their prey[29,30]. If killer whales are perceived as a potential predation risk for male sperm whales, we expect that the detection of predator presence should induce significant changes in the foraging or resting behaviour of sperm whales. Alteration of foraging should be reflected in a change of diving behaviour along with a change in the production of sounds associated with foraging such as clicks and buzzes. Alteration of resting behaviour should be reflected in a change in the stereotypical resting dives pattern[31]. The solitary nature of adult males leads to the prediction that social defences would not be part of the response repertoire, while their large aerobic diving capacity would enable a diving escape strategy[15–17]. Grouping of male sperm whales is indeed rarely observed in natural conditions[15], but a male sperm whale could alert other males in the area to enrol them in a social defence. Such social behaviour should be indicated by the grouping of several whales and the emission of social sounds called 'codas'[32,33].

Our objectives were therefore to investigate whether the detection of mammal-feeding killer whale sounds 1) alters the behaviour (i.e. foraging or resting) of male sperm whales, and whether they respond by avoiding the sound source and diving deeper and longer, and 2) induces an initiation of social response as an anti-predator strategy. To test what anti-predator strategies are employed by adult male sperm whales, we conducted playback of killer whale vocalizations to five male sperm whales off Norway and monitored the behavioural responses of the animals using a high resolution depth-and-sound-recording tag[8].

Results

Overall, the five tested whales changed their behaviour in response to killer whale sounds playbacks (abbreviated as KW) (see Table 1).

Change in foraging/resting behaviour. *Change in the dive profile*. Four animals of the five tested whales (sw09_141a, sw09_160a, sw10_149a and sw10_140a) were conducting deep foraging dives before the start of KW sounds playback and 1 whale (sw09_142a) was in a resting mode, performing stereotypical resting dives (Table 1).

Playback of KW sounds resulted in significantly shorter and shallower dives compared to the baseline (Fig. 1a, b), and none of the whales extended the duration of their dives. For all whales except one (sw09_160a), KW sounds elicited a clear interruption in the descent phase of the dive and a return to the sea surface (Fig. 2a, b, d and e). Two of the four whales that were foraging were also exposed to a broadband noise as negative control (abbreviated as CTRL) (sw10_149a and sw10_150a) and performed apparent similar foraging dives during CTRL playback compared to the baseline (similar duration and max depth) (Fig. 1a, b and Fig. 2d, e). The foraging whale that did not interrupt its dive during KW playback (sw09_160a) performed an unusual foraging dive pattern showing multiple vertical wiggles (i.e. short ascents) during the descent phase of the dive (Fig. 2c). The tagged whale sw09_142a that was in a resting mode preceding the KW sounds exposure stopped resting in response to KW playback (Fig. 2b) and performed a spyhop (raising of the whale's head above the sea surface) just after coming up to the surface.

Change in regular click production. During baseline periods, the foraging sperm whales spent most of their dive clicking (mean 77 ± 9.4% s.e.m., range: 54.7–94.5%, $n = 4$). Buzzes were produced for all baseline foraging dives (Fig. 2a, c, d, e). For the whale that was resting

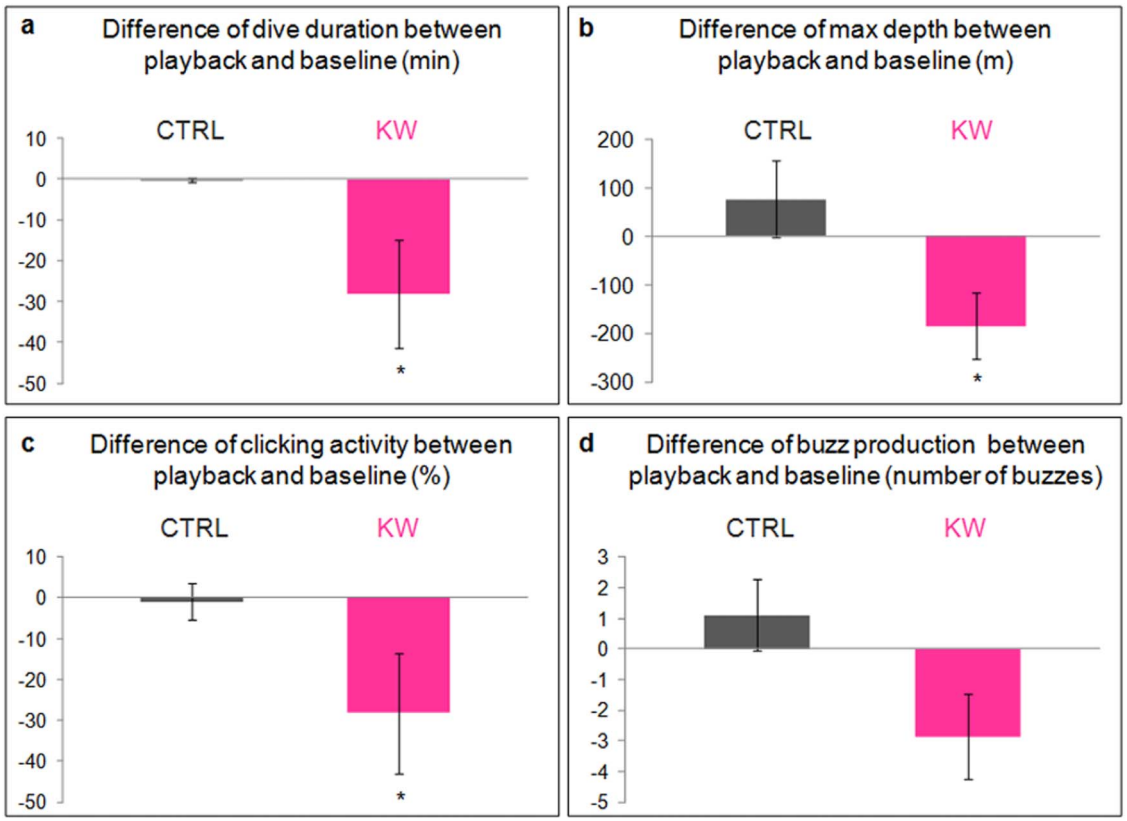

Figure 1 | Difference between baseline and playback (CTRL or KW) for dive duration (a), max depth (b), clicking activity (c) and production of buzzes (d). Values are given as mean ± s.e.m. A Wilcoxon matched-pair test was applied to assess difference between baseline and KW playback ($*P < 0.05$; $n = 5$).

during baseline, as expected, the clicking activity was close to zero and there was no buzz emitted during the dives (Fig. 2b).

Clicking activity was significantly lower during KW playback compared to baseline (Fig. 1c) ($P = 0.043$, $Z = 2.022$, $n = 5$) but appeared similar during CTRL playback compared to baseline. Buzz production was not significantly different between KW playback and baseline (Fig. 1d) although for two whales of four that interrupted their foraging dive to return to the surface in response to the KW playback, no buzz was produced during the dive (Fig. 2d, e).

Change in social behaviour (whale grouping and production of codas). Sperm whales were solitary during the baseline period preceding the playback experiments. During KW playbacks, we found evidence of a social response in three of the five tested whales (Fig. 2a, d, e and Table 1). Two tested whales appeared in association with other individuals at the first surfacing phase following KW playback (Fig. 2a, e). In addition, one of these 2 whales and another tested whale produced codas (Fig. 2a, d). We provide below a descriptive analysis of these behaviours along with Fig. 2 and Table 1.

For sperm whale sw09_141a, the tagged whale was observed solitary at the surface for the 3 h preceding the start of KW playback (group size: 1) (see Fig. 2a). During KW playback, the tagged animal interrupted its foraging dive and returned to the surface (group size: 1). At the first surfacing phase following the end of KW playback, three other whales appeared within 50 m apart from the tagged animal (group size: 1–4 whales). Simultaneously, twelve codas were produced by the group of individuals at the sea surface. At the next surfacing phase of the tagged whale, the animal was observed alone indicating that the group had spread out.

Sperm whale sw10_149a was solitary during the entire period preceding playback experiments. This whale produced one coda at the end of one single baseline dive, just before surfacing (3 h 30 before the start of KW playback) but did not produce any codas during the next baseline dives or during CTRL playback. Then, during KW playback, two codas were produced, one at the max depth of the dive and one when the animal returned to the surface (Fig. 2d). The animal was not observed with other whales and no more than one whale was acoustically detected by the passive acoustics equipment deployed in the water.

The tagged whale sw10_150a was observed as a single animal during baseline and CTRL playback (group size: 1) but then appeared with three more individuals at the first surfacing phase following the end of KW playbacks (group size: 3–4; distance of whales to the focal animal: 0–100 m) (see Fig. 2e). Then, at the next surfacing, the tagged whale appeared solitary again. No coda was recorded during baseline or during sound exposure.

Change in the direction of horizontal movement (avoidance or attraction). The visual tracks of the surfacing tagged whales indicated that four of the five tested whales (all except sw09_160a) changed their direction of horizontal movement in response to the KW playback. In two cases (sw09_141a and sw10_150a), the whales were originally moving towards the KW sound source but made a clear turn away from the source after they surfaced (avoidance). Sw09_160a did not show any apparent changes in direction of horizontal movement during the KW playback. This subject was moving towards the sound source before the playback started and kept this course during and after the KW playback. The two subjects that were exposed to CTRL playback (sw10_149a and sw10_150a) showed an avoidance response. Sw10_149a was moving towards the sound source before CTRL playback and made a clear turn away from the sound source during the playback. Sw10_150a slightly avoided the CTRL sound source during the playback and went back to its original course after the end of playback.

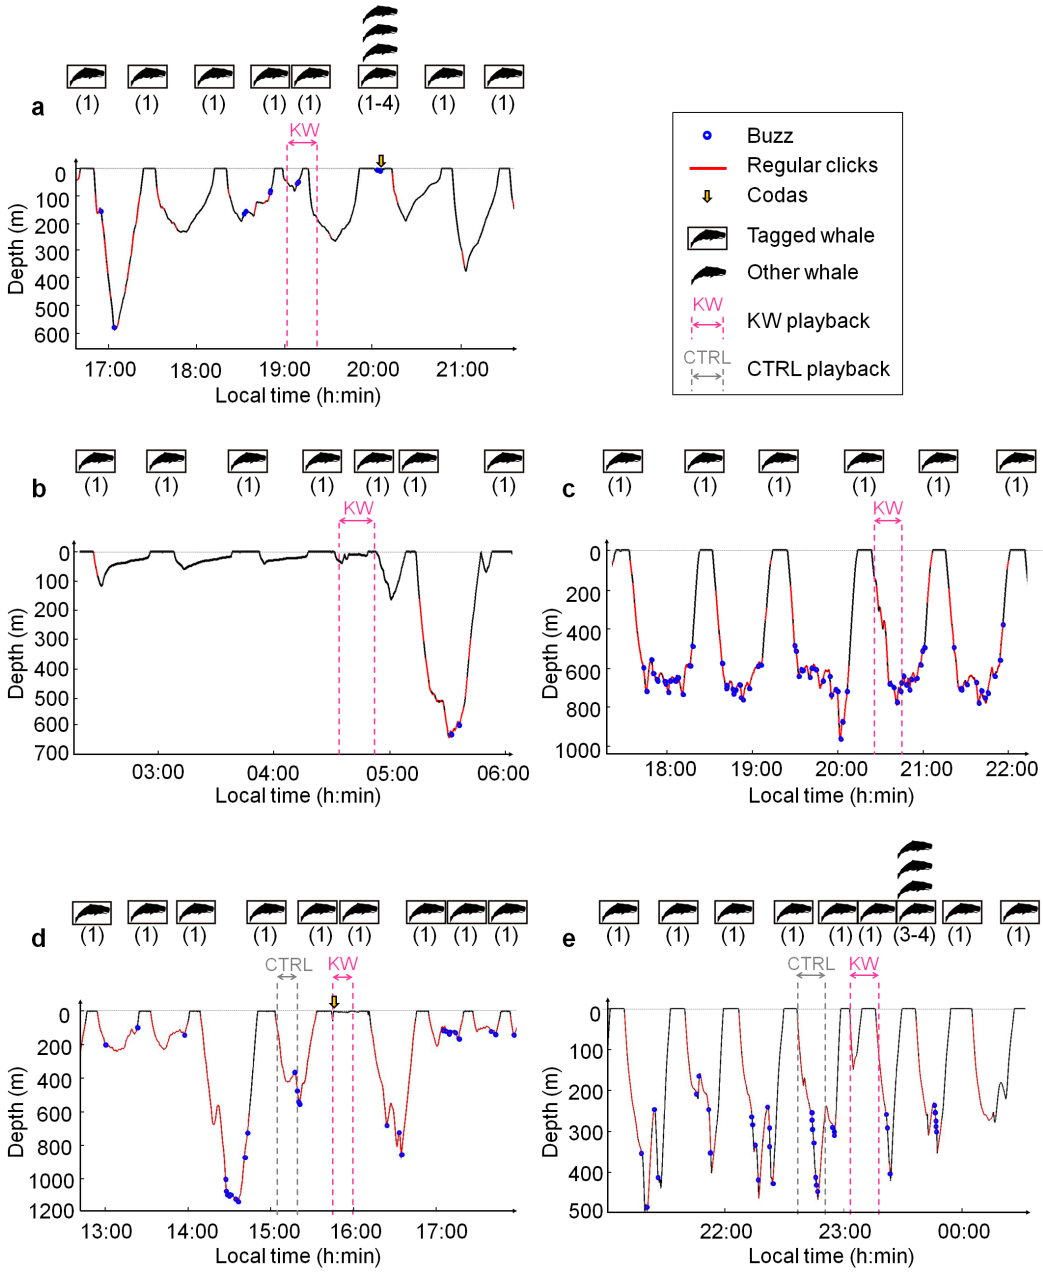

Figure 2 | Time-depth profile of tagged whales sw09_141a (a), sw09_142a (b), sw09_160a (c), sw10_149a (d) and sw10_150a (e) during baseline, CTRL and KW playbacks. The diving periods highlighted in red correspond to clicking activity, the blue circles represent emission of buzzes, and the yellow arrows indicate production of codas. For each surfacing phase, the range of group size is shown between brackets.

Responses to CTRL playbacks. The two individuals tested with CTRL playbacks (sw10_149a and sw10_150a) did not show any changes of behaviour except in the direction of horizontal movement (avoidance response). All the other behavioural parameters taken into account in our analyses had apparent similar values between CTRL playback and baseline period (Fig. 1 and Fig. 2d). Dive duration and maximum depth values during CTRL playback were essentially the same as those measured during baseline dives (Fig. 1a, b). Moreover, the rate of click production and number of buzzes indicating foraging activity appeared similar between CTRL playback and baseline (Fig. 1c, d). No indication of social behaviour, i.e., production of codas or association with other whales, was recorded during CTRL playback (Fig. 2d, e).

Discussion

Playbacks that simulated killer whale presence strongly changed the behaviour of five tested male sperm whales. This indicates that sperm whales have perceived the KW sounds in spite of the fact that the main frequencies of KW vocalizations are between 1–2 kHz which is outside the best hearing sensitivity (5–20 kHz) of sperm whales. Moreover, the fact that the two animals exposed to CTRL playback changed their direction of horizontal movement away from the sound source indicates that the whales also perceived the CTRL stimulus.

Animals that were initially foraging during the baseline exhibited significantly shorter and shallower dives compared to the baseline dives and produced less echolocation clicks and buzzes. In general, prey are predicted to alter their behaviour in response to the presence of predators by avoiding them or by reducing risk activities like feeding[5,6]. The best way for prey to avoid killer whales may be to keep quiet and hide from them by travelling to where the predator cannot follow. In offshore waters, deep diving species such as beaked whales or sperm whales may escape killer whales by going to great depths where killer whales cannot reach them[10]. Solitary male sperm

whales off Norway are not constrained by diving limitations of calves in their group so they could potentially use this strategy of escaping at depth. In contrast to this prediction, our results showed that during KW sounds playbacks, sperm whales interrupted their foraging or resting dive and returned to the surface. The animal's decision to reduce or stop foraging in response to KW playback represents a high energy cost and could be explained by the detection of a potential danger. A possible explanation for the behavioural response of the animals returning to the sea surface may be therefore that animals replenish their oxygen stores in preparation for a potential coming flight or deep avoidance dive if the predator approaches. At the surface, they might also search for additional cues of predator presence[34], a possible function of the spyhop observed by one of the tested whales.

In our study, all of the four sperm whales performing deep foraging dives at the start of exposure reduced vocal activity or silenced completely in response to the KW playback. In addition, three of these four whales and the initially resting whale interrupted their dive and returned to the surface, resulting in shorter and shallower dives compared to baseline. The two control experiments with the playback of a broad band noise (CTRL) showing the same frequency range than KW stimulus, verified that animals responded specifically to KW sounds and not to any unspecific acoustic stimuli.

On one hand, our findings are consistent with responses of six right whales (*Eubalaena glacialis*) exposed to experimental synthetic signals resembling to KW signals that interrupted their foraging dives and returned to the surface[35]. On the other hand, these results contrast with the typical straight avoidance responses reported in grey whales (*Eschrichtius robustus*) and belugas (*Delphinapterus leucas*) in response to KW playbacks[23,24]. Moreover, a Blainville's beaked whale (*Mesoplodon densirostris*), which is a deep diver like sperm whales, silenced and broke off the deep dive when exposed to a playback of KW sounds but returned to the sea surface only after an unusually slow ascent from depth[25]. Therefore, variations across cetacean species in their pattern of anti-predator responses to the detection of killer whale presence do not appear to be solely driven by physiological factors like diving capability.

We showed that in the feeding grounds off Norway, male sperm whales spend most of their time solitary and seldom produce codas, which is in agreement with the literature[15,36–38]. Indeed, male sperm whales were rarely observed socializing with other whales and when it happened, it was usually in cluster of two animals and for no more than few hours[15]. Moreover, codas, which play a major role in communication between conspecifics, have only rarely been recorded in the Norwegian Sea[36–38]. In contrast to females that live in cohesive groups, solitary males would not have the benefit of communal defence against predators. It has been suggested that as males are bigger than females, they would be less vulnerable to killer whale predation than females. Indeed, all documented predatory interactions between killer whales and sperm whales referred to attacks on group of female sperm whales with calves or wounded animals. However, in the present study, in three of five tested male sperm whales, KW playback induced a social response (clustering of animals at the sea surface and/or production of social/alerting sounds), indicating the initiation of anti-predator social strategy. This suggests that typically solitary males may also exhibit a social defence strategy in response to KW presence.

There have been observations of non-predatory interactions between killer whales and sperm whales or between killer whales and other species, where sometimes the prey ignores the predator[10,18]. A possible explanation for this absence of cetaceans' reaction facing their predator could be that animals can discriminate between vocalizations of different killer whale ecotypes and perceive as a potential predation risk only mammal-eating KW sounds. Thus, by intercepting KW sounds, prey would be able to assess food preference of killer whales and thus to evaluate the risk of predation. Here, we used unfamiliar mammal-eating KW sounds associated with foraging behaviour that may represent a higher threat for sperm whales compared to other sound types such as local fish-eating KW sounds that would likely pose no threat to them. Playback experiments using different KW sounds are needed to elucidate these questions, as has been explored in seals[22].

In summary, we found that the playback of unfamiliar mammal-eating KW sounds simulating potential predator presence modified the behaviour of five tested adult male sperm whale. Although, at the ecological scale, killer whale predation probably has a small role in regulating sperm whale populations[15], we show experimental evidence here that it must have at the individual scale a large impact on the behaviour and sociality of animals. Even if the predation risk might be lower for male sperm whales than for females with calves, it still induced a dramatic change in males' behaviour including the interruption of foraging or resting dives. Rather than taking advantage of their large aerobic capacities to dive away from the perceived predator, sperm whales returned quickly to the surface and initiated social responses, suggesting that high-latitude male sperm whales may have previously-unrecognized social interactions.

Methods

General protocol. Field work was conducted aboard a research vessel in the Northern Norwegian Sea during May/June 2009–2010[39,40]. The vessel had a dedicated observation platform from which visual data collection was conducted. A dedicated small motor boat was launched from the vessel for tagging operations and playback experiments. The protocol consisted of the following phases: 1) tagging, 2) start of visual tracking of the tagged animal, 3) collection of baseline behavioural data (before sound exposure), 4) collection of behavioural data during sound exposures, 5) end of visual tracking when the tag released, 6) tag recovery and data download for analysis.

Tagging and visual data collection. To monitor the behavioural response of sperm whales exposed to the playback sounds, we used an advanced miniature high-resolution movement-and-sound-recording tag called D-tag[8] (see Supplementary Material). We used the depth sensor and hydrophones on the tag to investigate potential changes in dive pattern and vocal production, respectively, in response to the playbacks. Using the VHF radio beacon on this tag, we were able to visually track the position of the animal at each surfacing event and to simultaneously assess whether the tagged whale was associated to other whales. At each surfacing phase, whale positions were determined at regular 2 min intervals (range: 3–8 recorded positions per surfacing phase) (see Supplementary Material).

Acoustic stimuli. Sperm whales were presented with playback of 'unfamiliar' mammal-eating KW sounds previously recorded in the North Pacific using D-tags[41] and corresponding to calls and clicks produced during eating activity. We expected these sounds to simulate a high risk of potential predation[22]. These KW sounds show a frequency range of 0.5–120 kHz with most energy distributed between 1 and 2 kHz which correspond to the fundamental frequency of the majority of the calls[42]. KW stimuli were transmitted through a speaker designed to broadcast in the 0.20–20 kHz frequency band. A large number of odontocetes are most sensitive in the 30–120 kHz[43,44] range whereas sperm whales show best hearing sensitivity between 5 kHz and 20 kHz[26] which matches with the frequency range covered by the speaker. Therefore, even if the frequencies of KW sounds above 20 kHz were transmitted by the speaker, sperm whales would probably hardly hear them. Our system of playback was thus appropriate to our species model. To control for sperm whales' reaction to any unspecific acoustic stimulus, two subjects were also exposed to a broad band noise (0.5–15 kHz) as a negative control (CTRL). CTRL stimuli were created from non-calling periods during the recordings from which KW stimuli were taken, amplified to get an average root mean square power equal to the KW stimuli. These CTRL stimuli had most energy between 1 and 2 kHz, like KW stimuli[42]. All stimuli had 15 min duration and were re-sampled at 44.1 kHz before being used for playback experiments. The average duration of the KW sounds within each 15 min KW stimulus was 7 min 21 sec ± 6 sec s.d. ($n = 3$). For each stimulus type (KW and CTRL), three different stimulus versions, i.e. collected from different acoustic recordings, were used among the tested whales to avoid pseudoreplication[45].

Playback experiments. We tested five male sperm whales encountered off Andenes, Norway. In 2009, three whales were tested with KW stimulus and in 2010, 2 whales were tested with both KW and CTRL stimuli. The baseline period was defined as the period preceding the start of the KW/CTRL playback experiments and had a duration of 5 h 12 min ± 1 h 49 min s.e.m. ($n = 5$). The three whales tested only with KW stimulus were previously exposed to sonar sounds as part of a parallel project[39]. For these whales, the baseline period was thus the period between the end of sonar exposure and the start of KW/CTRL playback experiments. Stimuli were transmitted using a M-Audio Microtrack II recorder and amplified by a Cadence Z8000 amplifier connected to a Lubell LL9642T underwater loudspeaker (frequency response: 0.2–20 kHz) submerged at a depth of 8 m[46]. To later measure the sound level of the source

and to ensure that sounds were faithfully played back by the system without distortion, playback stimuli were monitored using a calibrated hydrophone (Bruel & Kjaer 8105 amplified by a Bruel & Kjaer 2635 charge amplifier) placed 1 m from the source and recorded using a M-Audio Microtrack II recorder. The sound level of the KW stimuli ranged from 145 to 151 dBrms re 1 μPa (149 ± 1 dBrms re 1 μPa s.d., n = 3 stimuli) which corresponds to the source level of killer whale vocalizations observed in natural conditions[19]. The sound level of CTRL stimuli ranged from 145 to 150 dBrms re 1 μPa (147 ± 2 dBrms re 1 μPa s.d., n = 3 stimuli). After the baseline period during which we collected data on normal behavioural patterns, we waited until the tagged whale came up at the surface to then place the motor boat with the playback source at an approximate distance of 800 m from the tagged whale (713 ± 73 m s.e.m., n = 7 playback trials). At the end of a surfacing phase, the whale raises its flukes prior to diving[29,30]. We started to broadcast a sound stimulus at the end of a surfacing phase, just after fluking. For the two subjects that were first exposed to CTRL stimulus, the KW stimulus was played back after fluking of the next surfacing phase.

Measure of the behavioural response. *Quantification of the change in dive behaviour*. Vertical movements of the tagged animal were analysed using Matlab software (version 7.8.0). During the pre-exposure period (baseline), four sperm whales were conducting deep foraging dives interspersed with short surface periods and few shallow dives close to the surface[29]. For the analysis of the foraging dives, we excluded the shallow dives, i.e. dives with max depth <100 m. One whale was in a resting mode during baseline, performing characteristic resting dives (shallow dives <100 m, 20–30 min duration, no clicking[31]). For all dives performed during baseline and sounds exposure, we measured the dive duration (time from the fluke-up to the following surfacing) and the maximum depth. As an indication of what is a normal dive profile during foraging (n = 4 whales) or resting (n = 1 whale), we calculated for each whale the average of dive duration and max depth for all the dives performed during baseline (9 ± 3 s.d. baseline dives analysed/tagged whale, n = 5). Then, we compared the average baseline to the parameters measured for the dive performed during sound exposure (either KW or CTRL playback).

Quantification of the change in vocal production. Sound files recorded on the D-tags were viewed as spectrograms using Adobe Audition software (Blackman-Harris window; FFT length: 4096; time resolution: 21.3 ms). We identified on spectrograms the production of regular clicks and buzzes (associated with foraging) and codas (associated with socializing behaviour or alarm signalling). For each dive, we summed the duration of regular clicking periods to calculate the proportion of time clicking compared to the total duration of the dive, we scored the number of buzzes, and we monitored whether codas were produced.

Social behaviour. Simultaneously with visual recording of the tagged whales' positions, we scored the group size defined as the number of individuals within 200 m of the focal animal, and the group spacing defined as the distance between individuals in the group[47]. Group size and group spacing were compared between the baseline surfacing phases and the surfacing phase occurring right after the end of a stimulus playback (KW or CTRL).

Change in direction of horizontal movement. Potential changes of direction of horizontal movement were investigated using the visual tracks of the tagged whale recorded before, during and after the playbacks.

Statistical analyses. Statistical analyses were performed using Statistica software (version 6.0; StatSoft 2001). To test for differences in dive duration, max depth, proportion of clicking activity during the dive and number of buzzes between baseline (pre exposure) and KW playback exposure period, we used the non-parametric Wilcoxon matched-pair test suitable for small sample size. The sample size for CTRL playbacks was too small though (n = 2) to conduct the test comparison to baseline. A descriptive analysis was performed to assess production of codas and potential changes in direction of horizontal movement, group size and group spacing.

Ethical statement. All experiments comply with the current laws of the country where they were performed. Animal experiments were carried out with permission from the Norwegian Animal Research Authority (Permit No. S-2007/61201). Protocols were approved by the Animal Welfare and Ethics Committee of the University of St Andrews (AWEC, UK) and the Institutional Animal Care and Use Committee (IACUC) of the Woods Hole Oceanographic Institute (WHOI, USA).

Acknowledgments

Research funding was provided by the US Office of Naval Research, the Royal Norwegian Navy and Ministries of Defence of Norway and the Netherlands. RA was supported by WWF-Norway. CC was supported by Fondation Total and Fondation Bleustein-Blanchet. The authors are grateful to the many researchers and vessel crew members who helped to collect the data. The authors are also grateful to Volker Deecke for providing the D-tag acoustic recordings of killer whale sounds and for his thoughtful comments that improved the manuscript. The authors thank Marie Chalandre for offering her art skills on the whale drawing used in Figure 2.

Author contributions

All authors conducted the experiments and contributed extensively to the collection of the data. P.H.K. and P.J.O.M. are scientific project leaders. C.C. and P.J.O.M. were responsible for the protocol design of the playback experiments. F.V. elaborated the methodology for data collection on group size and group spacing. C.C. prepared the acoustic stimuli, performed the data analyzes and wrote the manuscript.

Additional information

Supplementary information accompanies this paper at http://www.nature.com/scientificreports

Competing financial interests: This study was mainly funded by three naval organizations: the US Office of Naval Research, the Norwegian Ministry of Defence and the Netherlands Ministry of Defence. In addition, WWF-Norway, Fondation TOTAL and the Fondation Bleustein-Blanchet also contributed financially. The funders had no role in study design, data analysis, or preparation of the manuscript. Authors are employed by government (Norwegian Defence Research Establishment), independent no-profit (Netherlands Organization for Applied Scientific Research and Kelp Marine Research), or academic (University of St. Andrews) research organizations. No authors are employed by naval organizations.

Potential Impacts of Seismic Energy on Snow Crab

Background

On October 20, 2000, the Canada Nova Scotia Offshore Petroleum Board (CNSOPB) received a directive from the federal and provincial energy ministers to conduct a Public Review on the effects of potential oil and gas exploration and drilling activities off the coast of Cape Breton. In order to provide scientific information to the commissioner, DFO scientists reviewed a series of working papers at a meeting of the Maritimes Regional Advisory Process (RAP) in 2001 (DFO Maritime Provinces Regional Habitat Status Report 2001/001).

This meeting concluded that there was a lack of information on the potential impacts of seismic activities on snow crab, specifically:

- *Acute mortality of eggs, larvae, juveniles, adolescents and adult males and females.*
- *Physiological impacts including structural damage to hearing, digestive and reproductive organs, the respiratory system, digestive tracts and embryos and functional damage to hearing and communicating capacity and the capacity of molting, feeding and hatching.*
- *Abnormal behaviour during mating or molting.*
- *Movement and migration during all life stages.*
- *Impact on catch rate in the fishery.*

The RAP also concluded that the area of interest off the west coast of Cape Breton is the location of a large and economically important snow crab fishery and an important area for larval settlement. All benthic phases and size groups of snow crab inhabit the area of interest and there are high landings and catch per unit of effort in the fishery.

In March 2003, DFO organized a workshop to produce an inventory of ecological factors that should be considered when dealing with referrals for seismic surveys in Canadian waters (DFO National Capital Region Habitat Status Report 2004/002). Some highlights from this report include:

- *Information is lacking to evaluate the likelihood of sub-lethal or physiological effects on crustaceans during pre-molt, molting and post-molt periods.*
- *The ecological significance of the effects is expected to be low, except if effects of exposure to seismic sounds were to influence reproductive or growth activities.*
- *The potential for seismic sound to disrupt communication, orientation, detection of predator/prey, locomotion and other functional uses of sound has not been studied.*

In recognition of the stated lack of knowledge on the potential effects of seismic activities on the health of the resident snow crab populations in Atlantic Canada, the Environmental Studies Research Fund (ESRF) funded a scientific study on the effects of seismic energy on snow crab (Chionoecetes opilio). The results of this preliminary study suggested no obvious effects on adult crab behaviour, health or catch rates (Christian et al., 2003). However, some uncertainty remained as the eggs of one female showed significant effects on development when exposed to seismic signals at a very close range (2 m).

In November 2003, the CNSOPB granted a permit to industry to conduct a seismic survey off the western coast of Cape Breton Island, Nova Scotia. DFO formed a partnership with CNSOPB, NS Department of Energy, Area 19 Snow Crab Fishermen's Association and Corridor Resources Inc. to conduct a collaborative study on the potential impacts of seismic energy on the reproductive biology of female snow crab. DFO's role was 1) to augment industry's regulatory compliance monitoring program based on sound-field measurements and 2) to expand the crab studies beyond a repeat of the preliminary study parameters undertaken by Christian et al. (2003) by adding a comprehensive cage-study design. The sources of funding, including in-kind contributions, are provided below:

Corridor Resources	*$170,000*
(field support and sound propagation studies)	
NS Dept of Energy	*$42,500*
DFO	*$223,500*
(logistical support, salary and partnership contribution to St. Francis Xavier U.)	
ESRF	*$100,000*
(field support – spring program)	
Total	*$536,000*

Summary

1. There were three definitive observations:
   - This seismic survey did not cause any acute or mid-term mortality of the crab, nor was there any evidence of changes to feeding in the laboratory.
   - Survival of embryos being carried by female crabs, and locomotion of the resulting larvae after hatch, were unaffected by the seismic survey.
   - In the short term, gills, antennules and statocysts (balance organs) were soiled in the test group but they were found to be completely cleaned of sediment when sampled five months later.

2. There were several significant differences between experimental results of test and control groups, even after five months. It was not known if these differences were due to environmental differences between the test and control sites. As a consequence, nothing definitive could be said about the results until further work is done:
   - The hepatopancreas (similar function to a liver) was found to be bruised in the test site.
   - Ovaries from animals at the test site were found to be bruised and had dilated oocytes with detached chorions (the outer membrane).
   - In one test group, embryo hatch was delayed by 5 days on average and resulting larvae were slightly smaller than controls.
   - Orientation (turnover rate), as measured by the time an overturned crab needs to right itself, was different between the test and control groups.

3. This experiment was the first of its kind in the world to test the potential impact of seismic exposure on snow crabs and it demonstrated the importance of careful experimental design and the type of work required in conjunction with future seismic surveys.

Introduction

On September 29, 2004 a scientific peer review was completed on the results of experiments designed to study the potential impacts of seismic energy on snow crab. This review evaluated the results from a preliminary study on the potential impact of low-level seismic energy (132 hours of survey time, low-volume 1,310 in^3 air-gun array) on the reproductive biology of female snow crab. The study included caging and laboratory experiments conducted in winter 2003 and spring 2004. The caging experiment was conducted at the location of potential hydrocarbon deposits off the western coast of Cape Breton. It also bordered the site of one of the highest concentrations of snow crab in the world. The caging experiment examined short (12 days) and medium (5 months) term differences in the morphology and physiology of snow crab at test and control sites. Snow crabs from both groups were also observed under laboratory conditions for differences in mortality, morphology, physiology, feeding and orientation (turnover rate) over a five month period.

The study was organized on short notice to take advantage of an operational seismic survey in late 2003. It was developed by a partnership with Corridor Resources, Area 19 snow crab fishermen, CNSOPB, NS Dept. of Energy and DFO. The study was preliminary because it was designed to reveal observations or issues that would merit more detailed investigation. The study was designed to accompany a seismic survey in late 2003 and because of the short preparation time, there were constraints on its scope and the amount of resources available. As a result it was decided to focus the study entirely at one test and control site and because of concerns about reproduction, on the same type of mature female snow crab.

It is important to note that the test and control sites were quite different in temperature, substrate and food availability, which made it difficult to clearly interpret the results. The test site was colder, shallower and may have had sediments with elevated levels of organic

material when compared to the control site. Temperature is an important variable controlling metabolism and healing of marine animals. In addition, it appeared that snow crab placed at the control site were slightly larger than crab at the test site despite both groups originating from the same place and time.

Finally, animals in the short- and medium-term experiments received different exposures of seismic energy. Forty-two hours of seismic testing were done after retrieving animals for the short-term experiments.

Responses to the Questions

1. Is there evidence from this study that indicates irreversible harm (including death) to female snow crab caused by these seismic operations?

- There were no significant differences in mortality between the test and control groups.
- In one of the four laboratory studies, observations of greater leg loss within the seismic test group may be linked to other causes such as conditions of transport.

2. Is there evidence from this study that seismic energy produced mortality or morbidity in female snow crab carrying eggs?

- There was no evidence of mortality or morbidity in the test group.

3. Is there evidence from this study that seismic energy produced long-term effects on the behaviour of female snow crab?

- This study was unable to adequately address this question, except there was a trend towards faster turnover rates in seismic-exposed crab.
- Over several months of observations in the laboratory, there was no difference in food consumption between test and control animals.

4. Is there evidence from this study that seismic energy produced long-term effects on the characteristics and morphology of gills and internal organs of female snow crab?

- There were differences between test and control groups in the characteristics of antennules, statocysts, gills, hepatopancreas and ovaries.
- Animals at the test site were found to have sediment (associated with organic material) in the antennules, statocysts and gills but they were clean when examined five months later.
- In the test group, there were changes in the cellular structure of the hepatopancreas consistent with a response to stress in both short- (12 days) and medium- (5 months) term conditions. It is not known if the noted differences were related to dissimilarity of control and exposed samples and/or different holding conditions in the environment instead of seismic exposure per se.
- There were abnormalities and some hemorrhaging in the ovaries of the test group. In addition, the mean diameters of oocytes from this group were also larger due to dilation. The cause is not known: see statement above.
- In terms of metabolic indices, levels of enzymes in the haemolymph (blood) were comparable between the seismic and control groups, suggesting no major cellular damage to organs like the hepatopancreas for fed animals kept in laboratory conditions.

5. Is there evidence from this study that seismic energy produced effects on the hatch of embryos carried by exposed female snow crab and subsequent morphology and locomotion of larvae?

- The rates of embryo survival to hatch were similar between the two groups.
- Embryo development within animals recovered from the vicinity of the seismic site appeared to be delayed. Furthermore, the larvae from the seismic site were smaller and had proportionally (to body size) smaller spines and eyes than the control larvae. This observation may be caused by environmental factors, such as temperature differences. In addition, 45

crab retrieved after 12 days from test and control groups were observed in the laboratory for differences in time to hatch and none were noted. In fact larvae from the test group appeared two days before those from the control group.

- There were no differences observed in swimming behaviour of larvae hatched from the two sites.

6. What further research would be useful, if any?

There are a number of short-term research initiatives that would help clarify the results:

- Biomass surveys were conducted both before and after the seismic survey. These surveys should be examined for changes in abundance of different categories of snow crab to see if there was any evidence of elevated natural mortality or redistribution. In addition densities of caged animals and wild animals should be compared.
- It would be helpful to summarize observations of egg loss for laboratory studies where possible and this information needs to be corrected for parental size because larger females produce more eggs.
- There was some evidence of bruising in gills of test animals and these observations should be completed for all test and control animals.
- Measurements of background or ambient sound were taken prior to the seismic testing and this information should be summarized.
- Information on leg loss should be summarized for all laboratory studies.
- Sediment from the test and control sites should be compared.
- An additional study was conducted in May 2004 to examine the dragging of cages during their retrieval and its impact on sediment observed in gills, statocysts and antennules. This work should be summarized.
- There were concerns that some of the observations could be related to size of animals. Thus a smaller subset of comparisons could be done with the same-sized animals for test and control observations.

This experiment was the first of its kind in the world and revealed the importance of careful experimental design and the value of continuing this type of work in conjunction with future seismic surveys. Examples of the type of work that would be helpful are:

- Baseline animals should be examined at test and control sites before any experiments are done.
- Video monitoring of snow crab behaviour in the field would be very helpful. Note that there were limited behavioural observations in the current study.
- It would be helpful to examine different categories of animals. For example the multiparous females (females carrying eggs that are not their first batch) examined in this study may not necessarily be the most sensitive stage.
- Future field work should include multiple control and test sites.
- Laboratory studies should be conducted under blind or double-blind conditions to ensure that there is no bias or observation error.
- It would be useful to understand how sound affects animals, i.e. sound pressure or motion of particles. It remains to be determined if seismic noise causes stress and if snow crab can actually hear the seismic signals.
- It would be useful to examine expected worst-case scenarios under controlled conditions. The advantage of lab study is that signal and exposure can be controlled precisely and a whole range of behavioural and physiological questions could be asked that are difficult or impossible to address in the field.
- It would be useful to examine other parts of the benthic community for potential impacts.
- Future work should examine effects of exposure to seismic signals when animals are buried in the sediment because signal levels may be higher in the substrate than the water column. The caging experiments did not allow animals to bury themselves.

- Future work should ensure that animals receive the maximum exposure to seismic energy that they are likely to encounter and the experiment should measure ambient and cumulative exposure to sound, including peak sound levels (RMS) and sound exposure levels (SEL).
- Future field experiments should include observations for longer time periods, up to one year to assess if there are long-term effects and/or recovery.
- It would be useful to examine exposure-distance relationships for the effects on egg development.
- Finally, it is important that information on potential impacts of seismic energy be communicated to other scientists working on these questions in other parts of Canada and globally.

7. How applicable are the results and conclusions of this study to other crustacean species (e.g. other crab species and lobster)?

- This work is very helpful because snow crab is a species that lives closely associated with fine bottom sediments and there are very few studies on the potential impact of seismic energy on substrate dwelling animals.
- Observations on larvae may be applicable to other animals with this life-history stage, such as other crab species and lobster.
- The questions and experiments raised by this study will help to guide future work.

Review of Scientific Information on Impacts of Seismic Sound on Fish, Invertebrates, Marine Turtles and Marine Mammals

Background

A Workshop to develop a "Decision Framework for Seismic Survey Referrals" held in March 2003 produced an inventory of ecological factors that DFO should consider when dealing with referrals for seismic surveys in Canadian waters. The workshop also discussed the sources of uncertainty about effects of seismic sounds on those ecological factors, and ways that the uncertainty could be presented in science documents evaluating possible impacts. The workshop did not attempt to review critically the scientific literature on impacts of seismic sounds or effectiveness of mitigation options. Consequently the meeting did not address tolerances for ecological impacts, if any, or operational standards for respecting such tolerances.

Following that Workshop, teams of scientists prepared major literature reviews of the primary and secondary literature that reports on experimental studies and field monitoring of effects of sound, particularly seismic sound, on marine organisms. Reviews were also contracted of the standards and mitigation methods applied by other national and international bodies which regulate seismic surveys in marine ecosystems, and of the strengths and problems with various sound propagation models in marine environments. These papers were reviewed at a National Advisory Process meeting on Seismic Impact Evaluation Framework in May 2004, although time did not allow a detailed critical review of the paper on standards and mitigation methods.

Figure 1: Map of Canada

Summary

- From the evidence available, it can be concluded that seismic sounds in the marine environment are neither completely without consequences nor are they certain to result in serious and irreversible harm to the environment. In the huge range of effects between those extremes, however there are many *potential* detrimental consequences. In general risks of these consequences are poorly quantified, often unknown, and likely to be variable with both conditions of the environment and of the organisms exposed to the sounds. The long and widespread history of seismic surveys globally in marine environments with no documented fish or invertebrate kills, and only circumstantial evidence of associations with infrequent strandings of marine mammals and giant squid, suggest that seismic surveys with fairly routine mitigation measures in place are unlikely to pose high risk of mortality of marine organisms. However, this suggestion must be qualified, because sublethal or longer-term effects could have occurred and not have been detected by the monitoring programs typically in place.

- Immediate behavioral reactions to exposure to seismic sound have been widely documented in marine organisms, especially marine mammals; particularly behaviors which would result in avoiding the immediate area where the sounds are being produced, or reducing vocalisations. The possible longer-term consequences of these short-term behavioral changes are debated among experts. The debate is largely speculative and there is little empirical basis to determine the likelihood of the full chain of events which would lead to serious longer-term consequences of the short-term behavioral reactions. However, the risk to be managed would be the combined probability of all the events in the chain occurring.

- Whatever the absolute level of risk posed by seismic sounds, there are mitigation measures available which the evidence available suggests can reduce the risk by varying, but sometimes substantial, amounts. The effectiveness of specific mitigation measures was not reviewed in detail at the meeting, but was generally agreed likely to depend on the effect of concern and how the measures are implemented. The impact on the seismic operations of application of some mitigation methods, such as not conducting surveys in critical times and places, will also vary with many factors, but sometimes also could be large. Clearly much more research and monitoring are needed to better clarify and quantify the unknown risks and uncertain effects, if they occur, and the effectiveness of mitigation measures to a wider range of potential effects. Towards that end, some key research needs are listed below.

Introduction

Literature reviews of the primary and secondary literature that reports on experimental studies and field monitoring of effects of sound, particularly seismic sound, on marine organisms were evaluated in May 2004, by a group of scientists from DFO, other federal and international agencies, the hydrocarbon exploration industry and environmental groups. The review indicated that information was incomplete to varying degrees in essentially all areas related to impacts of seismic sound on marine ecosystems. Nonetheless, the background papers and scientific deliberations resulted in a body of information that allowed the following conclusions to be reached.

These conclusions provide a science basis for developing a regulatory framework for use of sound in aquatic environments, at least in the frequencies used for seismic surveys. Some of the conclusions based on the laboratory studies reviewed may generalise to higher frequencies as well, but the review focused on scientific studies directly applicable to seismic sound. The conclusions also contribute to the scientific basis for an integrated approach to managing human impacts on marine ecosystems, and for dealing with referrals of applications for seismic surveys at the regional to national level within DFO.

Habitat Concern

The issue of concern was the effects of sound, particularly seismic sound, on marine organisms. Advice was sought to provide a scientific basis for developing a regulatory framework for use of sound in aquatic environments, at least in the frequencies used for seismic surveys.

Management Considerations

Overall Considerations:

1) The following statements and conclusions are based on information available and presented at the time of the Seismic Impacts Evaluation Framework workshop. Additional research is needed in many areas, and a number of these are identified in the meeting proceedings. These statements and conclusions

should be re-evaluated as new information becomes available.

2) When considering the possible impacts of seismic sounds on the marine ecosystem, it makes sense to embed these considerations within the larger framework of the impact of all anthropogenic noise on the ecosystem. The major anthropogenic sources of noise that might be appropriate to consider in a holistic view would include seismic sounds, shipping, explosives, construction, and low-frequency SONAR. Moreover, the significance of impacts of sound in the environment, if any, should be evaluated in the context of other uses of ecosystem.

3) The dearth of scientific information, especially concerning field experiments on fish, invertebrates, and the larger marine mammals, makes it extremely difficult to evaluate the impact of a particular type of seismic sound, or more generally noise, on a particular species. Restricting our consideration to only seismic sound impacts would have reduced the already-sparse information base to one that would not have supported any conclusions with an acceptable level of confidence, so we have looked more widely for relevant information.

4) If was not just for convenience that we looked for information more widely than just considering publications on effects of seismic sound on marine species. Given the scarcity of hard information on so many facets of this multi-dimensional problem, it is likely that a meaningful appreciation of risk can only be obtained by taking an integrated view of all the sources of information available.

5) Many conclusions refer to the likelihood of various biological effects, if animals were exposed to seismic sound. Likelihood is used in a relative sense, and not as the product of quantitative risk assessments, which are not possible with the information available. Saying that an event has a "high likelihood" does not mean we necessarily expect to see it in nine out of every ten animals exposed to the sound, or even in nine out of ten replicates of the same experiment. Rather, it means that compared to the expectation of the event in the absence of seismic sound, the likelihood of the event has increased substantially, and it would be observed if sought with due diligence. However, it still may not be the typical event. Where quantification of the probability of an event is possible, we use the term "probability" rather than "likelihood".

6) The conclusions that follow often refer to "seismic sound" and "field operating conditions". These terms are used colloquially and are not defined prescriptively. In this document "seismic sound" refers generally to that produced by the types of airguns and arrays normally used at present in Canadian waters. "Field operating conditions" refers to 2-D and 3-D seismic surveys using measures such as ramp-up of sound level at onset, and ceasing sound emissions when cetaceans are known to be in the proximity of the operations.

7) Both the likelihood and severity of biological effects that may result from seismic surveys are likely to vary with local conditions of the environment (ice coverage, bottom topography, sea state, etc.) and conditions of the organisms (breeding state, nutritive condition, etc.). These conditions should not be ignored when evaluating risks and the potential for mitigation, however regulatory frameworks do not need complex rules to be effective.

Limitations for quantitative conclusions:

8) It was agreed that the biologically meaningful aspect of seismic sound is the "received sound" by the organism(s) potentially being affected. However, "received sound" is multi-dimensional. Seismic sound (or noise in general) can

be characterised by its frequency spectrum (acoustic energy or pressure as a function of acoustic frequencies), peak pressure (a time domain concept, referring to the maximum instantaneous amplitude of the pressure signal), rms pressure (mean pressure averages over a time interval), Sound Exposure Level (a measure of the "dosage" of sound energy received over a time interval), and in other ways.

9) The mechanisms by which exposure to seismic sound could result in biological impacts are sufficiently varied that no one metric may be sufficient to describe the risk of impact from a particular type of seismic sound. Some mechanisms may be well characterised by one or two of these metrics; others may not be well characterised by any of them. For example, peak pressure may be the most relevant parameter for risk of trauma, whereas rms pressure may be the most relevant parameter for non-trauma effects such as Temporary Threshold Shifts [TTS]. The frequency band, intensity, and duration of exposure all contribute to auditory effects, because although the impact must occur within the frequency band of exposure, we anticipate that auditory impact is greater within the hearing range of a species, and will decline towards the margins of its hearing threshold.

10) Many studies of the impacts of seismic sound on marine animals reduce the information about the sound used or received to a few numbers. This practice often discards important information, and makes inter-comparison of results across studies very difficult.

11) Although careful experimentation ought to be able to determine which feature(s) of the sound stimulus caused the observed reactions (when they occurred), the existing literature on experiments with marine fish and invertebrates rarely describes completely enough the characteristics of the sounds used to allow biological observations to be interpreted with confidence.

12) The literature on experiments and field observations of marine mammals exposed to sound stimuli is more extensive than the literature on effects on other types of marine organisms, and therefore likely to provide a more complete (but still partial) basis for setting thresholds. However the results, taken together, were complex and inconsistent and were an insufficient basis for agreement on quantitative thresholds for impacts on marine mammals, even from those studies where there were adequate descriptions of the sound characteristics. The major review by the NMFS Acoustic Criteria Panel is devoting much more time to this information, and may contain a quantitative synthesis of stimulus-response relationships from the information available at present. That review, when released, may comprise a useful source of information for defining regulatory tolerances. Where sensitivities of marine turtles, fish, or invertebrates are documented to be greater than sensitivities of marine mammals those factors should be taken into account in the Canada standards, guidelines and/or regulations. It was conjectured that sedentary species that cannot leave an area may experience higher levels of exposure to seismic sound than mobile animals, and this factor may be taken into account in management as well.

13) Ecological "significance" can be a value-laden term, although in these conclusions "significant" is used only in the context of DFO's areas of responsibility. Specifically, DFO has a responsibility for conservation of aquatic species (except birds) and ecosystems, and where detrimental population-scale impacts are considered likely, DFO must ensure that the impacts are mitigated or remediated. Likewise, for aquatic species protected under Schedule 1 of SARA, if deaths, harm or harassment of individuals is considered likely to occur, DFO must

either act to ensure the impacts are ameliorated, or issue permits under the provisions of Section 73 of SARA.

Other limitations:

14) A number of studies reported sub-lethal effects on marine organisms, such as elevated stress-related chemicals, and damage to ears or other morphological structures. The dearth of long-term studies of marine organisms exposed to seismic sounds means that the long-term consequences of these effects, when they occur, are unknown.

15) The severity of impact at the population level may be higher for an effect like auditory masking, if it occurs, because masking has the potential to affect a very large geographical area for low frequency sounds. Masking also may have few immediately observable signs that impacts are occurring, so mitigation may be less likely to be triggered than with individual mortalities due to trauma, (which have limited geographical extent and are more easily observable).

Conclusions Regarding Fish

Physical Effects

1) There are no documented cases of fish mortality upon exposure to seismic sound under field operating conditions. With regard to the detectability of fish kills, if they occurred, it was noted that in Canada seismic surveys have frequently, but not always, included follow-on vessels instructed to watch for fish kills, and none have been observed. It was also noted that fish kills are not necessarily cryptic events, and kills caused by anoxic events, toxic spills etc are often readily detected. However, it was also argued that the efficiency of detecting fish kills by the follow-on vessels was not tested independently, so the possibility of undetected fish kills cannot be eliminated.

2) Under experimental conditions one study found that some subjects from three of four species tested suffered lethal effects from low-frequency (<500 Hz) tonal sounds, under exposure levels of 24 h at >170 dB. Participants noted that the experimental regime differed greatly from field operating conditions of seismic surveys, so extrapolation of the results to seismic surveys was not warranted. However some participants argued that the result indicates that risk of direct fish mortality from sounds with some characteristics of seismic sound cannot be discounted completely.

3) One anecdotal report of fish mortality upon exposure to an airgun less than 2 m away was discussed and found to be inconclusive when considered relative to field operating conditions. Overall, exposure to seismic sound is considered *unlikely* to result in direct fish mortality.

4) Under experimental conditions, sub-lethal and/or physiological effects, including effects on hearing, have sometimes been observed in fish exposed to an airgun. The experimental design made it impossible to determine to the satisfaction of all experts what intensity of sound was responsible for the observed damage to ear structures, nor the biological significance of the damage that was observed. Simulated field experiments attempting to study such effects have been inconclusive. Currently, information is inadequate to evaluate the likelihood of sub-lethal or physiological effects under field operating conditions. The ecological significance of sub-lethal or physiological effects, were they occur, could range from trivial to important depending on their nature.

Behavioral Effects

5) There is high likelihood of obtaining the following effects in some fish exposed to seismic sound:

   - startle response,

- change in swimming patterns (potentially including change in swimming speed, and directional orientation), and
- change in vertical distribution.

6) These effects are expected to be short-term, with duration of effect less than or equal to the duration of exposure, are expected to vary between species and individuals, and be dependant on properties of received sound. The ecological significance of such effects is expected to be low, except where they influence reproductive activity.

7) Several scientific studies have investigated other behavioral effects on fish during seismic surveys. Some have found the effects listed below and some have not:

- Change in horizontal distribution of fish not closely associated with habitat structures such as a reefs or pinnacles,
- Change in catchability of fish possibly related to changes in behavior. Differences in experimental regimes and lack of adequate controls in some of the experiments means that the published results are an insufficient basis to predict the nature of any change that may occur, or even if a change will occur.

8) The duration of these effects may or may not extend beyond the duration of exposure, are expected to vary between species and individuals, and be dependant on the properties of received sound. The ecological significance of such effects is expected to be low, except when they may lead to a dispersion of spawning aggregations or deflection from migration paths. The magnitude of effect in these cases will depend on the biology of the species and the extent of the dispersion or deflection.

Functional Uses of Sound

9) The potential for seismic sound to disrupt communication, detection of predators/prey, navigation and other functional uses of sound by fish has not been studied. There is speculation that the discontinuous nature of seismic signals may allow these functions to occur between sound "pulses". There is also speculation that behavioral responses may include cessation of sound production by fish. If it were to occur, hearing damage would also be expected to impact these functions. Ecological significance of such effects is unknown.

Conclusions Regarding Invertebrates

Physical Effects

1) There are no documented cases of invertebrate mortality upon exposure to seismic sound under field operating conditions. An anecdotal report of beachings of giant squid on two occasions, which corresponded to periods of seismic activity, was discussed and found to be inconclusive.

2) Under experimental conditions, lethal and/or sub-lethal effects, including effects on external structure, have sometimes been observed in invertebrates exposed close to (less than 5 m) an airgun.

3) Therefore, exposure to seismic sound is considered *unlikely* to result in direct invertebrate mortality.

Physiological Effects

4) There is a series of publications showing effects of extended exposure to non-seismic sounds on the physiology of crustacean under experimental conditions. Effects include reduced growth and reproduction rates and behavioral changes, which indicate the

sensitivity of some invertebrates to noise. In a gastropod (mollusc) the physiological effects (sign of stress) were reported under field seismic operating conditions. In other species such effects were rarely present, except for some sign of excitation of ensonified crabs compared to control crabs.

5) Currently, information is lacking to evaluate the likelihood of sub-lethal or physiological effects on crustaceans during pre-molt, molting and post-molt periods.

6) The ecological significance of sub-lethal or physiological effects, were they occur, could range from trivial to important depending on their nature.

Behavioral Effects

7) There is high likelihood of obtaining the following effects in some invertebrates exposed to seismic sound:

   - startle response,
   - change in swimming/movement patterns (potentially including change in swimming/movement speed, and directional orientation).

8) Both increases and decreases in catch rates of commercially exploited species have been documented, but changes do not occur consistently.

9) These effects are expected to be short-term, with duration of effect often less than the duration of exposure, are expected to vary between species and individuals, and be dependent on properties of received sound.

10) Some invertebrates are sedentary or have limited locomotive capacity. Therefore their capacity to avoid seismic sound is extremely limited compared to many fish and marine mammals. This may increase their exposure to seismic sounds, but there is no basis on which to assume that increased exposure makes such species inherently more or less sensitive to those sounds.

11) The ecological significance of the effects is expected to be low, except if effects of exposure to seismic sounds were to influence reproductive or growth (molting) activities, or lead to a dispersion of spawning aggregations or deflection from migration paths. The magnitude of effect in these cases will depend on the biology of the species and the extent of the dispersion or deflection.

Functional Uses of Sound

12) The potential for seismic sound to disrupt communication, orientation, detection of predators/prey, locomotion and other functional uses of sound by invertebrates has not been studied. Loud sounds will reduce the efficiency of communication and other functional uses of sounds, but the severity and conditions under which this occurs with invertebrates are unknown. It is not known if invertebrates can communicate acoustically during the inter-pulse intervals that occur between seismic transmissions. Ecological significance of such effects, if they occur, is unknown.

Conclusions about Zooplankton, Eggs and Larvae of Fish and Invertebrates

1) Few studies of the effects of seismic sound on eggs and larvae or on zooplankton were found. A number of these provided inadequate description of experiment design, properties of the sound applied as treatments, or had methodological shortcomings.

2) Data are generally insufficient to evaluate the potential damage to eggs and larvae of fish and shellfish (or other planktonic organisms) that might be caused by seismic sound under field operating conditions.

3) From the experiments reported to date, results do show that exposure to sound may arrest development of eggs, and cause developmental anomalies in a small proportion of exposed eggs and/or larvae; however these results occurred at numbers of exposures much higher than are likely to occur during field operation conditions, and at sound intensities that only occur within a few meters of the sound source.

4) Effects of seismic sounds on behavioral functions and sensory perception of fish and invertebrate eggs and larvae are unknown;

5) In general, the magnitude of mortality of eggs or larvae that models predict could result from exposure to seismic sound would be far below that which would be expected to affect populations. However, special life history characteristics such as extreme patchiness in distribution and timing of key life history events in relation to the duration and coverage of seismic surveys may require case by case assessment.

6) No studies were found which specifically investigated the role of seismic sounds in recruitment variation of marine fish or invertebrates. There have been a large number of research studies on causes of variation in recruitment of marine fish or invertebrates, and none has considered that there are recruitment anomalies (positive or negative) which might be linked in space or time to seismic survey operations. This negative evidence applies at the scale of stocks, but does not provide information about the potential for effects on local-scale recruitment dynamics.

Conclusions Regarding Marine Turtles

1) Auditory studies suggest that sea turtles, specifically loggerhead and green turtles, are able to hear and respond to low frequency sound, but their hearing threshold appears to be high.

2) In three studies, the following behavioral responses of sea turtles in enclosures exposed to airgun sounds were sometimes observed:

   - increased swimming speed,
   - increased activity,
   - change in swimming direction, and
   - avoidance.

3) Sea turtles may become accustomed to seismic sound over time, but results of three studies were inconclusive on this matter.

4) Loss of hearing sensitivity and physiological stress response has also been considered as a possible consequence of exposure of sea turtles to seismic sound, but the one study reviewed was inconclusive.

5) The response, if any, of free-ranging sea turtles to seismic sound conducted under field operating conditions is unknown.

6) Based on studies that have been conducted to date, it is considered *unlikely* that sea turtles are more sensitive to seismic operations than cetaceans or some fish. Therefore, mitigation measures designed to reduce risk or severity of exposure of cetaceans to seismic sounds may be informative about measures to reduce risk or severity of exposure of sea turtles to seismic sounds. However sea turtles are harder to detect both visually and acoustically than are many species of cetaceans, so mitigation strategies based on sightings or acoustic detection of turtles, are expected to be less effective for turtles than for cetaceans.

Conclusions Regarding Marine Mammals

Mortality and Physical Effects

1. There are no documented cases of marine mammal mortality upon exposure to oil and gas exploration seismic surveys. There is one case of a stranding event involving two whales coincident in space and time with a research vessel conducting seismic operations. There is one stranding event involving the same vessel and whales, coincident in time but not space, with no obvious mechanism that could bridge the distance between the vessel and the stranding site. In both cases the research vessel was also operating mid-frequency airgun systems that produce sound significantly more similar in character to the tactical mid-frequency sonar implicated in whale mass stranding events, than is seismic sound. The role of the different sound sources in the stranding events could not be resolved by the study. Therefore, although whale strandings have been linked to exposure to anthropogenic sound, exposure to seismic sound is considered *unlikely* to cause direct marine mammal mortality.

2. Under experimental conditions, sub-lethal, temporary elevations in hearing thresholds (TTS) have sometimes been observed in captive marine mammals exposed to pulsed sounds. Currently, the likelihood of these effects have not been evaluated under field operating conditions; for some species of marine mammals the levels and types of sounds which may produce TTS can be predicted, so such evaluations may be possible. The significance of such TTS effects, were they occur, are likely to be unimportant, unless:

    a. the threshold was elevated repeatedly or for an extended period of time, which could result in a Permanent Threshold Shift [PTS]; or

    b. other threats were present at the same time as the temporary elevations in hearing thresholds, and the threats were ones normally avoided by acoustic means, such as predators or entanglements in fishing gear.

3. There are no documented cases of a marine mammal experiencing damage to non-auditory body tissues upon exposure to seismic surveys under field operating conditions. Therefore, exposure to seismic sound under field operating conditions is considered *unlikely* to result in such types of tissue damage to marine mammals, but the presence of other sound sources operating simultaneously with seismic operations should be taken into account when proposals are evaluated.

Direct Behavioral Effects

<u>Displacement and Migratory Diversion:</u>

4) There is documented displacement and migratory diversion in some marine mammal species exposed to seismic sound. The duration of these effects may or may not extend beyond the duration of exposure. The effects are expected to vary between contexts, species, gender and age class, and individuals, and be dependant on the properties of received sound. The ecological significance of such effects is expected to be low, but may be higher if they:

- displace feeding marine mammals from areas where there are no alternates,
- displace marine mammals from resting areas where there are no alternates,
- displace marine mammals from breeding or nursery areas, or
- divert migrating animals from routes for which their alternate routes either do not exist or would incur substantially greater costs to traverse.

5) The magnitude of effect in these cases will depend on the biology of the species and the extent and duration of the dispersion or deflection. Also, there is a risk that a seismic project occurring in another area could cause incursion of displaced competitors into the critical habitat or area of high biological productivity occupied by other species.

6) In summary, exposure to seismic sound can result in displacement and/or migratory diversion in some marine mammals, but this effect is species, individual, and contextually-related. The ecological significance of such effects is *unknown*, but there are conditions under which the worst-case scenarios could be high.

Changes in Dive and Respiratory Patterns

7) There are documented changes in dive and respiratory patterns in some marine mammal species (e.g., bowhead whales, harbour and grey seals) exposed to seismic sound. There are records of the duration of these effects extending beyond the duration of exposure. The effects are expected to vary between contexts, species and individuals, and be dependant on the properties of received sound. The ecological significance of such effects is expected to be low, except if such effects:

   - interfere with feeding, or
   - incur substantial energetic costs;

   The magnitude of effect in these cases will depend on the biology of the species and the extent and duration of the dispersion or deflection.

8) In summary, exposure to seismic sound can result in changes in dive and respiratory patterns in some marine mammals, but this effect is expected to vary with species, individual, and context. The ecological significance of such effects is *unknown*, but there are conditions under which the worst-case scenarios could be high.

Changes in Social Behavior

9) Social behavior can include a wide variety of activities such as mating, cooperative feeding, play, aggressive interactions, and communication (see below). Studies of behavioral changes in other subsections of this summary describe effects on some of the activities that could be considered "social". However, there have been no directed studies of the effects of seismic sounds on mating, cooperative feeding, play, or aggressive interactions.

10) In summary, it is *unknown* if exposure to seismic sound can result in changes in marine mammal social behavior, but if it were to occur there are conditions under which the worst-case consequences of such changes could be highly significant.

Changes in Vocalisation Patterns

11) There have been direct studies of the potential for anthropogenic sound to cause changes in the vocalisation patterns of marine mammals. For most cetacean species studied, there were measurable changes in vocalisation patterns, but these studies were not conducted during seismic operations. In the UK, Norway, and the Sable Gully, sperm whales did not stop calling when exposed to seismic sounds. A study off Heard Island, found that sperm whales did not call during distant (690-1070 km away) seismic transmissions in some parts of the study, but did call during seismic transmissions during another part of the study. Blue whales in the NE Pacific stopped calling for approximately one hour when within 10 kilometers of a small (1600 in^3) seismic array; they resumed calling as they swam away from the array.

12) There is evidence that exposure specifically to seismic sounds has sometimes caused changes in vocalisation patterns in marine mammals. However, it has not been possible to measure the functional consequences of

these changes (such as loss of contact between individuals or reduced ability to coordinate social behaviors), if any, nor the percent of time which they would occur.

13) In summary, it is *known* that exposure to seismic sound can result in changes in marine mammal vocal behavior, and when it occurs there are conditions under which the worst-case consequences could be highly significant.

Functional Consequences of Physical and Behavioral Effects

Reduced Communication Efficiency

14) Many species of marine mammals both produce and respond to sounds. Studies have shown these vocalisations to sometimes communicate information that is functionally important for feeding, breeding, parental care, predator avoidance, or maintenance of social groupings. Studies have also found vocalisations can occur when there are no observable functional consequences, although in such cases it is unclear if the vocalisations had no consequences, or if the effects were longer term or farther afield than the studies. Hence it is difficult for research to produce conclusive results about the frequency of occurrence and consequences of disruption of communication by anthropogenic activities, including seismic sounds.

15) There have been no published studies of the potential for seismic sound to reduce the efficiency of communication in marine mammals. Loud sounds will reduce the efficiency of communication but the severity and conditions under which this occurs with marine mammals are poorly known. When seismic sounds are produced there are inter-pulse intervals which present the opportunity for cetaceans to place vocal communication signals, but cetaceans have not been shown to use this mechanism in the field. Moreover, there is unpublished information that when multi-path echoes occur, such as in areas of complex bathymetry, the pulses of the seismic sound may smear over distance and time, such that the quieter inter-pulse intervals may be reduced or eliminated. This creates the potential for calls of cetaceans such as blue whales to be masked by seismic sounds although the distances over which the masking would be effective, if it were to occur, are unknown. It is unknown if whales could reduce the effects of masking through processes such as changes in their calling patterns, and the consequences of these changes (if they occur) are unknown. This facultative response has been documented in some other marine mammal species exposed to loud manmade sounds. Therefore, it is *unknown* if exposure to seismic sound can result in such reduced communication efficiency in marine mammals.

Reduced Echolocation Efficiency

16) There have been no direct studies of the potential for seismic sound to reduce the efficiency of echolocation in marine mammals. Therefore, it is *unknown* if exposure to seismic sound can result in reduced echolocation efficiency in marine mammals.

Hampered Passive Acoustic Detection of Prey

17) There have been no direct studies of the potential for seismic sound to hamper the passive acoustic detection of prey by marine mammals. In a published study on the effects of whale watching vessels on killer whale behavior, it was postulated that sounds from these vessels could reduce the ability of killer whales to detect their prey. It is not known if such an effect could result during exposure to seismic sounds, or even which species of marine mammals use passive acoustic detection of prey as an important feeding strategy. However the potential for an effect is greatest for mysticetes whose best hearing sensitivity is thought to be at lower frequencies than other marine mammals. Therefore, it is *unknown* whether exposure to seismic sound could hamper the passive acoustic detection of prey by marine mammals.

Hampered Passive Acoustic Detection of Predators

18) There have been no direct studies of the potential for seismic sound to hamper the passive acoustic detection of predators by marine mammals. The potential for an effect is greatest for mysticetes, whose best hearing sensitivity is thought to be at lower frequencies than other marine mammals. However it is not known if such an effect occurs during exposure to seismic sounds, and if so, to what extent. Therefore, it is *unknown* whether exposure to seismic sound could increase the vulnerability of marine mammals to predators.

Hampered Avoidance of Anthropogenic Threats (such as ship strikes, net entanglement)

19) There have been no direct studies of the potential for seismic sound to reduce the ability of marine mammals to avoid anthropogenic threats. There are published reports of other types of sounds interfering with the ability of individual whales to avoid anthropogenic threats such as ship strikes and net entanglements, but it is not known how widespread this response is. It is also not known if such an effect could result from exposure to seismic sounds. Therefore, it is a *concern* that exposure to seismic sound could reduce the ability of marine mammals to avoid anthropogenic threats, but the risk has not been demonstrated.

Hampered Parental Care or Bonding

20) There have been no direct studies of the potential for seismic sound to hamper parental care or bonding in marine mammals. Therefore, it is *unknown* if exposure to seismic sound can hamper parental care or bonding in marine mammals.

Chronic Effects (e.g., stress-related physiological changes, reduced fecundity)

21) There have been no studies of the potential for seismic sound to induce chronic effects, such as immunosuppression or reduced fecundity, in marine mammals. Therefore, it is *unknown* if exposure to seismic sound can result in such chronic effects on marine mammals.

Indirect Effects (e.g., reduced prey availability)

22) There have been no studies of the potential for seismic sound to reduce prey availability, through displacement or reduced catchability, for marine mammals. Therefore, it is *unknown* if exposure to seismic sound can result in such indirect effects on marine mammals.

Research Needs

In the review a large number of areas of future research were identified. Some emerged as particularly helpful in increasing the information available to those quantifying and those managing the risks of seismic surveys in marine ecosystems.

1) More work is required to determine the sound characteristics and environmental conditions under which seismic effects on behavior, physiology, and physical well-being of all types of marine species might occur.

2) The available information on the effectiveness of mitigation measures needs to be more fully evaluated, as a basis for both interim advice on appropriate operational requirements in the short term and additional research needs to increase our knowledge in the longer term.

3) In addition to targeted research, there is great value to linking a program of structured collection of information to the conduct of seismic surveys, to facilitate learning-by-doing. However, such information collection programs must be well coordinated, and accompanied by the resources to analyse, interpret, and apply the new information, as it is collected and submitted to scientific authorities.

4) A few representative studies on distance-effect relationships for all taxa, but particularly eggs and larvae, would greatly aid understanding of potential risks posed by seismic sound. The potential for effects stemming from sound exposure level (cumulative over a survey) as well as peak received sound pressure level should be considered, including under conditions of 3-D surveys.

5) Specific research is needed on the level of received sound experienced by sessile invertebrates, and the effects of seismic sounds on such organisms. The physics of the sound levels to which benthic organisms are exposed is complicated due to shear effects interacting with pressure effects, and the proximity to the bottom substrates. Hence results of generic sound propagation models are likely to be misleading with regard to exposure levels of sessile benthic species. However, the errors could be in any direction, and in sites of complex bathymetry there could be very patchy distributions of areas with higher intensities of exposure than predicted by sound propagation models and other areas with lower intensities.

6) There is a specific absence of information on the effects of seismic sounds on molting of invertebrates with hard exoskeletons.

7) There is a need to further clarify the best sound propagation models for the areas likely to host seismic exploration, and how habitat characters should influence model selection. Generic models also need to be evaluated relative to the sensitivity and precision of their predictions relative to requirements for evaluating potential impacts, although site-specific implementations of generic models will continue to be desirable.

8) Better data input is needed during modelling of the expected pattern of spread of seismic sounds during surveys. Near-and far-field sound measurements should be encouraged as part of seismic operations planned for an area that has not been surveyed previously, or if previous models have been shown to be inaccurate.

9) Further research on potential impacts of seismic sound on marine mammals is urgently needed. The issues in most need of attention through scientific research or further analysis of existing data include:

    a) An important scientific unknown limiting our ability to predict the effects of seismic surveys on marine mammal populations is knowledge of their spatio-temporal distribution, and physiological state and needs. Without knowledge about what species are present in which areas at what time of the year and for what purpose, there will always be risks of disturbance and injury to sensitive species. An effort should also be made to characterise the degree of

long-term natural variation in abundance and residency.

b) There is a need for significantly more information regarding the reactions of marine mammals (and their prey) to underwater sound from seismic arrays. Baseline studies prior to seismic operations, plus comparative reports during periods with and without seismic would contribute important new data.

c) There is a need for better and more accurate information on naturally-occurring and man-made noise in the ocean.

d) The effectiveness of all potential mitigation measures needs to be explored and documented more fully. In particular there is a need to document the extent to which passive and/or active acoustic monitoring of marine mammals from the source vessel is an effective mitigation strategy.

e) There is a particular need for directed studies of social behavior of marine mammals during seismic exposures, given the importance of these activities to marine mammals' biology.

f) The effects of anthropogenic sounds on the vocalisation patterns of marine mammals are well documented, but the effects of specifically seismic sounds are poor known, and warrant further study.

Many of these factors are also poorly known for many taxa of marine turtles, fish, and invertebrates. Research to fill in such knowledge gaps, particularly with regard to spatio-temporal distribution of important prey taxa and their reactions to seismic sound, would be valuable, although the topics listed above were given higher priority. A number of other topics requiring additional research were proposed by various individuals, and are recorded in the meeting proceedings.

Development of a Closed Area in NAFO 0A to protect Narwhal Over-Wintering Grounds, including Deep-sea Corals

Context

This report provides background information on the development of effort restrictions for the Greenland halibut fishery in the southeast area of the Northwest Atlantic Fisheries Organization (NAFO) Div. 0A. The decision to close this area was taken by Fisheries Management in April 2006 and set out in the draft 2006-2008 Fisheries Management Plan for Greenland Halibut in NAFO SA0 that was circulated to stakeholders for comment in September 2006. A summary of narwhal life history and biology is included while more detailed information is available in the publications listed under Sources of Information. DFO policies related to this issue are under development. The material summarized here comes from published scientific literature and as additional research is undertaken, the advice provided in April 2006 may be modified to reflect the results.

Effort restrictions were first established in 1998 following consultation between DFO Fisheries Management, Science and the Nunavut Wildlife Management Board. There were concerns about the concentration of bottom trawl fishing effort in the southern narwhal over-wintering area and potential for habitat destruction and local depletion of Greenland halibut, a significant food resource of narwhal. These restrictions were subsequently included in the 2003-2005 Management Plan. During the consultation meeting for the 2006-2008 Management Plan, held February 7 and 8, 2006 in Iqaluit, there was general agreement that these restrictions would continue. With the introduction of gillnets to the fishery in 2004, the risk of narwhal entanglement in lost gillnets had increased. Gillnets were lost in both the 2004 and 2005 fishery. There was also new information provided in March 2006 on the potential ecosystem effects of the first few fishing events on sensitive habitat. Fisheries Management, following discussion with Science, decided in early April 2006 to close the area rather than continue with fishing effort restrictions. The draft 2006-2008 Management Plan defines the closed area as: Point A) 68° 15' N / 58° 30' W in the Northeast; Point B) 68° 15' N / 60° 30' W in the Northwest; Point C) 67° 15' N / 60° 30' W in the Southwest and Point D) 67° 15' N / 57° 50' W in the Southeast. This area corresponds to the core of the southern narwhal over-wintering ground and includes three of the four locations where deep-sea corals have been found.

Background

Prior to 1996, there had been very little fishing with otter trawl or any other gear in Div. 0A. The Greenland halibut fishery had been concentrated in Davis Strait on the Div. 0B fishing grounds with annual catches of approximately 5,500 t. An exploratory fishery for Greenland halibut began in 1996 with an allocation of effort rather than total allowable catch (TAC). Fishing was carried out by an otter trawl vessel. The effort for 1996 was set at 32 days (catch was 329 t). Div. 0A was also divided into four "sub-zones" with a minimum of six days to be fished in each sub-zone in an attempt to distribute fishing effort. In 1997, a similar approach was used with Div. 0A being further sub-divided into 18 sub-zones and three otter trawl vessels were licensed for a fixed number of days with catches totaling 241 t. These vessels were free to spend time

fishing where they chose but also had to fish a certain amount of time in specific sub-zones in order to distribute effort and allow assessment of Greenland halibut distribution within Div. 0A. In both years, a majority of the tows were conducted in sub-zone 2.1 in the south-east corner of Div. 0A (Appendix 1).

During this same period, marine mammal researchers were analyzing tracking data and dive behaviour data from narwhals tagged in Eclipse Sound, Baffin Island and Melville Bay, Greenland. Narwhals from these summering areas over-wintered in heavy pack ice (Heide-Jørgensen *et al.* 2002 and 2003) in the same area where the Greenland halibut fishery was concentrated in 1996 and 1997 (Appendix 2). The Greenland halibut fishery begins in late July and continues through to the middle of November. Narwhals arrive on their over-wintering grounds in late October or early November and leave the following April. Narwhals do not feed extensively on their summering grounds but are known to rely on Greenland halibut as a major food source during fall and winter (Laidre *et al.* 2004a). It was noted that during the time narwhals were on the southern over-wintering grounds they spent considerable time diving to depths over 800 m which corresponds to the depth where Greenland halibut are most abundant (Laidre *et al.* 2003 and 2004b, Treble *et al.* 2000 and 2001).

The closed area defined above corresponds very closely to the southern narwhal over-wintering grounds as shown in Laidre *et al.* 2004a which is based on satellite tracking data from three narwhals from Eclipse Sound and two from Melville Bay that spent time in the over-wintering area (Dietz *et al.* 2001 and Laidre *et al*. 2003). Additional whales were tagged and information on timing and direction of migration and dive behaviour were collected but the signal was lost before they reached the wintering ground. As new information becomes available the boundaries of the closed area could be adjusted.

Concern was expressed by Fisheries and Oceans Canada (DFO) as well as our co-management partner, the Nunavut Wildlife Management Board (NWMB), that narwhals could be impacted if the bottom habitat were damaged and their food supply depleted in the southern over-wintering area. The Greenland halibut fishery becomes concentrated in the southeast portion of Div. 0A late in the season because of encroaching sea ice. This increase in effort occurs immediately prior to the arrival of the narwhal. In 1998, fishing restrictions were put in place to limit fishing activities in sub-zone 2.1, which was found to correspond very well with the core of the narwhal's over-wintering grounds and later described by the points listed above. Three vessels were restricted to a combined total of 12 days of fishing in this area. This was approximately the level of effort observed in 1996 and 1997. This restriction has been maintained as policy for vessels fishing in the Greenland halibut fishery since 1998, although in some years, it was mistakenly omitted from certain exploratory licenses and compliance may not have been monitored.

Up to 2005, the harvest of Greenland halibut from the restricted area has comprised a relatively small portion of the overall harvest within Div. 0A based on a review of catch data from vessel daily hails and logbook data provided to the Eastern Arctic Area Office. In 2003, for example, 1.3% (55.4 t) of the trawl catch and 6.6% (272 t) of the overall catch came from the restricted area. In 2004, 3.0% (114 t) of the trawl catch and 5.0% (191 t) of the overall catch and in 2005 0.2% (8 t) of the trawl catch and 5.4% (233 t) of the overall catch came from the restricted area. During this period, there were effort restrictions in place but in each year there was at least one vessel that did not comply with these restrictions. Effort displaced by a complete closure of this area should be able to re-locate to other grounds within Div. 0A.

In 1999 and again in 2001, deep-sea coral species (including gorgonian species) were identified at several locations within the narwhal over-wintering grounds during multi-species trawl

surveys conducted by DFO. Division 0A has been surveyed several times (1999, 2001, 2004 and 2006) and gorgonian deep-sea corals have not been found anywhere else within Div. 0A.

Gillnet vessels were first introduced into the Div. 0A fishery late in 2004. In 2005, 26% of the catch came from gillnet vessels and in 2006 their share of the Div. 0A catch had increased to approximately 40%. The use of gillnets in the narwhal over-wintering area increases the risk of narwhals becoming entangled in lost nets. Bio-degradable mesh or similar technology is in development but it has not been used in this fishery. In 2004, there were 174 gillnets lost, approximately 16 km (each net is approximately 50 fathoms by 2 fathoms or 91.5 m by 3.7 m). DFO Science advised against the use of gillnets throughout Div. 0A in a briefing note submitted to the NWMB in March 2005. Rather than restricting their use however, an end date to the gill net season of Nov. 15th was established in an effort to reduce the risk of gear loss due to late season ice conditions. There were 291 (27 km) and 135 (12 km) gillnets reported lost in Div. 0A in 2005 and 2006, respectively.

Restrictions were not placed on vessels fishing for shrimp because they fish in shallow waters (<400 m). Dive behaviour showed that narwhals used depths >800m and deep-sea corals were found at depths >500 m.

The Committee on the Status of Endangered Wildlife in Canada (COSEWIC) re-assessed the status of narwhal in Canada in 2004 and recommended the designation of “Special Concern” for all populations (COSEWIC 2004). COSEWIC cites uncertainty about numbers, trends, life history parameters, and levels of sustainable hunting as reasons for this designation. The developing fishery for Greenland halibut, one of the main prey species of narwhal, and the presence of lost gillnets in the narwhal over-wintering areas could be considered potential risks to the population that were not identified by COSEWIC.

At their April 2006 meeting the Canada/Greenland Joint Commission on the Conservation and Management of Narwhal and Beluga noted that “…under some scenarios of a high loss rate and/or a low rate of population increase, there is a risk that present catch levels are not sustainable in one of the small units (Admiralty Inlet sub-stock.” (JCNB 2006). Admiralty Inlet is one of three sub-populations of narwhals that are known to over-winter in southern Baffin Bay. On the interaction between Greenland halibut (turbot) and narwhal the JCNB noted that “… the Scientific Working Group indicated that turbot, an important commercial species, forms a significant part of the diet of narwhal. The Commission, at their May 2004 meeting noted that interactions between these two species may become a management concern.” (JCNB 2004).

Literature and Policy Review

Narwhal Life History and Biology

Research on narwhal in Baffin Bay beginning in 1997 has continued with tagging programs conducted in Eclipse Sound in 1997, 1998 and 1999, Creswell Bay, Somerset Island in 2000 and 2001 and in Admiralty Inlet, Baffin Island in 2003 and 2004. Narwhals from Eclipse Sound (n=3, Dietz *et al.* 2001, Heide-Jørgensen *et al.* 2002, Laidre *et al.* 2003), and Admiralty Inlet (n=18, unpublished data) off Baffin Island and from Melville Bay (n=2, Dietz *et al.* 2001, Laidre *et al.* 2003) off Greenland were observed to over-winter in the south-east area of Baffin Bay, identified as the “southern narwhal over-wintering area”. Narwhals from Creswell Bay, Baffin Island over-wintered further north, in the “northern narwhal over-wintering area” (Heide-Jørgensen *et al.* 2002, Heide-Jørgensen *et al.* 2003, Laidre *et al.* 2003). The northern over-

wintering area lies completely within Greenland waters, while the southern area lies primarily within Canadian waters (Appendix 2).

An examination of dive behaviour data showed that the number of surface dives (0 to 50 m) and time at the surface declined between summer and winter and clear differences were noted between the two over-wintering areas (Laidre *et al.* 2003) (Appendix 3). In the northern over-wintering area (Somerset sub-populations) narwhal spent most of their time diving to between 200 and 400 m while narwhal in the southern over-wintering area (Eclipse and Melville sub-populations) spent less time at shallow depths and most of their time diving to 800 m or deeper, spending over 3 hours at these depths per day and traveling 13 min. per round trip (Laidre *et al.* 2003) (Appendix 3).

Stomach contents of 94 narwhals harvested in the Eastern Canadian high Arctic and West Greenland were examined to assess feeding activity and prey selection (Laidre and Heide-Jørgensen 2004). Stomachs collected from summer harvests in Eclipse Sound, West Greenland near Inglefield Bredning and Melville Bay (n=21) contained Arctic cod, polar cod and squid but most were found to be empty (Laidre and Heide-Jørgensen 2004). Samples were collected in late fall from Uummannaq, West Greenland (n=51 stomachs from). Winter samples were collected 20 km offshore from Disko Island in approx. 800 m of water (n=22 stomachs) (Laidre and Heide-Jørgensen 2004). Greenland halibut, squid and shrimp were most common prey items in the fall and winter samples with Greenland halibut constituting a significant winter resource. Greenland halibut were found in 64% of the narwhal stomachs collected in winter and were the only prey species found in almost half of all stomachs sampled (Laidre and Heide-Jørgensen 2004 and Laidre 2003). There were no narwhals sampled from the over-wintering ground which is well off-shore with heavy ice conditions making sampling dangerous.

Laidre *et al.* 2004a investigated deep-ocean predation by narwhals using a bio-energetic model, narwhal satellite data and data on fish abundance, density and length frequencies. The bio-energetic model was used to estimate the biomass of Greenland halibut needed to sustain the sub-population(s) of narwhals for the five months that they spend on their winter grounds. The authors noted that energy budget models are not assumption-free and their model was no exception. They developed a “minimum realistic” model with results that compared well with one developed for beluga whale (Welch *et al.* 1993 in Laidre *et al.* 2004a). Estimates were made for varying levels of Greenland halibut in the narwhal diet, 25%, 50% and 75%. Assuming a diet comprised of 50% Greenland halibut Laidre *et al.* (2004a) estimated a daily consumption of 90 t and a mean consumption overall of 13,500 t (95% CI of 5,400 t – 28,300 t) for the southern narwhal over-wintering area that at the time was estimated to support 5,000 narwhal. They also found that the difference in Greenland halibut biomass between an area with high predation by narwhals and a comparable area without whales was approximately 19,000 t and corresponded well with the predicted biomass removed by the narwhal, assuming a diet of 50%-75% Greenland halibut (Laidre *et al.* 2004a).

The current narwhal population estimates for the Melville Bay and Eclipse Sound sub-populations that over-winter in the southern wintering ground is 20,000 and there is now evidence that approx. 5,000 narwhals from Admiralty Inlet also use this over-wintering area. Extrapolating to these new estimates of population size and assuming a diet of 50% Greenland halibut, the three sub-populations of narwhals may consume in the order of 67,500 t of Greenland halibut over the five months spent on their wintering ground. The most recent estimate for Greenland halibut biomass in southern Div. 0A is 86,176 t (S.E. 12,502) (Treble 2005) and for all of Baffin Bay it is 222,336 t (Jørgensen 2005). While the estimate for narwhal consumption on the southern over-wintering ground is higher than what was first reported by Laidre *et al.* (2004a) it still falls within the estimated biomass of Greenland halibut. Laidre *et al.*

(2004a) also found that mean densities and length distributions of Greenland halibut inside and outside of the narwhal wintering grounds correlated well with predicted whale predation levels based on diving behaviour (Appendix 4), which further supported their conclusions that narwhals were targeting Greenland halibut in the southern over-wintering grounds.

The TAC established for the Greenland halibut fishery in Baffin Bay (NAFO Div. 0A and 1A(offshore) and 1B) is lower than that set in other Greenland halibut fisheries. This approach was taken because of the difficulty in monitoring the Baffin Bay Greenland halibut stock, the possibility of reduced growth due to colder oceanographic conditions and predation of a significant amount of Greenland halibut by narwhals.

The northern over-wintering ground supports a larger number of whales (approx. 45,000 in 1996) and was estimated to require 700 t per day with a mean consumption over five months of 110,700 t (95% CI of 53,000 t - 310,300 t). This estimate for the northern over-wintering area was greater than the abundance of Greenland halibut estimated in a 2001 survey (36,416 t (Jørgensen 2005)). Laidre *et al*. 2004a suggest that Greenland halibut likely do not play the same role in the diet of narwhals in the northern area that they do in the southern area. An increase in the number of dives and time spent at mid-water for narwhals in the northern over-winter area compared to those in the southern over-winter area supports this conclusion (Laidre *et al.* 2003) (Appendix 3). Also, pelagic polar cod increase in abundance with increase in latitude (Laidre *et al.* 2004a) (Appendix 5) suggesting that schools of polar cod may be an alternative food source to Greenland halibut in the northern over-wintering ground (Laidre *et al.* 2004a).

Top predators are thought to congregate at predictable sites in response to elevated availability of prey resources driven by physical oceanographic processes (Guinet *et al.* 2001 and Thompson *et al.* 2003 in Laidre *et al.* 2004b). Also, marine trophic interactions are complex and are not easily measured so physical habitat features such as depth or bottom temperature are often used as proxies for the distribution of prey resources. Laidre *et al.* (2004b) found that bottom temperature was the strongest predictor of fall and winter movements and dive behaviour of narwhals. Bottom temperature on the west side of Baffin Bay rarely exceeded 1° C while bottom temperatures were much warmer on the east side, as high as 4.0 to 4.5^{o} C.

Greenland halibut are relatively abundant throughout Baffin Bay and Davis Strait (Appendix 4) so prey distribution alone would not account for the overwintering concentration of narwhals. Winter distribution of narwhals may result from a combination of prey abundance, oceanographic conditions such as sea-ice concentration and predator (killer whale) avoidance, so how readily narwhal would shift their over-wintering area in response to local depletion of prey is unknown.

Deep-sea Coral Locations in Baffin Bay

The distribution of coral in Atlantic Canada based on data from DFO groundfish trawl surveys (including those described below) and fisheries observer reports is reviewed in Gass (2002) and Gass and Willison (2005).

Scientific surveys were conducted using otter trawl gear in Baffin Bay in 1999, 2001, 2004 and 2006. During the 1999 survey, a large mound or reef of gorgonian coral (predominantly comprised of *Keratoisis ornata*) was encountered at 67° 58' N and 59° 30' W. The trawl filled with the heavy coral after only nine minutes and could not be brought back on board. The twine gave out due to the weight and only the doors and rigging lines were retrieved. This location fell within the southern narwhal over-wintering grounds and the restricted fishing zone (2.1)

described above (Appendix 1 and Appendix 6). In 2001, several cold-water coral species including two gorgonian species (*Acanella arbuscula, Paragorgia arborea*) and a *Flabellum* sp. were identified at three locations within the southeastern portion of Baffin Bay and within the narwhal over-wintering grounds (Appendix 6). Two of these locations fell within the restricted fishing zone and at one of these locations three different species were caught in a single 30 minute tow. No hard corals have been found in any other area of Div. 0A.

It could be argued that the entire area surrounding the locations where deep-sea coral were located should be protected from trawl gear. However, this would include most of the southeastern portion of Div. 0A, that area east of 60°W, and would create a significant problem for the fishery. The compromise was to close an area which corresponds to approximately 50% of the total area encompassed by locations where corals have been identified.

The bathymetry in the closed area is characterized by a very steep gradient between the 400 m and 1000 m depth contours, leveling off somewhat between 1000m and 1500 m. Given that coral was found at different randomly selected stations there is a good chance conditions would be suitable for coral growth in other locations as well. With the low level of fishing effort in the early years of the Greenland halibut fishery and the effort restrictions in place since 1998 it may be reasonable to assume that there is still habitat in this area that has not been impacted by bottom trawl gear. However, it is not possible to determine the actual status of any coral areas without conducting video or Remote Operated Vehicle surveys and there are no plans for this type of research in the near future.

In 2003, DFO drafted a national strategy for conserving deep-sea gorgonian corals which identified fishery closures as an interim management tool that could be implemented through fisheries management plans to protect known or newly discovered areas of significance. Since then, DFO conducted a National Advisory Process meeting in March 2006 to review impacts of trawls (DFO 2006) and a Policy for Managing the Impacts of Fishing on Sensitive Benthic Areas is under development (see below).

DFO Draft Policy for Managing the Impacts of Fishing on Sensitive Benthic Areas

DFO is developing policy to guide the management of impacts of fishing on sensitive benthic areas. Restrictions applied to the Greenland halibut fishery in 1998 were also established to minimize gear impacts from trawling on benthic organisms and physical structures that provide habitat for Greenland halibut and their prey. The decision to restrict fishing effort in a significant portion of the southern narwhal over-wintering area is consistent with the intent of the draft policy for protecting sensitive benthic areas. New information suggests the greatest damage to ecosystems that are most vulnerable to fishing activity occurs with the first few fishing events (DFO 2006). The area in question could have been considered a “frontier area” in 1998 (DFO 2006), and a decision to close the area completely to bottom trawl fishing at that time might have been more appropriate. Since then we have new information concerning deep-sea corals and although fishing has occurred in the area effort has been restricted and it is believed that a closure to bottom impacting gears would be in keeping with the precautionary approach to fisheries and ecosystem-based management.

DFO Draft Policy on Fisheries for Forage Species

DFO is developing policy as a guide for fisheries targeting forage species. The management decision taken in 1998 to restrict fishing effort in a significant portion of the southern narwhal

over-wintering area is consistent with the goals of this draft policy for forage species. While Greenland halibut might not be thought of as a typical forage species there are aspects of the policy that could apply. For example, Greenland halibut is a significant component of the diet for three sub-populations of narwhals that over-winter in southern Baffin Bay. Restrictions were also applied to the Greenland halibut fishery in 1998, in part, to ensure that local depletion of the narwhal food supply did not occur in the southern narwhal over-wintering area. In October and November, ice conditions in Baffin Bay force fishing effort to concentrate in the southern area of NAFO Div. 0A. If no restrictions were in place, the increased effort in this area could result in a depletion of Greenland halibut immediately prior to the narwhal's arrival in November. Greenland halibut are not a sedentary species so they would move in to re-occupy depleted areas but the rate at which this would occur is not known. If dispersal takes a number of days or weeks local depletion might not impact the narwhals but if it takes a number of months or up to a year then local depletion could be an important consideration. Given the uncertainties effort restrictions in this area are warranted.

Ecosystem-based Management

The Oceans Act, passed in 1997, requires the consideration of impacts of all human activities on an ecosystem level, not just impacts on a single species or stock. As a result DFO Science and Fisheries Management have been working towards an "ecosystem approach" to fisheries management by developing mechanisms with which to incorporate ecosystem considerations within single species assessment and management. The Fishery Management Plan for Greenland Halibut in NAFO SA0 includes several Biological Objectives one of which is to "Protect critical habitat, ecosystems and other species" (DFO 2006 in prep.). The management measure to restrict fishing in the narwhal over-wintering ground was implemented to help achieve this objective which is further enhanced by the decision to close the area entirely for all fishing gears.

Conclusions

Since 1998, the Greenland halibut fishery in NAFO Div. 0A has expanded to a level of 6,500 t TAC and a combination of otter trawl and gillnets is currently being used in this fishery. Since 1997, new information on narwhal migration, over-wintering areas and diet added further support to continue the 1998 decision to establish fishing effort controls in the southern narwhal over-wintering grounds. The introduction of gillnet gear into the fishery in 2004 and this fleet's concentration in the southern portion of Div. 0A introduced the potential for narwhal entanglement in lost gear. In addition, the identification of deep-sea coral and a greater understanding of fishing gear impacts on sensitive benthic habitat suggested that further steps should be taken to protect the area. In April 2006, DFO Fisheries Management, following discussions with DFO Science, decided that a significant portion of the southern narwhal over-wintering grounds that includes deep-water coral locations should be closed to all Greenland halibut fishing (fixed and mobile gears). A description of the closed area was included in the draft 2006-2008 Fisheries Management Plan for Greenland Halibut in SA0.

In summary, the rationale for closing an area of NAFO Div. 0A to the Greenland halibut fishery :

1) COSEWIC has assessed narwhal, including the high Arctic populations as "Special Concern". Important over-wintering habitat for three sub-populations is located in the southeast corner of NAFO Div. 0A where bottom temperatures are the warmest. The size of the closed area was based on tagging data from five narwhals from two of the sub-populations. The boundaries will be re-examined as more data becomes available.

2) Greenland halibut are an important forage species for narwhal, particularly the three sub-populations, Melville Bay, Eclipse Sound and Admiralty Inlet, that utilize the southern over-wintering area located in the southeast corner of NAFO Div. 0A. Continued research on narwhal diet and bio-energetic requirements is needed to further refine estimates of Greenland halibut consumption.
3) Narwhals feed primarily during the period spent on their over-wintering grounds. By closing a significant portion of the grounds to Greenland halibut fishing, we would ensure this important food resource does not become locally depleted prior to the narwhal's arrival on these grounds.
4) The only deep-sea corals found to date in Division 0A came from by-catch during scientific groundfish surveys conducted in 1999 and 2001 and were located within the southern narwhal over-wintering area. The role deep-sea coral plays in the ecosystem is still being investigated. Using a precautionary approach, measures should be taken to protect these areas from bottom impacting gears in the interim. The closed area covers approximately 50% of the total area encompassed by locations where corals were identified. It was recognized that this does not protect all the known coral locations but was a compromise in recognition of the developing fishery. The size of the closed area to protect coral habitat could be re-examined in the future.
5) While gillnets don't have the same degree of impact on benthic habitat as bottom trawls they can disturb habitat. However, in this case the risk of narwhal entanglement in lost gear, in an area where narwhals aggregate for several months at a time, is a concern and this risk is reduced by excluding gillnet gear in a significant portion of the over-wintering area.

The draft policies discussed above will undergo a consultation process prior to being adopted as policy. The advice provided in April 2006, summarized in this report, may be modified in the future as more information is gathered on benthic habitat, narwhals and coral in Southeast Baffin Bay. In the meantime, DFO is being guided by a broad ecosystem approach provided in part by these draft policies which includes the need to consider the impacts of fishing on forage species and on benthic habitat, with a view to determine ways of mitigating those impacts.

STOCK DEFINITION OF BELUGAS AND NARWHALS IN NUNAVUT

Beluga by G. Kuehl

Narwhal by R. Phillips.

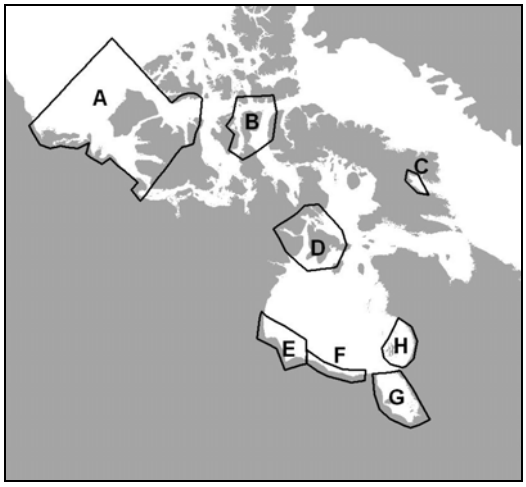

Figure 1: Summer aggregations of Nunavut beluga whales (A: Eastern Beaufort Sea; B: Eastern High Arctic-Baffin Bay; C: Cumberland Sound; E-D-F: Western-Northern-Southern Hudson Bay (Western Hudson Bay population); G: James Bay; H: Eastern Hudson Bay).

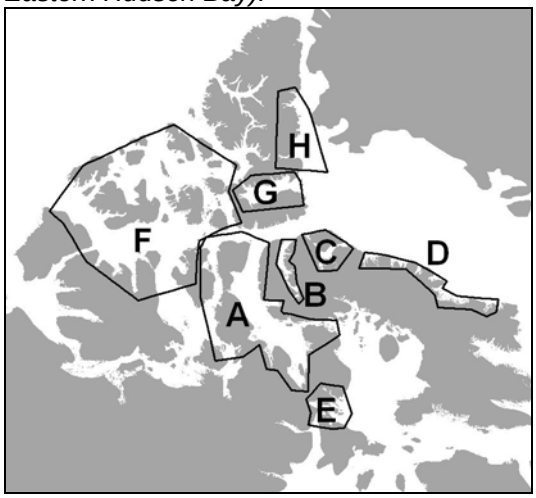

Figure 2: Summer aggregations of Nunavut narwhals (A: Somerset Island; B: Admiralty Inlet; C: Eclipse Sound; D: East Baffin Island; E: Northern Hudson Bay F: Parry Channel; G: Jones Sound; H: Smith Sound).

Context :

The Nunavut Wildlife Management Board (NWMB), in its review of advice provided by DFO Science on Total Allowable Harvest (TAH) for Nunavut beluga and narwhal stocks, has asked DFO to provide clarification on its rationale for providing science advice on the basis of known summering stock aggregations rather than at the population level. The NWMB also asked for clarification about various terms used (e.g., population, stock, sub-stock, management unit) and for an update on the current stock identity of belugas harvested by hunters from Iqaluit and Kimmirut.

In response to the request from the NWMB, this document provides the rationale to support previous science advice for harvest levels based on summering stock aggregations. It also provides information relevant to the definition of stocks of belugas and narwhals in Nunavut.

SUMMARY

- There is good evidence that Nunavut belugas are segregated geographically on a seasonal basis and, in many cases, year-round. There is also good evidence of genetic, contaminant and morphological differences between many of these beluga stocks.
- Six stocks of belugas potentially occur in Nunavut waters: Eastern Beaufort Sea, Eastern High Arctic-Baffin Bay, Cumberland Sound, Western-Northern-Southern Hudson Bay, James Bay and Eastern Hudson Bay.
- Evidence for narwhal segregation between stocks is largely based on tracking data, although some genetic and contaminant analyses also suggest some degree of geographical partitioning.
- Five stocks of narwhals occur in Nunavut waters: Somerset Island, Admiralty Inlet, Eclipse Sound, East Baffin Island, Northern Hudson Bay
- Managing harvest based on stocks reduces the potential for local depletions.
- Using current stock information is an appropriate and precautionary approach to co-management particularly for hunting communities that rely on a predictable seasonal occurrence of animals for their subsistence harvest.

INTRODUCTION

The term “stock” generally refers to a resource unit: a group of animals that are subject to hunting. The biological definition of a population is a reproductively-isolated group of animals. Stocks defined here may or may not be populations in that sense but they are geographically segregated groups subject to hunting. The term “sub-stock” was used by the Scientific Working Group of the Joint Commission on Conservation and Management of Narwhal and Beluga (JCNB) and the North Atlantic Marine Mammal Commission (NAMMCO) to subdivide the previously known “Baffin Bay Narwhal” stock into smaller management units to reflect information on the “sub-stocks” seasonal segregation. It essentially means “stock”. This analysis refers only to management “stocks”, keeping in mind that some of these stocks may or may not be “populations” in the biological sense.

Factors such as demographic and life history variability, habitat patchiness, environmental change, genetic sub-structuring and adaptability may result in temporally- or spatially-structured populations. It is possible to have localized depletions or extinctions if these factors are not considered when harvesting occurs. It is important to choose the definition of stock to suit the management goal. In this case, avoiding local depletion is one such goal, particularly for hunting

communities that rely on a predictable seasonal occurrence of animals for their subsistence. This goal also promotes the conservation of genetic diversity which may result from adaptation to local conditions. An example of the depletion of a local beluga stock is the Ungava Bay stock, which has been severely depleted, perhaps eradicated, by commercial whaling.

ANALYSIS

Methods

Stock definition of beluga and narwhal populations in Nunavut (Richard 2009) was derived from various sources of information:

1) studies of the seasonal range of the species in Nunavut and adjacent waters by documenting local and written reports of their occurrence,
2) appearance and behavioural differences of animals from different areas of Nunavut and adjacent waters,
3) studies of genetic and contaminant differences among animals from different parts of Nunavut and adjacent waters, and
4) tracking animals, using satellite-linked transmitters, to estimate their seasonal range and delimit areas of aggregations.

Results

Beluga Stocks

The combination of the above-mentioned data sources has allowed the identification of six beluga stocks (Fig. 1 A: Eastern Beaufort Sea; B: Eastern High Arctic-Baffin Bay; C: Cumberland Sound; E-D-F: Western-Northern-Southern Hudson Bay[1]; G: James Bay; H: Eastern Hudson Bay) in Nunavut.

The stock harvested by hunters from Iqaluit is not known for certain but is thought to be the Western-Northern-Southern (WNS) Hudson Bay beluga stock (Fig.1 E-D-F), to whom they are most similar genetically. This stock is very large (~63,000 animals) and winters in Hudson and Davis Straits. Most belugas caught around Kimmirut are taken in the autumn when the WNS Hudson Bay stock has moved into Hudson Strait (Smith 2008). Belugas found in Frobisher Bay and hunted by Iqaluit residents in summer are thought to be strays from this large stock.

Narwhal Stocks

Stock definition in Nunavut narwhals is not as clear as it is for belugas. Tracking results offer the best indication of geographic segregation in summer and, in the case of the Northern Hudson Bay stock, year-round. There is also some evidence from genetics and contaminants of stock partitioning in High Arctic narwhals. On that basis, five Nunavut narwhal stocks are identified (Fig. 2 A: Somerset Island; B: Admiralty Inlet; C: Eclipse Sound; D: East Baffin Island; E: Northern Hudson Bay) and three more (Fig. 2 F: Parry Channel; G: Jones Sound; H: Smith Sound) are hypothesized to exist based on the fact that narwhals have been sighted or hunted

[1] This corresponds to the Western Hudson Bay population of belugas assessed by the Committee on the Status of Endangered Wildlife in Canada (COSEWIC).

in these areas in summer and also because other stocks are sedentary during the same season.

Sources of Uncertainty

The stock definitions are provisional since they are based on an incomplete state of knowledge, particularly for narwhal stocks, for which information is equivocal in some cases and all but absent in others. There is uncertainty about the beluga stock present in Frobisher Bay during the summer months. These stock definitions can be altered if any new information changes these conclusions.

CONCLUSIONS AND ADVICE

The use of summering stocks as management units as we have done here is considered precautionary. As mentioned above, it is possible to have localized depletions or extinctions if this consideration is not taken into account when harvesting occurs. Even with information that is preliminary and based on small samples, by adopting as many stock units as are suggested by this information, co-managers reduce the risk of over-exploitation. For example, over-exploitation could occur if smaller stocks are assumed to be part of a larger- and wider-ranging stock, when in fact they are segregated for all or part of the year and have some annual site fidelity to specific areas.

Statement of Canadian Practice with respect to the Mitigation of Seismic Sound in the Marine Environment

Context

The Statement of Canadian Practice with respect to the Mitigation of Seismic Sound in the Marine Environment specifies the mitigation requirements that must be met during the planning and conduct of marine seismic surveys, in order to minimize impacts on life in the oceans. These requirements are set out as minimum standards, which will apply in all non-ice covered marine waters in Canada. The *Statement* complements existing environmental assessment processes, including those set out in settled land claims. The current regulatory system will continue to address protection of the health and safety of offshore workers and ensure that seismic activities are respectful of interactions with other ocean users.

Definitions

Cetacean: means a whale, dolphin or porpoise.

Critical habitat: means the habitat that is necessary for the survival or recovery of a listed wildlife species and that is identified as the species' critical habitat in the recovery strategy or in an action plan for the species.

Marine Mammal Observer: means an individual trained to identity different species of marine mammals and turtles that may reasonably be expected to be present in the area where the seismic survey will take place.

Marine mammals: means all cetaceans and pinnipeds.

Passive Acoustic Monitoring: means a technology that may be used to detect the subsea presence of vocalizing cetaceans.

Pinniped: means a seal, sea lion or walrus.

Ramp-up: means the gradual increase in emitted sound levels from a seismic air source array by systematically turning on the full complement of an array’s air sources over a period of time.

Seismic air source: means an air source that is used to generate acoustic waves in a seismic survey.

Seismic air source array(s): means one or a series of devices designed to release compressed air into the water column in order to create an acoustical energy pulse to penetrate the seafloor.

Seismic survey: means a geophysical operation that uses a seismic air source to generate acoustic waves that propagate through the earth, are reflected from or refracted along subsurface layers of the earth, and are subsequently recorded.

“Statement:” means the Statement of Canadian Practice for the Mitigation of Seismic Sound in the Marine Environment.

Whale: means a cetacean that is not a dolphin or porpoise.

Application

1. Unless otherwise provided, the mitigation measures set out in this Statement apply to all seismic surveys planned to be conducted in Canadian marine waters and which propose to use an air source array(s).

2. The mitigation measures set out in this Statement do not apply to seismic surveys conducted:
   a. on ice-covered marine waters; or
   b. in lakes or the non-estuarine portions of rivers.

Planning Seismic Surveys

Mitigation Measures

3. Each seismic survey must be planned to

   a. use the minimum amount of energy necessary to achieve operational objectives;

   b. minimize the proportion of the energy that propagates horizontally; and

   c. minimize the amount of energy at frequencies above those necessary for the purpose of the survey.

4. All seismic surveys must be planned to avoid:

   a. a significant adverse effect for an individual marine mammal or sea turtle of a species listed as endangered or threatened on Schedule 1 of the *Species at Risk Act*; and

   b. a significant adverse population-level effect for any other marine species.

5 Each seismic survey must be planned to avoid:

   a. displacing an individual marine mammal or sea turtle of a species listed as endangered or threatened on Schedule 1 of the *Species at Risk Act* from breeding, feeding or nursing;

   b. diverting an individual migrating marine mammal or sea turtle of a species listed as endangered or threatened on Schedule 1 of the *Species at Risk Act* from a known migration route or corridor;

   c. dispersing aggregations of spawning fish from a known spawning area;

   d. displacing a group of breeding, feeding or nursing marine mammals, if it is known there are no alternate areas available to those marine mammals for those activities, or that if by using those alternate areas, those marine mammals would incur significant adverse effects; and

   e. diverting aggregations of fish or groups of marine mammals from known migration routes or corridors if it is known there are no alternate migration routes or corridors, or that if by using those alternate migration routes or corridors, the group of marine mammals or aggregations of fish would incur significant adverse effects.

Safety Zone and Start-up

Mitigation Measures

6. Each seismic survey must:

   a. establish a safety zone which is a circle with a radius of at least 500 metres as measured from the centre of the air source array(s); and

   b. for all times the safety zone is visible,

      i. a qualified Marine Mammal Observer must continuously observe the safety zone for a minimum period of 30 minutes prior to the start up of the air source array(s), and

      ii. maintain a regular watch of the safety zone at all other times if the proposed seismic survey is of a power that it would meet a threshold requirement for an assessment under the *Canadian Environmental Assessment Act*, regardless of whether the Act applies.

7. If the full extent of the safety zone is visible, before starting or restarting an air source array(s) after they have been shut-down for more than 30 minutes, the following conditions and processes apply:

   a. none of the following have been observed by the Marine Mammal Observer within the safety zone for at least 30 minutes:

      i. a cetacean or sea turtle,

      ii. a marine mammal listed as endangered or threatened on Schedule 1 of the *Species at Risk Act*, or

      iii. based on the considerations set out in sub-section 4(b), any other marine mammal that has been identified in an environmental assessment process as a species for which there could be significant adverse effects; and

   b. a gradual ramp-up of the air source array(s) over a minimum of a 20 minute period beginning with the activation of a single source element of the air source array(s), preferably the smallest source element in terms of energy output and a gradual activation of additional source elements of the air source array(s) until the operating level is obtained.

Shut-down of Air Source Array(s)

Mitigation Measures

8. The air source array(s) must be shut down immediately if any of the following is observed by the Marine Mammal Observer in the safety zone:

   a. a marine mammal or sea turtle listed as endangered or threatened on Schedule 1 of the *Species at Risk Act*; or

   b. based on the considerations set out in sub-section 4(b), any other marine mammal or sea turtle that has been identified in an environmental assessment process as a species for which there could be significant adverse effects.

Line Changes and Maintenance Shut-downs

Mitigation Measures

9. When seismic surveying (data collection) ceases during line changes, for maintenance or for other operational reasons, the air source array(s) must be:
    a. shut down completely; or
    b. reduced to a single source element.

10. If the air source array(s) is reduced to a single source element as per subsection 9(b), then:
    a. visual monitoring of the safety zone as set out in section 6 and shut-down requirements as set out in section 8 must be maintained; but
    b. ramp-up procedures as set out in section 7 will not be required when seismic surveying resumes.

Operations in Low Visibility

Mitigation Measures

11. Under the conditions set out in this section, cetacean detection technology, such as Passive Acoustic Monitoring, must be used prior to ramp-up for the same time period as for visual monitoring set out in section 6. Those conditions are as follows:
    a. the full extent of the safety zone is not visible; and
    b. the seismic survey is in an area that
        i. has been identified as critical habitat for a vocalizing cetacean listed as endangered or threatened on Schedule 1 of the Species at Risk Act, or
        ii. in keeping with the considerations set out in sub-section 4(b), has been identified through an environmental assessment process as an area where a vocalising cetacean is expected to be encountered if that vocalizing cetacean has been identified through the environmental assessment process as a species for which there could be significant adverse effects.

12. If Passive Acoustic Monitoring or similar cetacean detection technology is used in accordance with the provision of section 11, unless the species can be identified by vocal signature or other recognition criteria:
    a. all non-identified cetacean vocalizations must be assumed to be those of whales named in sections 8(a) or (b); and
    b. unless it can be determined that the cetacean(s) is outside the safety zone, the ramp-up must not commence until non-identified cetacean vocalizations have not been detected for a period of at least 30 minutes.

Additional Mitigative Measures and Modifications

Mitigation Measures

13. Persons wishing to conduct seismic surveys in Canadian marine waters may be required to put in place additional or modified environmental mitigation measures, including modifications to the area of the safety zone and/or other measures as identified in the environmental assessment of the project to address:
    a. the potential for chronic or cumulative adverse environmental effects of
        i. multiple air source arrays (e.g., two vessels on one project; multiple projects), or
        ii. seismic surveys being carried out in combination with other activities adverse to marine environmental quality in the area affected by the proposed program or programs;
    b. variations in sound propagation levels within the water column, including factors such as seabed, geomorphologic, and oceanographic characteristics that affect sound propagation;
    c. sound levels from air source array(s) that are significantly lower or higher than average; and
    d. species identified in an environmental assessment process for which there is concern, including those described in sub-section 4b).

14. Variations to some or all of the measures set out in this Statement may be allowed provided the alternate mitigation or precautionary measures will achieve an equivalent or greater level of environmental protection to address the matters outlined in sections 6 through 13 inclusive. Where alternative methods or technologies are proposed, they should be evaluated as part of the environmental assessment of the project.

15. Where a single source element is used and the ramping up from an individual air source element to multiple elements is not applicable, the sound should still be introduced gradually whenever technically feasible.

Abstract Twenty-one narwhals tagged in 2003 and 2004 in Admiralty Inlet showed a different summer distributional pattern than previous narwhal-tracking studies from Somerset Island, Eclipse Sound and Melville Bay. The migration of the narwhals tracked from Admiralty Inlet moved out through Lancaster Sound 15 days earlier ($P < 0.0001$) than the narwhals summering around Eclipse Sound, whereas the Admiralty Inlet narwhals reached the mouths of Eclipse Sound 18 days later ($P < 0.0001$) than the Eclipse Sound summering population. The winter range of the Admiralty Inlet narwhals overlapped with the winter range of narwhals from Melville Bay and Eclipse Sound in central southern Baffin Bay and Northern Davis Strait, but not with the winter range of narwhals from Somerset Island that wintered further north. Distribution size of range, and population size did not appear to be related. An example of considerable year to year variation between area of summer and winter distribution in the 2 years was believed to be related to the sample size and number of pods of whales tagged, rather than to differences in sex or age classes.

Introduction

The narwhal (*Monodon monoceros*) is an Arctic odontocete that measures up to 5 m in lengh. Males have an ivory tusk that erupts from the upper left jaw (Hay and Mansfield 1989). The narwhal lacks a dorsal fin, but has a low irregular dorsal ridge along the posterior half of its back (Hay and Mansfield 1989). Narwhals occur in inshore areas of northeastern Canada and Greenland during the open-water season from July to September (Born et al. 1994; Dietz et al. 1994; Richard et al. 1994). The narwhal is also found on the east coast of Greenland and further east into the European Polar Basin, with most observations close to Svalbard and Franz Josef Land (Dietz et al. 1994). In the autumn, narwhals leave inshore areas of northeastern Canada and Greenland and make long-distance movements to their wintering grounds (Dietz and Heide-Jørgensen 1995; Dietz et al. 2001; Heide-Jørgensen et al. 2002, 2003a, b) which are covered with dense pack ice from November to July (Koski and Davis, 1994; Laidre et al. 2004b).

Narwhals are hunted in both Canada and Greenland, and therefore knowledge of stock discreteness or relatedness is important to provide advice on the management of these hunts. Understanding the degree of exchange between populations is also important in the design of comparative studies of contaminant loads in narwhals (Dietz et al. 2004). Finally the migration route and timing of their migration are of importance for impact assessments of human activities, such as shipping, commercial fishing and development of non-renewable resources (e.g. offshore oil and gas).

Although gross patterns of seasonal migrations have been inferred from statistics on Inuit catches of narwhals and from aerial surveys at different seasons (e.g. Born et al. 1994; Koski and Davis 1994; Richard et al. 1994), satellite

tracking methods have provided considerable detailed knowledge about narwhal seasonal range, migratory patterns and seasonal ecology (Martin et al. 1994; Dietz and Heide-Jørgensen 1995; Heide-Jørgensen and Dietz 1995; Dietz et al. 2001; Heide-Jørgensen et al. 2001, 2002, 2003a, b; Laidre et al. 2002, 2003, 2004a, b; Lydersen et al. 2007). Nevertheless, there is still much to learn from tagging as well as from other approaches. Little is known about the genetic exchange relative to the movements during the breeding season. A study of the population structure based on mtDNA revealed low nucleotide diversity, but significant levels of heterogeneity were detected between a number of combinations of three West Greenlandic sampling areas and a combined group from eastern Canada and northwestern Greenland (Palsbøll et al. 1997). The sample size from Canada was, however, too small ($N = 29$) to show conclusively any population structure. In areas where it has proven difficult to capture and tag narwhals (e.g. the Inglefield Bredning and Uummannaq area in Northwest Greenland), a combination of more indirect methods (genetics, contaminant and stable isotope analyses) has been used to elucidate stock connections (Palsbøll et al. 1997; Dietz et al. 2004).

The objectives of this study were to: (1) assess the degree of site tenacity of Admiralty Inlet narwhals during the open-water season, (2) to determine the migration routes and wintering range of this population, and (3) to examine the level of overlap in the winter range with the winter range of narwhals from other summer aggregations.

Materials and methods

The tagging area

The whales were tagged at Kakiak Point (72°41′00″N–86°41′20″W) in Admiralty Inlet, Baffin Island, Nunavut, Canada, a fjord which is approximately 250-km long and up to 35-km wide, with maximum depths of up to 700 m. The fjord is bordered by high (≥500 m) steep-sided cliffs of the Brodeur Peninsula Plateau to the west and Borden Peninsula to the east, but also by promontories of low bluffs or raised beaches with shores of sand and gravel. This fjord is a well-known narwhal summering area, where these whales are regularly hunted by Inuit of the hamlet of Arctic Bay/Ikpiarjuk.

According to local hunters, the fast ice usually clears the fjord at the end of July, although some years pack ice can remain throughout the summer. Little ice was present in the vicinity of Kakiak Point from 11 to 22 August of 2003 and 2004.

Local hunters hold Kakiak Point as one of the best spots in Admiralty Inlet to hunt narwhals because of the tendency of these whales to approach the coastline at that point. It also proved to be an excellent location for live-capture operations. In addition to narwhals, bowhead whales (*Balaena mysticetus*) and ringed seals (*Phoca hispida*) were regularly observed close to the campsite in both years.

Live-capture methods

Narwhals were captured in nets set close to the surface and perpendicular to the shoreline. Due to the large number of narwhals in the area, only one net section, 50-m long, was set approximately 50 m from shore. The net was black and 10 m deep with 40 × 40 cm mesh sizes. They were kept afloat with 40-cm white buoys along the top line. Larger (100 cm) white buoys marked both ends of the net. It was anchored to a large stone on the beach and several heavy stones on the bottom at the seaward end. The net was under constant surveillance day and night and the presence of narwhals anywhere close to the net triggered increased preparedness in the capture team. Soon after whales became entangled, two inflatable boats were paddled out to the captured animals. Both nets and narwhals were raised to the surface to ensure that the animals could breathe comfortably. Whales were then dragged to shore after releasing the net from the seaward anchor and secured by a tail rope. The net was cut off the whales and a hoop net was placed around its head to control it, unless it had a large tusk to hold on to. Both methods were used to keep the blowhole out of the water. Transmitters were attached to the back ($n = 21$) and, in some cases, also on the tusk ($n = 3$) of the animals. After instrumentation, the animals were pushed to deeper water and released. Average handling time was 30 minutes.

Instrumentation of narwhals

Thirteen narwhals were caught between 10 and 23 August 2003, and eight narwhals were caught between 10 and 23 August 2004. The sex, standard length, tusk length (for males) and fluke width were recorded and they were instrumented with backpack transmitters of type SPOT2 ($n = 7$), SPOT3 ($n = 6$) or SPOT4 ($n = 8$) (Table 1). All backpack transmitters were produced by Wildlife Computers (Redmond, WA, USA). Three of the animals were also instrumented with tusk tags (ST-10: Telonics Inc.; housing: Wildlife Computers). With their larger batteries (6 lithium C cells), tusk tags were programmed to provide 500 transmissions every day, while the backpack tags which had smaller batteries (2 AAA lithium batteries) were programmed to transmit 200 transmissions every third day. Further details on weight and size of transmitters and attachment methods are available from Dietz et al. (2001) and Heide-Jørgensen et al. (2003a). Data from the transmitters

were relayed via the ARGOS DCLS system (Service Argos Inc. 1989; Harris et al. 1990).

Data collection and analysis

Data on location and transmitter status were collected via the Argos Location Service Plus system (Toulouse, France; Harris et al. 1990). The SAS program Argos_Filter (V6.0) (David Douglas, USGS, Alaska Science Center, Alaska, USA; http://alaska.usgs.gov/science/biology/spatial/douglas.html) was used to filter locations that passed plausibility criteria. The criteria used were a minimum angle threshold of 5° between movement vectors of consecutive locations and a maximum speed of 10 km/h calculated from distance travelled and time span between locations. Locations of quality class 3 were always retained. In addition the program calculated distances travelled and migration speeds. Excel 97 (SR2) and StatView (V5.0.1) were used for statistical analysis and graphs. Maps of narwhal movements were generated using ArcMap (V8.3). Bathymetric contours based on 1° resolution data were obtained from the International Bathymetry Chart of the Arctic Ocean (IBCAO, Jakobsson et al. 2000). ESRI ArcView (V3.2) with ArcView's Animal Movement (V2.0) (Hooge and Eichenlaub 2000) and Spatial Analyst extensions was used to generate tracklines and kernel home-range estimates. Single daily locations with the highest (best) location class were selected, using the PICKDAY = 1 function of the Argos_Filter. The Animal Movement extension was then used to generate 95% kernel home range contours with this subset. The purpose of this selection was to reduce problems associated with temporal auto-correlation. Average home range for both years was calculated using combined 2003 and 2004 daily "best" locations. Land was not subtracted in the home range calculations to make the calculated figures methodologically comparable between summer and winter situation.

Results from this study were compared and contrasted to previous tracking studies of narwhals including summer and winter home ranges, migration routes and distances. The previous studies include narwhals tagged in Melville

Bay, Greenland (1993: $n = 5$; 1994: $n = 4$), and from Canada in Eclipse Sound (1997: $n = 5$; 1998: $n = 5$; 1999: $n = 7$) and around Somerset Island (2000: $n = 10$; 2001: $n = 7$) (Dietz and Heide-Jørgensen 1995; Heide-Jørgensen and Dietz 1995; Dietz et al. 2001; Heide-Jørgensen et al. 2002; 2003).

Results

Duration of transmitter uplinks

The duration of the tags' uplinks ranged between 23 and 257 days. Average and maximum longevity increased in the latest produced transmitter model: ST-10 (mean = 54; range 24–78; $n = 3$), SPOT2 (mean = 81; range 25–132; $n = 7$), SPOT3 (mean = 141; range 25–237; $n = 6$) and SPOT4 (mean = 162; range 23–357; $n = 8$). Summer range was defined as release dates in (Table 1) to 10 September, the overall average date that tagged whales started to move in a directed manner out of Admiralty Inlet and the other compared summer populations (Dietz and Heide-Jørgensen 1995; Dietz et al. 2001; Heide-Jørgensen et al. 2002, 2003). Data on summer range for Admiratly Inlet was available for 13 narwhals in 2003 and 8 narwhals in 2004. Winter range was defined as 15 November to 25 April. This was based on the overall average date when all the whales had terminated their fall migration and switched from directed travel to more local movements. Nine Admiralty Inlet narwhals transmitted through the winter period in 2003–2004 and six in 2004–2005.

Movements

In summer of 2003, the tagged whales ranged over most of Admiralty Inlet (Figs. 1a, 2a), but in 2004 they concentrated in the central portion of the inlet (Figs. 1b, 2a). The estimated summer home range of the whales tagged in 2003 was therefore 4.8 times larger than the corresponding summer range in 2004 (Table 3; Fig. 2a). A similar pattern was observed on the wintering ground in southern Baffin Bay and northern Davis Strait. The winter home range of the whales tagged in 2003 was 6.7 times larger than the winter range for the 2004 deployment (Table 3). Four narwhals tagged of the 2003 sample went much further south than any of the narwhals tagged in 2004. One of the 2003 whales (#7928) reached latitude 63.0°N in February 2004 (Figs. 1a, 2b), while the southernmost winter latitude reached by a 2004 whale (#37228 in October 2004) was approximately 65.7°N, that is 300 km further north (Figs. 1a, 2b). The 2003 deployment was a larger sample size (13 animals in 9 groups: A–I) compared to the one in 2004 (eight animals in five groups: J–N). This could explain the differences in their ranges (Table 1). The winter home range of the whales tagged in 2003 was 21.3 times larger than the corresponding summer home range. Similarly, the following year, the winter range was 15.4 times larger than the summer distribution.

Seasonal distribution against latitude

A plot of latitude against Julian day (JDay) provides a summary of the seasonal movement patterns of narwhals in 2003 and 2004 (Fig. 3). Movement out of Admiralty Inlet (i.e. to latitudes north of 73.8°N) took place between 14 September and 11 October (JDay: 254–284). Most of the tagged whales used the southern coastline on their eastward migration out of Lancaster Sound. Their southbound movement along the east coast of Baffin Island took place between 29 September and 10 November (JDay: 272–314) and most of the narwhals migrated beyond the 500 m isobath (Figs. 1a, 1b). The tagged narwhals arrived at their wintering ground between approximately 17 October and 15 November (JDay: 290–319, Fig. 3). At first glance, there was no obvious pattern in winter latitudinal distribution between animals of different sex or age class, nor did it appear to be related to the timing of their departure from Admiralty Inlet. The first narwhal to leave Admiralty Inlet was an adult female (#3961; Fig. 3, red line) whose migration ended with an average winter latitude around 68°N, whereas the last departing animal was a juvenile male (#7928; Fig. 3, orange line) which moved to the southernmost latitude (63°N) reached by any of the tagged narwhals.

The two animals with transmitters functioning the longest (#37288 and 37286) started their northbound spring return migration around 25 April (JDay: 115) and continued transmitting for 2 months, until approximately 25 June (JDay: 176). This northward migration occurred in heavy pack ice. These whales took a less direct route than the autumn migration in open water and the duration of their migration took approximately three times as long.

Comparative results from double-tagged whales

Three males were equipped with both a backpack and a tusk transmitter. The tusk tags provided locations for 24–78 days (mean: 54 days), while backpack tags provided locations for 25–132 days (mean: 94 days) (Table 2). In two cases, tusk tags lasted only 48–59% (Mean: 53.5%) of the time from which positions were obtained from the backpack transmitters. It is unknown why the tusk tags failed earlier, but likely explanations are either that the tags came loose or that their electronics or antenna were damaged by contact with the seabed. Underwater footage has revealed that, when submerged, narwhals swim upside down and fairly close to the bottom (Dietz et al. 2007). In the third

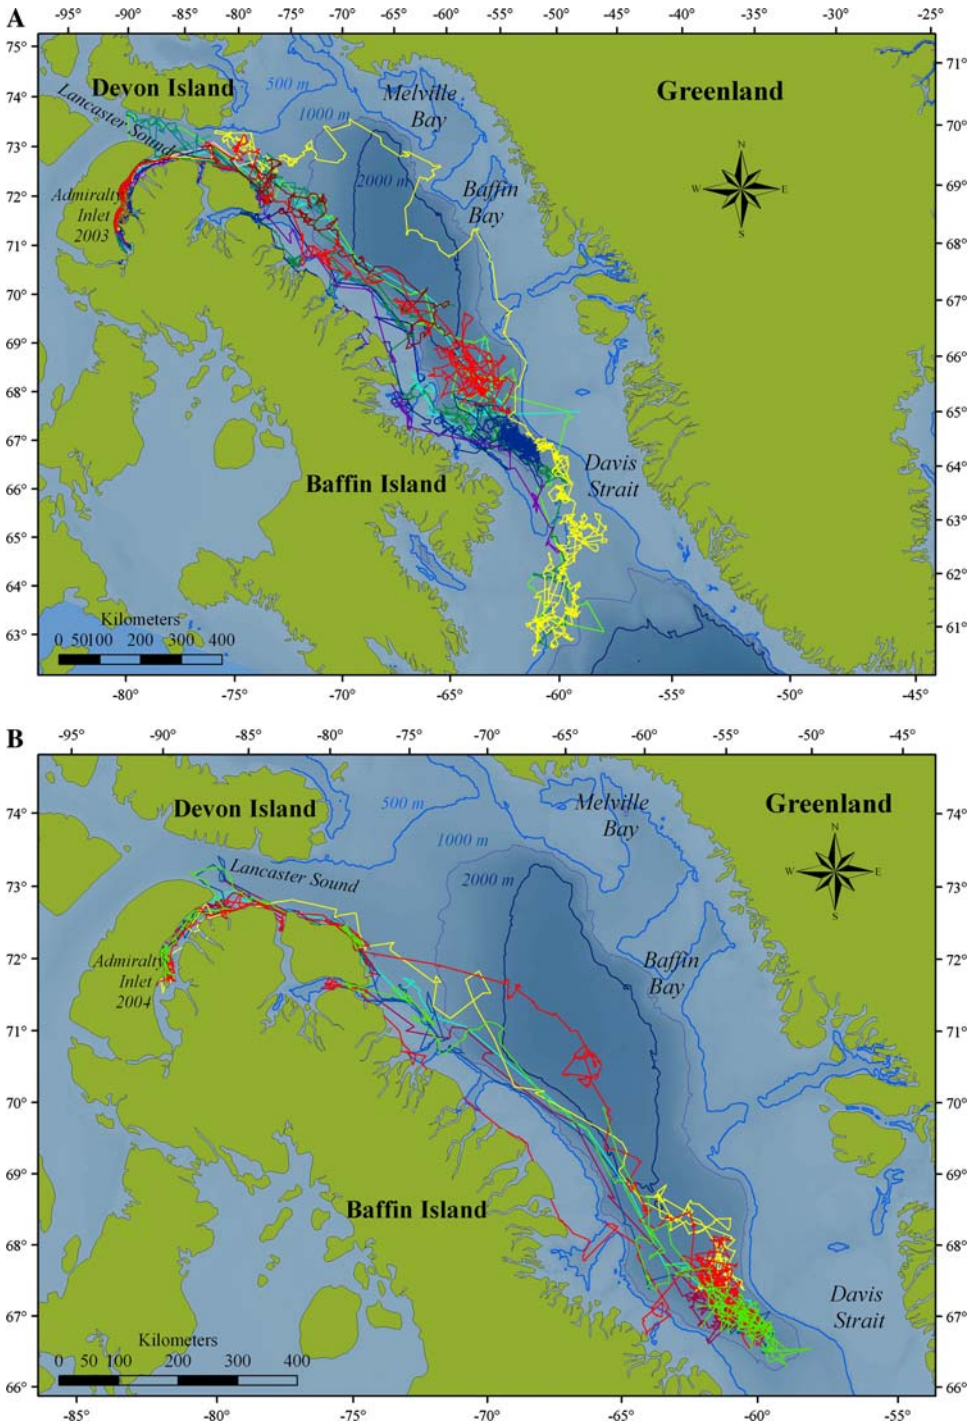

Fig. 1 **a** Tracklines from 13 narwhals tagged in August 2003 in Admiralty Inlet, Canada. Of these, nine transmitters lasted beyond 15 November where the whales reached their wintering ground in southern Baffin Bay and northern Davis Strait. The transmitters lasted from 25 to 237 days. **b** Tracklines from eight narwhals tagged in Admiralty Inlet in 2004. Of these six transmitters lasted beyond 15 November, where the whales reached their wintering ground in southern Baffin Bay and northern Davis Strait. The transmitters lasted from 23 to 357 days. See Table 1 for further information

case (#20165/20157), both tusk and backpack transmitters only lasted for a short period of time (24 and 25 days, respectively).

The backpack transmitters were programmed to transmit only 200 uplinks every third day, while tusk tags provided 500 uplinks every day. Therefore, the backpack transmitters gave only 22.6% (range 12.5–32.9%) of the number of uplinks obtained from the tusk tags over the same period of time. The reduced number of uplinks likewise resulted in shorter travel distances calculated from the backpack transmitters being only 33.1% (range 22.1–43.1) of the distances calculated from the tusk tag data (Table 2). If we correct for this bias (using the inverse of 33.1%), the narwhal equipped with backpack tag #37288 which migrated an estimated 11,470 km distance of the 357 days, could in fact have moved 34,653 km or more during that period, which, for the sake of comparison, is a good portion of the circumference of the earth (40,075 km).

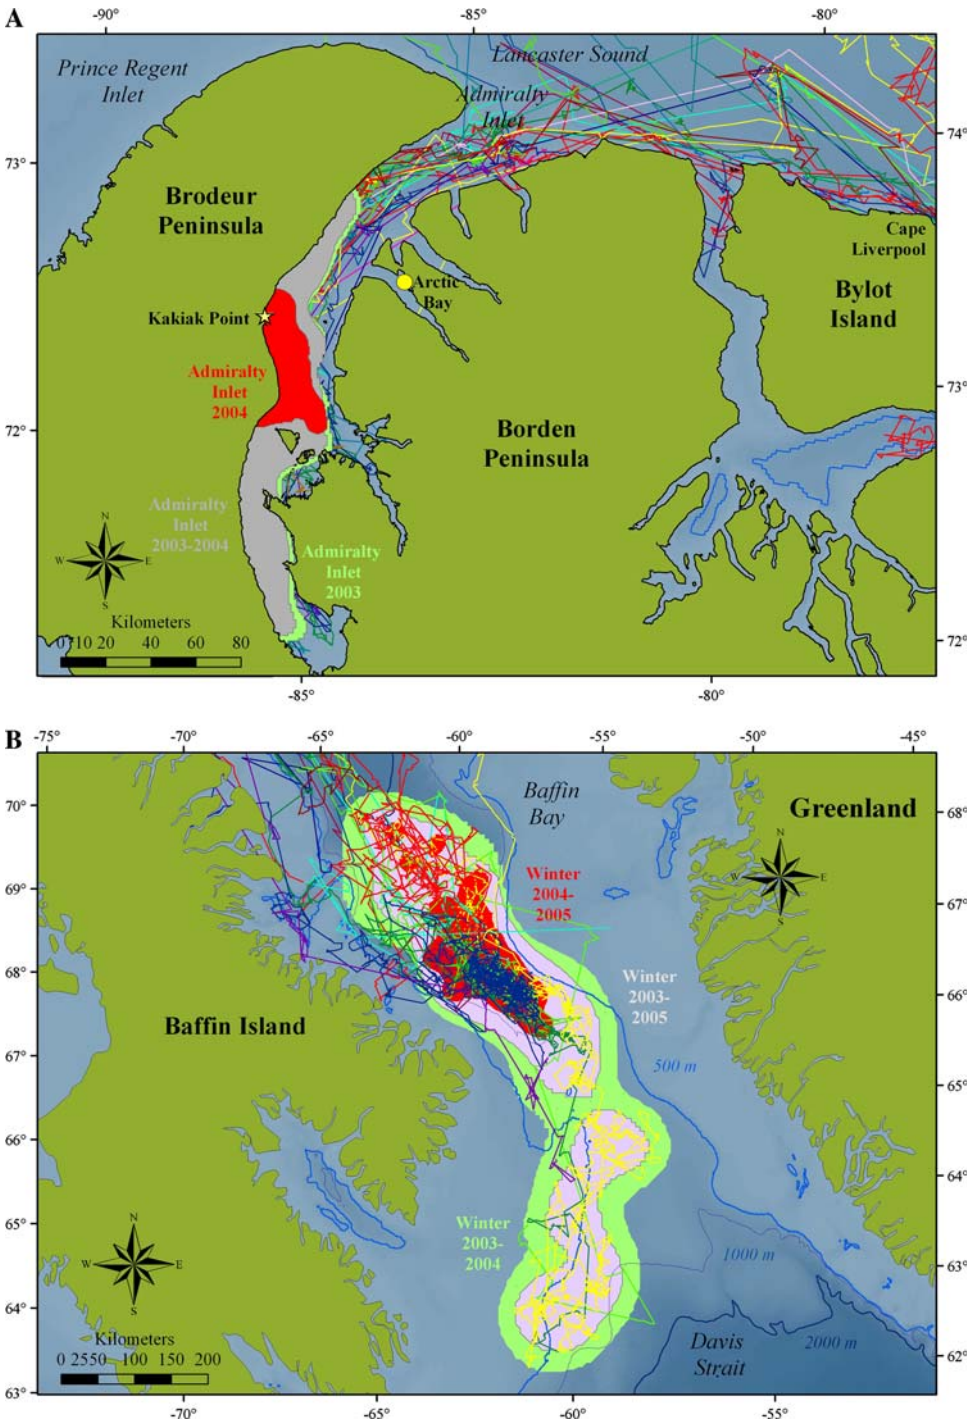

Fig. 2 **a** Close up of Admiralty Inlet with tracklines and 95% kernel home range polygons calculated for 21 narwhals tagged in August 2003 and 2004 The polygons shows the summer range of distribution of 2003 (*light green*) and 2004 (*red*) separately as well as the average of both years (*grey*). Summer was defined from tagging data in August to 15 September. **b** Tracklines for the 15 narwhals that were tracked to their wintering grounds in 2003 and 2004. The 95% kernel home range shows the winter range of the instrumented whales in 2003–2004 (*light green*) and 2004–2005 (*red*) separately as well as the average of both years (*grey*)

Year round tracking

An adult female (#37288) provided locations for almost an entire year (357 days). This animal spent the winter at latitudes between 68° and 69°N (Fig. 3). It entered Lancaster Sound on 25 June and moved westward towards the mouth of Admiralty Inlet reaching just north of Elwin Inlet (73°35′45″N, 84°01′55″W) by 13 July 2005. The female did not enter Admiralty Inlet, most likely because the fast ice had not left the fjord at that time and it was not possible to move south into the Inlet. It later turned eastward moving along the north coast of Borden Peninsula towards the mouth of Navy Board Inlet on 16 July 2005. The narwhal continued further east along the north coast of Bylot Island and finally turned back west towards Lancaster Sound on 28 July. Contact with this animal was lost on 6 August, when it was still near the mouth of Lancaster Sound, east of Cape Liverpool, Bylot Island (73°41′20″N, 78°27′06″W).

The transmitter did not last long enough to determine if the animal ever returned to Admiralty Inlet.

Discussion

Comparison with other tagged populations

During summer months, the home range of tagged whales from Admiralty Inlet did not overlap with any home ranges of the 9 Melville Bay narwhals tagged in 1993–1994, the 17 Eclipse Sound narwhals tagged in 1997–1999, or the 17 Somerset Island narwhals tagged in 2000–2001) (Fig. 4a, b; Dietz and Heide-Jørgensen 1995; Dietz et al. 2001; Heide-Jørgensen et al. 2002, 2003). The winter distribution of three of those four population samples overlapped. Based on their estimated winter home ranges, Admiralty Inlet, Eclipse Sound and Melville Bay tagged narwhals showed varying degrees of overlap in their wintering grounds as well as differences in home range size. Somerset Island narwhals, however, wintered further north than tagged animals from the three other populations. All three population's tagged animals stayed south of the 2,000-m abyss in central Baffin Bay and showed affinity for the slopes in southern Baffin Bay and northern Davis Strait over depths of about 500–1,000 m. The southern range of the distribution of Admiralty Inlet whales tagged in 2003 extended more than 300 km further south than any previously tracked winter locations.

The movement of tagged narwhals out of Admiralty Inlet was observed on average over 15 days earlier ($P < 0.0001$; T test) (Mean: 28 September, 95% CL:

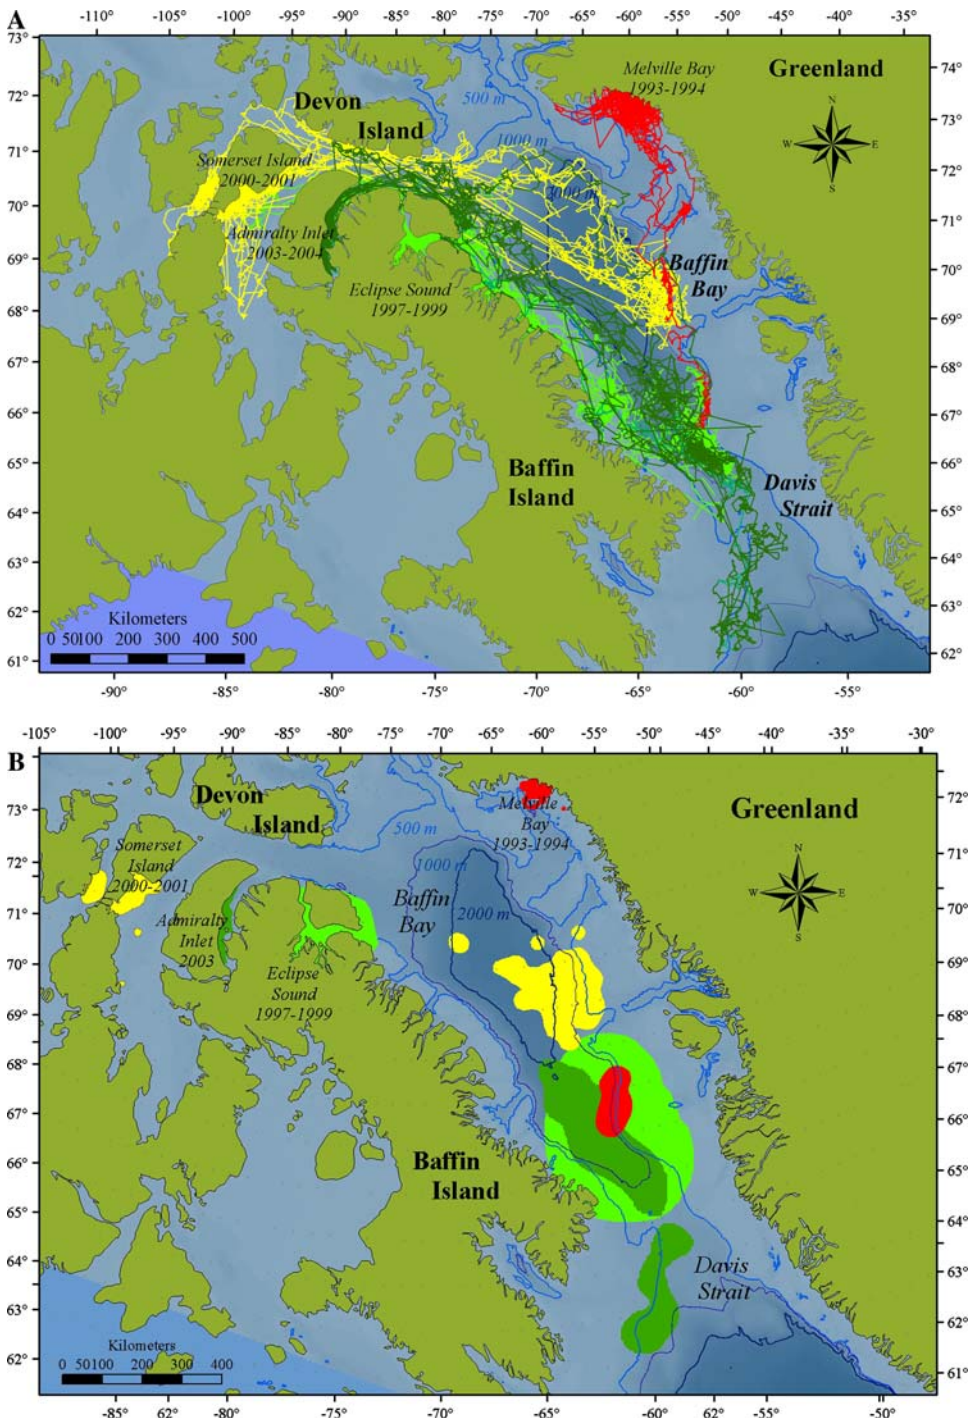

Fig. 4 **a** Tracklines; **b** kernel home range polygons for the narwhals tagged in 2003 and 2004 in Admiralty Inlet compared with previous tagging published by Dietz and Heide-Jørgensen (1995), Dietz et al. (2001), Heide-Jørgensen et al. (2002, 2003). *Dark green*, *yellow*, *light green* and *red* indicates narwhals tagged in Admiralty Inlet, Somerset Island, Eclipse Sound and Melville Bay, respectively

25 September–1 October) than the average date when tagged narwhals from Eclipse Sound (Mean: 13 October, CL: 8–18 October) passed the mouth of Admiralty Inlet on their eastward movement out of Lancaster Sound (Dietz et al. 2001; Heide-Jørgensen et al. 2003). In addition, most of the Admiralty Inlet narwhals used the southern coastline of Lancaster Sound, while the Somerset Island narwhals mainly moved out through Lancaster Sound along the northern side of the sound, along Devon Island, in a similar manner to migrating belugas from around Somerset Island (Richard et al. 1998a, b, 2001; Heide-Jørgensen et al. 2003). This suggests that during their migration out of Lancaster Sound, contact between the two narwhale populations is rather unlikely.

The tagged Admiralty Inlet narwhals ($n = 17$) reached eastward of Eclipse Sound on average 18 days later

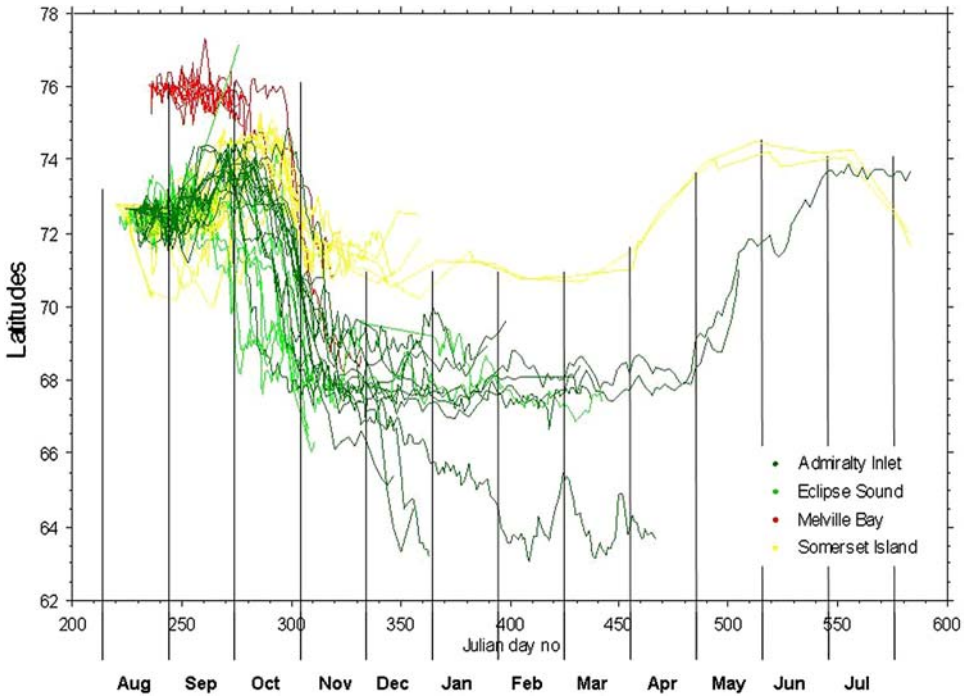

Fig. 5 The seasonal movements depicted as latitudinal presence and as a function of Julian day of the Admiralty Inlet narwhals compared to previously tagging conducted on the Melville Bay, Eclipse Sound and Somerset Island populations (Dietz and Heide-Jørgensen 1995; Dietz et al. 2001; Heide-Jørgensen et al. 2002, 2003). Julian days <220 are depicted as Julian day +365 days to obtain graphic continuity from the tagging date in August over the autumn and the following year

($P < 0.0001$; T test) in 2003 and 2004 (Mean: 12 October, CL: 8–15 October) than when the Eclipse Sound narwhals ($n = 11$) left their summering area in 1997, 1998 and 1999 (Mean: 24 September, CL: 15 September–3 October; Dietz et al. 2001; Heide-Jørgensen et al. 2002). This difference in timing could explain why Eclipse Sound narwhals had a longer migration, moving more closely along the coastline of eastern Baffin Island and sometimes (five out of nine monitored whales) entering fjords, while most of the Admiralty Inlet narwhals migrated 100 km or further offshore from the coastline on the 500 m depth contour or deeper water (Dietz et al. 2001; Heide-Jørgensen et al. 2002). The Somerset Island narwhals' southward migration took place even further offshore in Baffin Bay and ended farther north than tagged narwhals from the other areas. The Melville Bay narwhals started further east so their autumn migration was straight south, cutting through the eastern part of the Somerset Island narwhals wintering home range (Dietz and Heide-Jørgensen 1995; Laidre et al. 2003).

Two Somerset Island narwhals started their northward migration approximately a month earlier (late March) than the two Admiralty Inlet narwhals (late April; Fig. 5) and arrived in Lancaster Sound 1.5 month earlier (mid May) than the Admiralty Inlet narwhals (early July). When tagged Admiralty Inlet narwhals reached Lancaster Sound around the end of June, tagged Somerset Island narwhals had already moved 300 km westward into the sound. Even though based on a small sample size ($n = 3$), this migration pattern may suggests that the two narwhal populations, Admiralty Inlet and Somerset Island, may not enter into contact during their migration through Lancaster Sound. The Admiralty Inlet and Somerset Island narwhals therefore seem to be separated either in space or time making genetic exchange between these two stocks unlikely.

Year to year variability in range of distribution and migration

The 2003 sample of 13 narwhals tagged in Admiralty Inlet resulted in much larger summer home range compared to the 2004 sample of eight narwhals. Differences in the winter range of distribution could also be detected between 2 years as monitored by nine narwhals in the winter of 2003–2004 relative to six in the winter of 2004–2005. Differences in winter range of distribution can also be observed in tagging studies on other narwhal populations. It is therefore likely that the number of whales/pods tagged has an impact on the estimated home range and it is conceivable that it also affected our understanding of the routes and timing of migration.

The average size and age of the narwhals tagged in 2003 was larger than in 2004. Garde et al. (2007) found that the average length at physical maturity is 396 cm for females and 457 cm for males, respectively. Thus, females tagged in 2003 and 2004 and males tagged in 2004 are likely to all be adults, but three of 11 tagged males in 2003 (#7927, 7928 and 7931) measured between 335 and 365 cm and were probably sub-adults.

Nevertheless, the age or sex composition of the tagged whales does not clearly explain differences in home range between the 2 years. Juvenile males, adult males and adult

Table 3 Estimated 95% Kernel home range of narwhals at different seasons and from animals of different tagging locations and population estimates

Tagging location/year	Summer home range (km^2)	Winter home range (km^2)	Winter/summer home range	Population estimate	SE of estimate
Admiralty Inlet 2004/2004–2005	1,305	20,043	15.4	5,363[b]	2,688
Admiralty Inlet 2003/2003–2004	6,287	133,618	21.3	5,363[b]	2,688
Admiralty Inlet 2003–2004/2003–2005	5,503	82,411	15.0	5,363[b]	2,688
Somerset Island 2000–2001/2000–2002	15,399	44,183	2.9	45,358[a]	15,875
Eclipse Sound 1997–1999/1997–2000	57,702	131,772	2.3	20,216[b]	7,315
Melville Bay 1993–1994/1993–1995	4,586	14,747	3.2	4,676[c]	3,974

[c] GINR (unpublished)

females all used the entire Admiralty Inlet home range in 2003. In winter, the four 2003 tagged whales that ranged farther south into Davis Strait were of mixed age–sex composition: an adult male, an adult female, and two juveniles. The two 2003 tagged juveniles (#7927 and 7928) wintered for the most part south of the 2004 winter range, while the third 2003 juvenile (#7931) spent the winter north of 68.2°N, in the northern part of the range. Only two adult animals, a 416-cm adult female (#3960) and a 448-cm adult male (#37235), both tagged in 2003, visited the area south of the 2004–2005 winter range. As only two adults out of six frequented this southern region during the winter 2003–2004, and none of the six adult narwhals monitored during the 2004–2005 winter went as far south, it is possible that this area is of lesser importance to Admiralty Inlet adult whales.

Comparison of home range size between narwhal populations and between seasons

The Admiralty Inlet animals had a smaller average winter home range than the Eclipse Sound animals, but the 2003 Admiralty Inlet home range was of comparable size (Table 3). Both of these home ranges were substantially larger than Somerset Island and Melville Bay winter home ranges. The Melville Bay tagged narwhals had the smallest home ranges both in summer and winter, although the data for winter only included two males for a short period of November and December 1993 and 1994. These home ranges do not seem to be related to the size of the population estimates. The Somerset Island population is estimated to number 45,358 narwhals while the other three populations are smaller in size (Table 3). For each population, the winter home range distribution of tagged narwhals was larger than the summer distribution, and in the case of Admiralty Inlet narwhals, that difference is particularly substantial (15 times). A likely explanation for this difference between summer and winter at least for three of the Canadian summering areas is that the fixed size of the fiords and bays they inhabit in summer limits their distribution while, in winter, their range is limited by suitable habitat in the large expanse of water of Baffin Bay and Davis Strait. Narwhals feed more during winter and may be competing for food (Greenland halibut, *Reinhardtius hippoglossoides*) and *Gonatus fabricii)* with other narwhal populations in Baffin Bay and Davis Strait, while in summer, they have a more limited food intake (Laidre and Heide-Jørgensen 2005). Finally, the dynamic pack ice in their winter range may force narwhals to move around more to find cracks in the ice to breathe. The overlap in winter range between several populations for several months suggests that there is some competition for available prey.

Year round tracking

One adult female narwhal almost provided locations for an entire year. On its return migration, this animal attempted to reach the entrance of Admiralty Inlet on July 12. However, the narwhal did not enter the fjord, probably because it was blocked by fast ice, and the transmitter did not last long enough to determine if the animal did in fact return later to Admiralty Inlet where it had been tagged the previous summer. Only two narwhals have previously been tracked longer than a year (Heide-Jørgensen et al. 2003). In that case, two narwhals instrumented in Creswell Bay, Somerset Island, in August 2000 returned to Peel Sound in August through September in the following year. Peel Sound is part of the summer home range of Somerset Island narwhals. These observations are suggestive of stock segregation and site fidelity in summer. Differences in migration routes and timing of migration noted above are also suggestive of stock segregation in the autumn and spring. In both cases, the sample sizes are small and the results could therefore be purely fortuitous.

More tracking data would be required to address this question.

Concluding remarks

This study provided information on the seasonal distribution of the Admiralty Inlet narwhal population, and added to a series of similar studies on neighboring narwhal populations. It suggests that this population's home range in summer is not likely to overlap with other narwhal populations in summer. In addition the autumn migration also seems to be separated in time and partly in space. The winter home range of the Admiralty Inlet narwhal population did not overlap with narwhals tagged around Somerset Island, but showed some overlap with narwhals from the Eclipse Sound and Melville Bay. One Admiralty Inlet animal's return migration together with previous long-term tracking of two Somerset Island narwhals provides some evidence of inter-annual site fidelity of narwhals to their summering areas. Consequently, these populations should be managed as separate stocks. This study has generated information on an additional summer population which together with previous information will be used in case-by-case advising and assessment to reduce potential conflicts with, e.g. oil and gas developments and fisheries.

Acknowledgments This study was funded by the Danish National Environmental Research Institute, the Greenland Institute of Natural Resources, Department of Fisheries and Oceans, Canada, the Nunavut Wildlife Research Trust Fund and the Danish Cooperation for the Environment in the Arctic (DANCEA). We wish to thank hunters from Arctic Bay for their participation in the live-capture of these narwhals. In addition, Mehdi Baktiari, Sandy Black, Greg O'Corry Crowe, Henrik Egede Lassen, Moe Keenainak, Martin Nweeia, Jim Orr, Ari Shapiro and Keith Yip participated in the capture and handling of the narwhals in 2003 and 2004. The Polar Continental Shelf Project provided important logistic support to the field camp during our stay in Admiralty Inlet. Software developed by David C. Douglas (Marine and Freshwater Ecology Branch, USGS Alaska Science Center, Alaska, USA) was used for filtering locations.

Summer and Fall Movements of Narwhals (*Monodon monoceros*) from Northeastern Baffin Island towards Northern Davis Strait

R. DIETZ,[1,2] M.P. HEIDE-JØRGENSEN,[3] P.R. RICHARD[4] and M. ACQUARONE[1]

(*Received 1 February 2000; accepted in revised form 2 November 2000*)

ABSTRACT. Ten narwhals (*Monodon monoceros*) were instrumented with satellite-linked radio transmitters in Tremblay Sound in August 1997 (N = 5) and August 1998 (N = 5). All whales stayed in the waters around Bylot Island until the end of September. On the basis of these animals and others tagged previously (total N = 24), it is believed that the Bylot Island summering population has limited or no contact with other summering populations in Canada or Greenland. Four whales were monitored during their southward movement along the east coast of Baffin Island. Three of them travelled close to the shore, visiting several fjords and bays, during September and October. The fourth whale started the southward migration at the same time as the other three, but it returned to the area east of Pond Inlet and made two trips northeast of Bylot Island. It headed south on 21 October 1998. South of Royal Society Fiord, it travelled offshore along the continental slope (1000 to 1500 m), probably because of ice formation in inshore areas. This narwhal and another male tagged in 1997 moved east toward the northern parts of the Davis Strait, reaching an area midway between Canada and Greenland in early November. Their winter movements were monitored until 30 January. The same wintering area in northern Davis Strait was previously documented for two male narwhals tracked from Melville Bay, NW Greenland, in 1993 and 1994. The whales showed a preference for deep areas, including deep fjords and the continental slope, where depths ranged between 500 and 1500 m. Even deeper areas, where maximum daily dives exceeded 1000 m, were also visited occasionally.

Key words: narwhal, *Monodon monoceros*, High Arctic, satellite telemetry, movements, migration, population, stock identity

RÉSUMÉ. On a équipé 10 narvals (*Monodon monoceros*) d'émetteurs radioélectriques en liaison avec un satellite dans le détroit de Tremblay en août 1997 (N = 5) et en août 1998 (N = 5). Toutes les baleines sont restées dans les eaux entourant l'île Bylot jusqu'à fin septembre. En considérant ces animaux et d'autres équipés précédemment (N total = 24), on pense que la population estivale de l'île Bylot n'a que peu, sinon pas de contact avec d'autres populations estivales du Canada ou du Groenland. Quatre baleines ont fait l'objet d'un suivi au cours de leur déplacement vers le sud le long de la côte est de l'île de Baffin. Durant les mois de septembre et d'octobre, trois d'entre elles longeaient la côte de près, effectuant des pauses dans divers fjords et baies. La quatrième a commencé sa migration vers le sud en même temps que les trois autres, mais elle est retournée dans la zone à l'est de Pond Inlet et s'est rendue par deux fois au nord-est de l'île Bylot. Elle a mis le cap vers le sud le 21 octobre 1998. Au sud du fjord Royal Society, elle s'est dirigée vers le large et a longé la pente continentale (à environ 1000 à 1500 m du rivage), probablement en raison de la formation de glace dans la zone côtière. Ce narval ainsi qu'un autre mâle équipé en 1997 se déplaçaient en direction de l'est vers la partie nord du détroit de Davis, atteignant début novembre une zone située à mi-chemin entre le Canada et le Groenland. En hiver, leurs déplacements ont été suivis jusqu'au 30 janvier. La même zone d'hivernage dans le nord du détroit de Davis a déjà été rapportée pour deux narvals mâles suivis en 1993 et 1994 depuis la baie Melville, au N.-O. du Groenland. Les baleines affichaient une préférence pour des zones profondes, y compris des fjords encaissés et la pente continentale, où la profondeur allait de 500 à 1500 m. De temps à autre, les baleines se rendaient aussi dans des zones encore plus profondes, où les plongées maximales quotidiennes dépassaient les 1000 m.

INTRODUCTION

The narwhal (*Monodon monoceros*) occurs in inshore areas of northeastern Canada and Greenland during the open-water season, from July through September (Born et al., 1994; Dietz et al., 1994; Kingsley et al., 1994; Richard et al., 1994). By the time the Arctic fjords and bays freeze over in autumn, narwhals are leaving these areas. They apparently make long-distance movements between summering and wintering grounds (Dietz and Heide-Jørgensen, 1995). During winter and early spring (8–10 months), narwhals frequent areas covered with dense offshore pack ice (Koski and Davis, 1994). Although gross patterns of seasonal migration have been inferred from whaling records and various observational studies (e.g., Born et al., 1994; Koski and Davis, 1994; Richard et al., 1994), little is known about genetic exchange and movements of individual narwhals between summer and winter areas. Although a study of the population structure based on mtDNA revealed low nucleotide diversity, a significant level of heterogeneity was detected between a number of combinations of three West Greenlandic sampling areas and a combined group from eastern Canada and northwestern Greenland (Palsbøll et al., 1997). However, the sample size from Canada was too small (N = 29) to support conclusive analyses of population structures there.

Narwhals are hunted in both Canada and Greenland. Knowledge about stock discreteness is important for managing this exploitation. Other human activities such as shipping, commercial fishing, and development of nonrenewable resources (e.g., offshore oil and gas) may also have impacts on the feeding ecology and migrations of narwhal populations.

The remoteness and inaccessibility of areas inhabited by narwhals make these animals difficult to study in the field using traditional methods. Recent advances in satellite tracking have made it possible to monitor the movements of narwhals (Martin et al., 1994; Dietz and Heide-Jørgensen, 1995; Heide-Jørgensen and Dietz, 1995).

The objectives of the present study were to 1) assess site tenacity in coastal areas where narwhals congregate during the open-water season; 2) identify critical habitats, migration routes, and wintering grounds; and 3) examine the exchange among whales from different open-water aggregations.

MATERIALS AND METHODS

Study Area

The whales were all tagged off the Alpha River delta in Tremblay Sound (72°21.382′ N, 81°05.951′ W). Tremblay Sound is a narrow (down to 1.5 km wide) fjord about 45 km long with maximum depths of up to 275 m. The fjord is bordered with high (500 m or more) steep-sided mountains of the Lancaster Plateau (Sempels, 1982). The shores of Tremblay Sound are hence mainly steep-sided cliffs, but also promontories of low bluffs or raised beaches with shores of sand and gravel (Sempels, 1982). This fjord is a well-described narwhal habitat, and whales have previously been successfully captured and tagged there (Kingsley, 1993; Kingsley et al., 1994; Martin et al., 1994).

According to Inuit hunters camped in Tremblay Sound, the fast ice left the fjord in the middle of July 1998, and the first narwhals were seen on 28 July (J. Mucktar, pers. comm. 1998). No ice was present in the vicinity of the Alpha River during the tagging period (5 to 30 August) in either 1997 or 1998. Similar ice-free conditions were experienced in 1989 and 1991, whereas the fjord was packed with ice in 1993 and 1999 (Kingsley, 1993; Dietz and Heide-Jørgensen, pers. observation 1999).

In 1997, no hunting activities were observed close to the Alpha River, but a few boats travelled the sound, and two groups of hunters camped in Tremblay Sound during our stay. In addition to the narwhals, two bowhead whales (*Balaena mysticetus*), several ringed seals (*Phoca hispida*) and Greenland sharks (*Omnicephalus maximus*) were observed in the sound that year. Again in 1998, few boats were observed in the fjord. No bowheads were observed in 1998, but ringed seals, pods of harp seals (*Phoca groenlandica*), and Greenland sharks were observed in addition to the narwhals that year.

Capturing and Handling of the Whales

Five narwhals were caught in nets at the Alpha River delta between 8 and 24 August 1997 and tagged with satellite-linked transmitters. In 1998, five narwhals were likewise tagged at the same spot between 14 and 25 August. As in previous studies, the whales were captured in nets set close to the surface and perpendicular to the shoreline. The nets used in 1997 were deep, dark green and 5 m deep, with 20 × 20 cm mesh. Those used in 1998 were black and 10 m deep, with 40 × 40 cm mesh. The 1998 nets proved to be more effective, as almost no whales avoided them or became aware of their presence before entanglement.Three sections of net, each 50 m long, were kept afloat by white buoys. The nets were anchored at one end to a large stone on the beach and attached at the other end to a 200 L oil drum filled with stones, which served as an anchor in the water. The nets were kept under daily constant surveillance, and the presence of narwhals in the fjord was also monitored. Immediately after a whale became entangled, two inflatable boats were paddled or pulled towards the captured animal. Use of outboard engines was avoided as far as possible to minimize acoustic stress on the whales. The nets and narwhals were pulled to the surface to ensure that the animals could breathe and position them for the tagging operation. Oars (2.5 m) were placed between the boats through the nets to secure the animals during handling and to keep the boats separated. Ropes and transport belts were placed around the chest, tail, and tusk to secure the animal while the transmitters

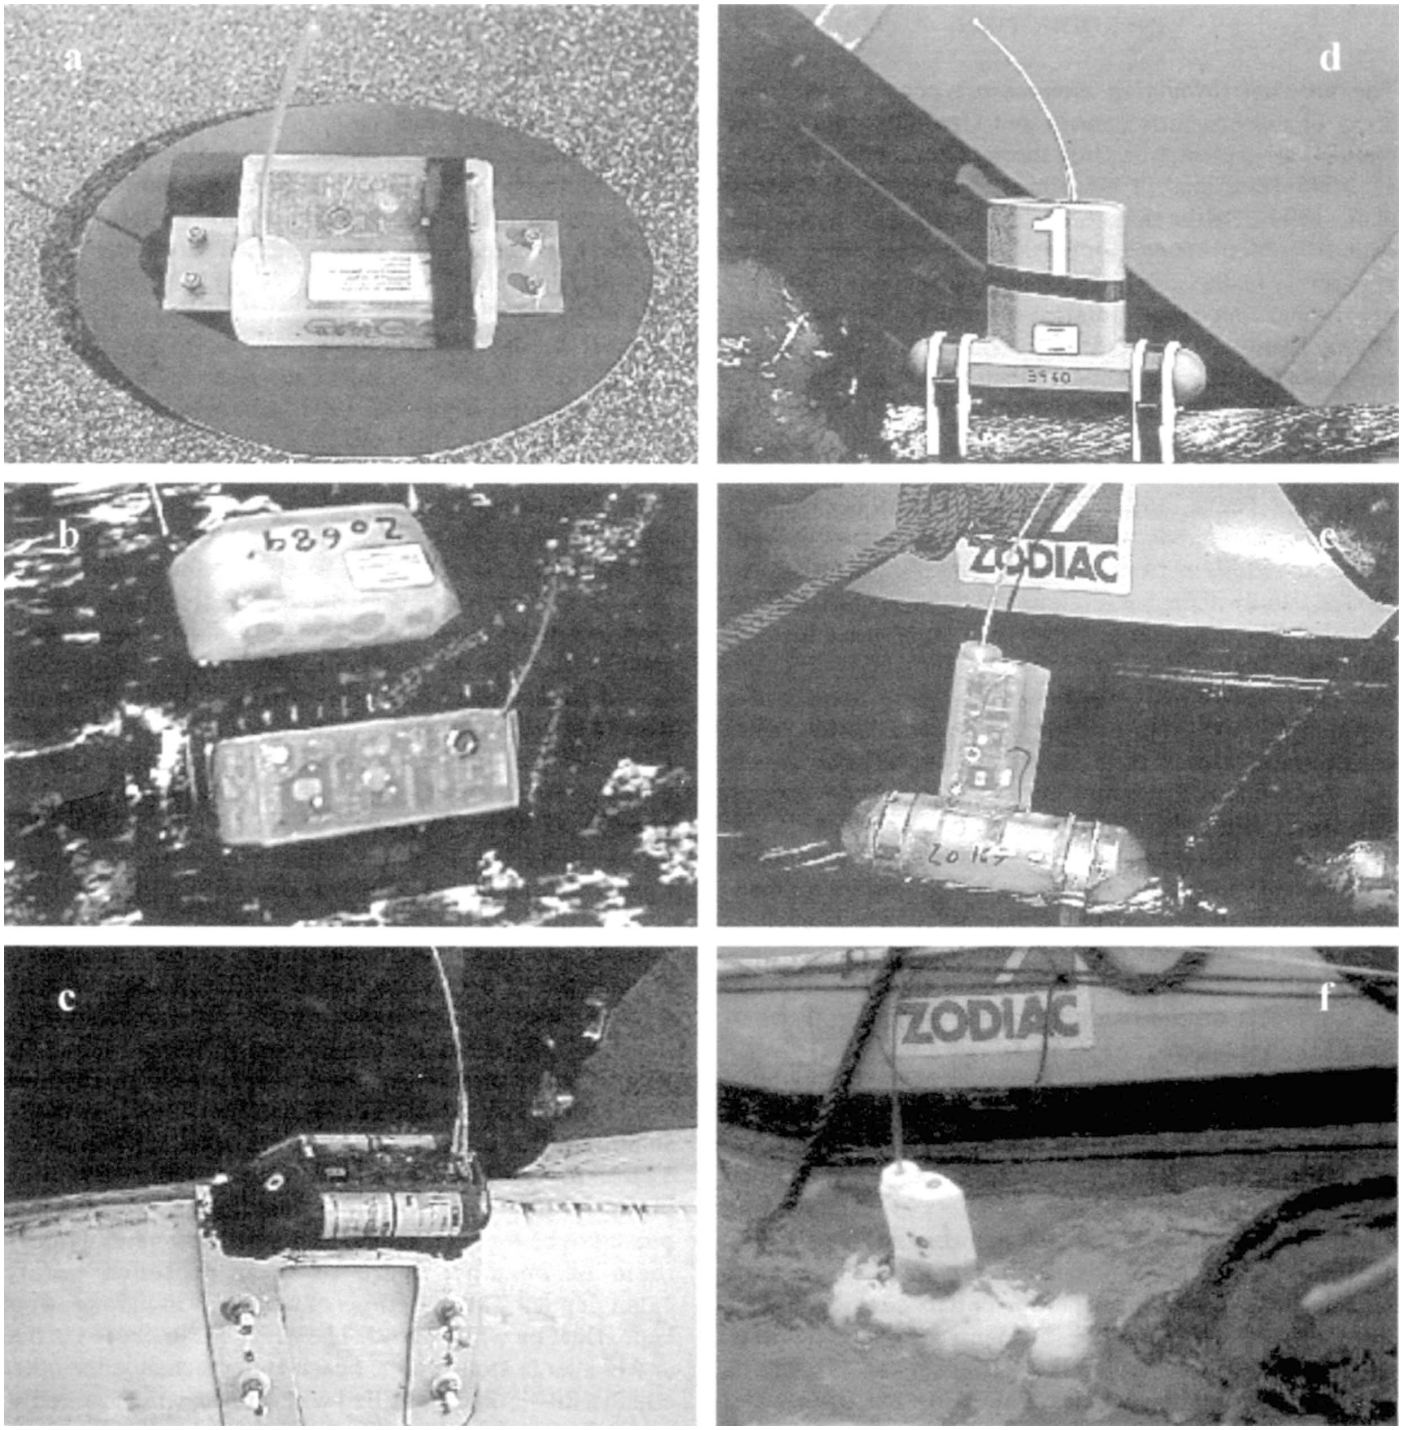

FIG. 1. Three first generations of narwhal (and beluga) backpack satellite transmitters (a–c) and three tusk transmitter generations (d–f).

were attached. After instrumentation, the nets were removed from the animals. Finally, the transport belts were detached at one end and the whales were released.

Instrumenting the Whales

Four whales, one female and one small male with a 40 cm tusk (external) in 1997 and two adult females in 1998, were instrumented with backpack transmitters that were pinned through the dorsal ridge. These transmitters had a power output of 0.5 W (ST-6, Telonics, Mesa, Arizona) and were programmed and cast in epoxy by Wildlife Computers (Woodinville, Washington). Three of the transmitters (#20682, #20691, and #20692) were of the second generation, each with two housings measuring $3 \times 4.5 \times 14$ cm, one covering the battery package and the other the ST-6 transmitter (see Fig. 1a-c). The unit weighed approximately 950 g in air and 150 g in water. The saddle, 20 cm

long and 24 cm wide, was made of a rubber material 5 mm thick (Ureol® polyurethane, composed of type XB 5073-1 and 6414 B in the proportion 100:18). Each transmitter, powered by four lithium C cells (3.5 V), was capable of 54 000 transmissions at 0°C. The third female (#20696) was instrumented with a fourth-generation transmitter with a single housing (3 × 4.5 × 14 cm) covering both the ST-10 transmitter and the battery package (four 3.5 V lithium C cells). This unit also weighed approximately 950 g in air and 150 g in water. The transmitter was glued to a saddle made of 1.5 mm thick belt material (Fig. 1c). The saddle was 20 cm long, with a belt in each end extending 15 cm to each side. Each belt was 5 cm wide and pre-punched with a row of holes. Excess belt material beyond the selected holes was cut off to minimize drag during swimming. The saddle was secured to the animal with two 8 mm pins of flexible polyethylene (PEHD 1000) held in place by washers and nuts. The ends of the pins were cut to a length of 1 cm and compressed with pliers to prevent the nuts from loosening.

Six male narwhals with tusks measuring between 0.6 and 2.1 m (external length) were fitted with 0.5 W satellite-linked UHF transmitters (ST-6, Telonics, Mesa, Arizona), also manufactured by Wildlife Computers (Redmond, Washington) (Fig. 1d-f). The housings of the second- and third-generation transmitters both measured 8 (3.5) × 21 (6.5) × 27 (8) cm (width × height × length; max (min) measures) and weighed approximately 1 kg in air and about 400 g in water. We deployed four second-generation transmitters with a pressure transducer maximum of 1000 m (cast in transparent epoxy) and two third-generation transmitters with a pressure transducer maximum of 1500 m (cast in yellow epoxy; see Fig. 1e-f). The transmitter housings were hydrodynamically designed to minimize both water resistance and reflection of sonar signals. These transmitters were powered by eight lithium C cells (expected capacity of 180 000 transmissions at 0°C).

The housing units were attached to the tusks by two 316-type stainless steel bands that were 19 mm wide (Band-it, Houdaille, Denver, Colorado). The tusk is assumed to rotate towards the left as it grows (e.g., Thompson, 1963; Kingsley and Ramsay, 1988); therefore, the transmitters were tilted slightly to the right side of the animal, so that the antennae would remain in an upright position for a longer time. None of the transmitters were duty-cycled. In 1997, a daily maximum of 500 transmissions was programmed to save battery power, but as this limit was seldom reached, no such upper limit was programmed in 1998. A saltwater switch triggered transmissions 0.2 s after the switch emerged from the water. The minimum time between transmissions (repetition rate) of the transmitters was 45 s. Each transmission contained 14 bytes of information. A status message was relayed every 15th transmission with information on sum of transmissions as well as the battery voltage. Data from the transmitters were relayed via the ARGOS DCLS system (Service Argos Inc., 1989; Harris et al., 1990).

Signal Monitoring in the Field

Before deploying the transmitters, we tested them in the field using a local uplink receiver (Telonics: TSUR-B Argos Uplink Receiver). The uplink receiver was connected to a PC to log and monitor signals within the fjord, evaluate whale behaviour after release, and determine how long the animals stayed in Tremblay Sound after the tagging. The uplinks also kept the team updated on the presence of whales nearby.

Maps

Only good-quality positions of Class 1 to 3 were used for the drawing of the maps. The Argos system predicts the accuracy of the best quality, Class 3, to be 150 m or less from the animal's real position for 68% of the locations The corresponding predictions are 350 m or less for Class 2 and 1 km or less for Class 1. Studies on seals have shown that the distances between predicted and observed positions are on average two to three times higher than ARGOS predicts. (e.g., Stewart et al., 1989; McConnell et al., 1992; Goulet et al., 1999). These positions were used to map the routes taken by 6 of the 10 tagged narwhals that had 24 or more "good" positions.

Maps were produced with ArcView GIS system for Windows NT by ESRI, using digital coastline and bathymetry derived from the GEBCO Digital Atlas (GEBCO 97 edition). Place names mentioned in the text and figures were extracted from Canadian Hydrographic Service nautical charts.

We included data from two of nine narwhals tagged in Greenland in 1993 and 1994 (Dietz and Heide-Jørgensen, 1995) to illustrate the common wintering area and the timing and rate of the southward migration.

RESULTS

Bylot Island Fjord Complex as a Summering Area

Table 1 gives information on the dates of capture, sex, and size of the 10 narwhals equipped with satellite-linked transmitters off the Alpha River delta during 8–24 August 1997 and 14–25 August 1998.

During the summer period of both years (10 August–22 September), the whales stayed within the Bylot Island area, including Tremblay Sound, Milne Inlet, Eclipse Sound, Navy Board Inlet, Oliver Sound, and Pond Inlet (see also Fig. 2 and Table 2). Only one position was obtained from Navy Board Inlet, suggesting limited use of this part of the fjord complex. No positions were obtained from Lancaster Sound or the more western summering areas of Admiralty Inlet and Prince Regent Inlet.

No good-quality positions were obtained from Tremblay Sound (or Milne Inlet) in 1997 even though the animals stayed for a considerable time (up to 12 hours after the

TABLE 1. Information on ten narwhals instrumented with satellite-linked transmitters.

Tag #	Type[1]	Date	Sex	Length (cm)	Tusk length (cm)
1997:					
20682	B	August 8	Female	400	–
3963	T	August 19	Male	375	83
20691	B	August 21	Male	306	40
3964	T	August 21	Male	370	63
6335	T	August 24	Male	440	137
1998:					
3960	T	August 14	Male	400+	148
20692	B	August 19	Female	380	–
20162	T	August 21	Male	475	190
3961	T	August 25	Male	500	210
20696	B	August 25	Female	380	–

[1] B = Backpack transmitter; T = Tusk transmitter.

tagging) in Tremblay Sound, as monitored in the field by a local uplink receiver (Fig. 3a, b). In contrast with the 1997 results, the 1998 tagging produced good-quality positions from both Tremblay Sound and Milne Inlet (including its offshoot, Koluktoo Bay) (Fig. 4a-d), indicating a connection between the whales that frequent these fjords. In both 1997 and 1998, the whales showed a preference for deep areas (500 to 750 m) in Eclipse Sound and Pond Inlet, whereas few or no positions were obtained from Navy Board Inlet and the narrow fjords east of Milne Inlet. The whales may have avoided some of these areas because they lack deep water (e.g., Assumption Harbour and Ragged Island Sound, both less than 170 m deep). However, even fjords with intermediate depths (up to 430 m) were not visited (e.g., Eskimo Inlet, White Bay, and Paquet Bay), and no visits were recorded in the rather deep Tay Sound (up to 640 m). Of the two fjords for which we have no information on depth (Oliver Sound and Stevenson Inlet), only Oliver Sound was visited, and that was only once by one animal (see Table 2).

Eastern Baffin Island and the Autumn Migration

In 1997, only one narwhal was monitored on its southward migration, whereas in 1998 three whales were tracked as they moved south along the east coast of Baffin Island (Fig. 5). In both years, the whales left the Bylot Island area between 20 and 29 September (Figs. 3b, 4b-d).

Narwhal #6335 was tracked for 76 days in 1997, over more than 4026 km (Figs. 3b, 6, 7). While moving south along the east coast of Baffin Island, this whale visited a number of fjords (Table 3). It showed a preference for deep areas at the mouths of Royal Society Fiord (400–550 m; north of Bergesen Island), Clark Fiord (500–700 m), and Sam Ford Fiord (550–660 m), as well as for the continental slope (500–1000 m) east of Home Bay and Kangeeak Point, all of which are deeper than the shallow (< 200 m) banks on the continental shelf (Figs. 3b and 6). Narwhal #6335 also clearly avoided the shallow (down to 14 m) Hecla and Griper Bank on its way south. It is uncertain whether it visited other fjords (e.g., Clyde Inlet), but the lack of positions and the rapidity of the southward migration suggest that it would have had little time for such visits. This animal travelled as far south as Broughton Island, and then moved northeast towards the deep southern part of Baffin Bay. It was tracked to the continental slope, where it transmitted the last position on 7 November at around 69°N, 59°W, in the very same area that had been frequented by two male narwhals from Melville Bay in early December of 1993 and 1994 (Dietz and Heide-Jørgensen, 1995). The last position of #6335 was only 3.5 km from the closest position of the narwhals tagged in Melville Bay.

Narwhal #20696, tagged in 1998, was the only female tracked on its southward migration. It covered more than 2742 km over the 49 days of tracking (Figs. 4b and 6). This female left the Bylot Island area on 28 September, one week later than the two males tracked the same autumn. Moving southward along the east coast of Baffin Island, female #20696 visited five of the nine fjords frequented by all four narwhals tracked along this route. When we lost contact with the transmitter on 13 October, the female had reached 69°N, 66°W east of Home Bay.

The two male narwhals tracked southward in 1998 (#20162 and #3961) left Bylot Island on the same date (20 September) and migrated from Coutts Inlet along Baffin Island, visiting deep fjords, e.g., Buchan Through (500–700 m), Buchan Gulf (200–800 m), and Royal Society Fiord (Figs. 5 and 6). Narwhal #20162 remained in this area for two days, whereas narwhal #3961 continued south along Baffin Island: following a route similar to that of narwhal #6335 in 1997, it visited Scott Inlet (250–700 m), Sam Ford Fiord (400–600 m), and the continental slope (500–1000 m) east of Home Bay and Kangeeak Point. As in 1997, the whales showed no interest in the shallow areas (less than 200 m) of the continental shelf along Baffin Island and the shallow Hecla and Griper Bank (only 14 m deep). Narwhal #3961 started to move east off Broughton Island but then decided to head farther south to Cape Dyer, where contact was lost on 4 November.

After the two days' stay in Royal Society Fiord, #20162 returned north on 22 September towards an area east of Pond Inlet, where it stayed from 26 September to 4 October (Figs. 4d, 6, 8). It then moved north to an area east of Bylot Island, at the north end of the deep, narrow basin. On 8 October, it returned to the mouth of Pond Inlet, then moved north again, this time to the deepwater areas farther east of Bylot Island, where it stayed until 21 October. Narwhal #20162 then moved southward towards Royal Society Fiord, taking essentially the same route that it had taken a month earlier in company with #3961. Thereafter, it moved farther east towards the 1500 m contour, which it followed, without visiting any of the Baffin Island fiords, until it reached the latitude of Broughton Island. It moved 6 latitudinal degrees south (more than 650 km) in 16 days (Fig. 8).

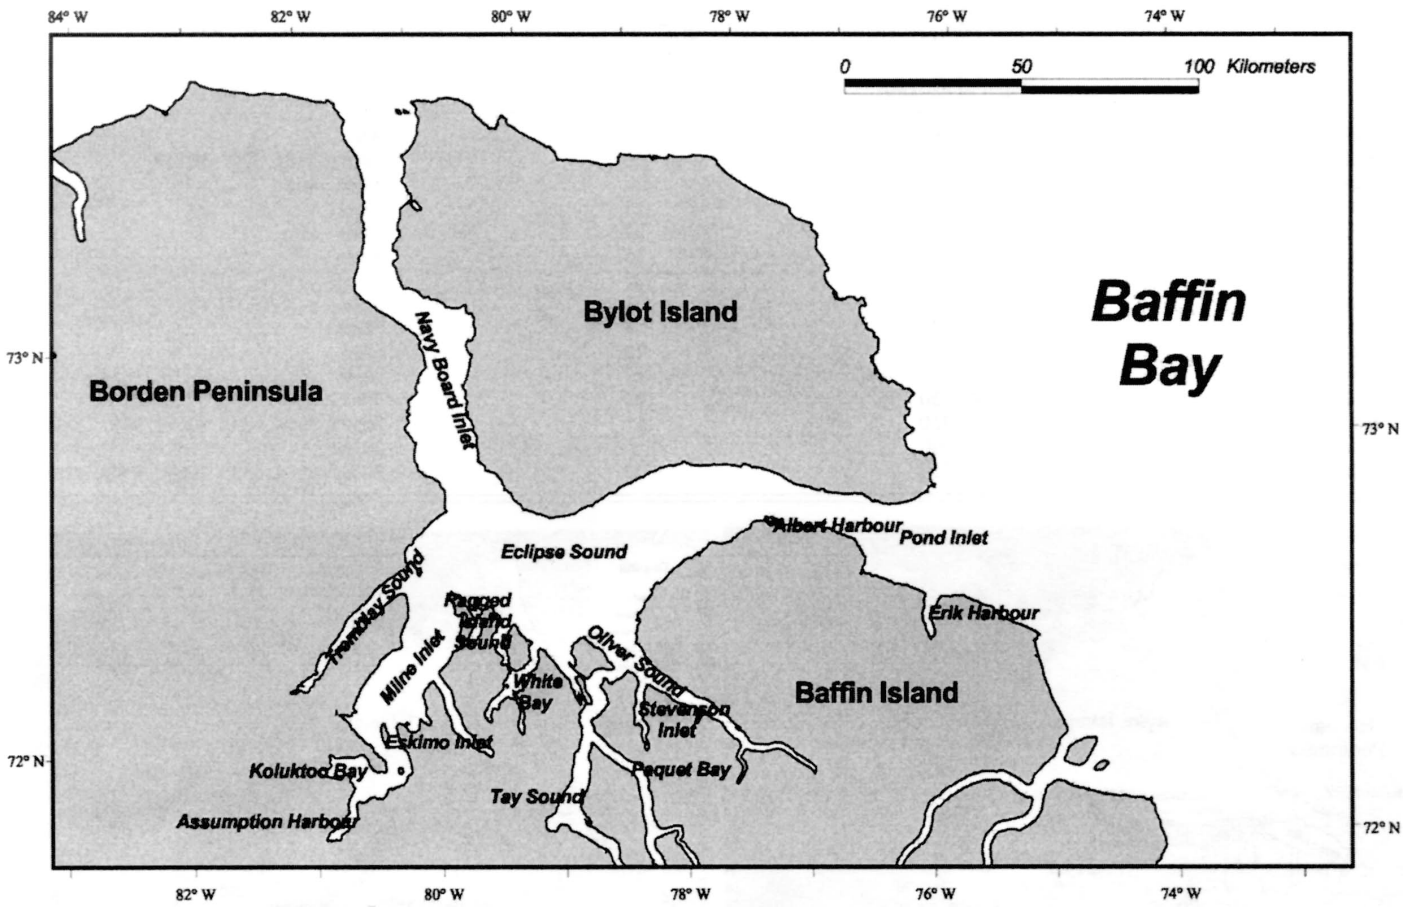

FIG. 2. Map showing place names in the Bylot Island area.

The whales that had time to visit the fjords of Baffin Island on their way south clearly preferred the deep fjords that extend close to the continental slope. Their rapid southward migration may have precluded visiting deep fjords situated or extending farther west (see Table 4).

Offshore Wintering Areas

After narwhal #6335 had reached its southern limit, it continued moving east until it reached the area used by the narwhals from Melville Bay. It arrived there, however, on 7 November, two weeks earlier than the Melville Bay narwhals. As the last contact with #6335 was on that date, it is impossible to conclude, from the 1997 data, whether it (and other narwhals) remained in the area for the winter.

Narwhal #20162 started moving east towards the 1000 m contour off Greenland on 5 November 1998, arriving there on 10 November (Figs. 6 and 7). This was the same area (69° N, 59° W) frequented by the "Canadian" narwhal (#6335) tagged in 1997 and by the two male narwhals from Melville Bay, and the arrival dates of all four whales were within a two-week period of November (Figs. 6 and 7). Narwhal #20162 stayed between 59° and 60° W and travelled south and north along the 1000 m contour between 67° and 70° N. It reached 68°18′N, 60° W on 10 November. From there it went south and arrived at its most southern latitude, 67°48′ N, on 15 November. Over the next two weeks, it went north to its most northern wintering latitude, 69°36′ N. Between 29 November and 7 January, narwhal #20162 went south and north twice between 68°30′ N and 69°30′ N. It then moved south to 68° N, perhaps because of severe ice conditions (NOAA satellite ice map from January 1999). It stayed at that latitude from 18 to 30 January, after which the transmitter stopped operating (Figs. 6 and 7).

Timing and Rate of the Southward Movement

The rate of southward movement by "Canadian" narwhals was similar to that of the narwhals from Greenland (Dietz and Heide-Jørgensen, 1995). However, the narwhals from the Bylot Island area started their southward movement approximately one month earlier (22–29 September) than the Melville Bay whales (ca. 22 October). One exception was male narwhal #20162, which went back north and stayed another month east of Bylot Island. As most narwhals from the Bylot Island area moved only 4.5° (500 km) south, compared with 7.5° (833 km) for the Melville Bay narwhals, the Bylot Island area animals took less time than the narwhals from Melville Bay (3 weeks vs. 4–5 weeks) to reach their southernmost positions (Fig. 8).

TABLE 2. The fjords of the Bylot Island area, showing depth and length characteristics and visits by narwhals in 1997 and 1998.

Fjord	Depth Range (m)	Length (km)	Visited by Narwhal No:
Tremblay Sound	90–260	41	All
Milne Inlet	150–850	52	3960, 20696, 3961, 20162
Koluktoo Bay	150–320	20	3960, 3961
Assumption Harbour	150–170	15	None
Eskimo Inlet	30–285	24	None
Ragged Island Sound	40–110	15	None
White Bay	40–410	26	None
Tay Sound	100–640	61	None
Paquet Bay	300–430	54	None
Oliver Sound	?	72	6335
Stevenson Inlet	?	19	None
Navy Board Inlet	100–550	120	3963
Eclipse Sound	100–750	111	20691, 3964, 6335, 20696, 3961, 20162
Albert Harbour	10–090	4	20162
Pond Inlet	100–750	52	20691, 3964, 6335, 20696, 3961, 20162

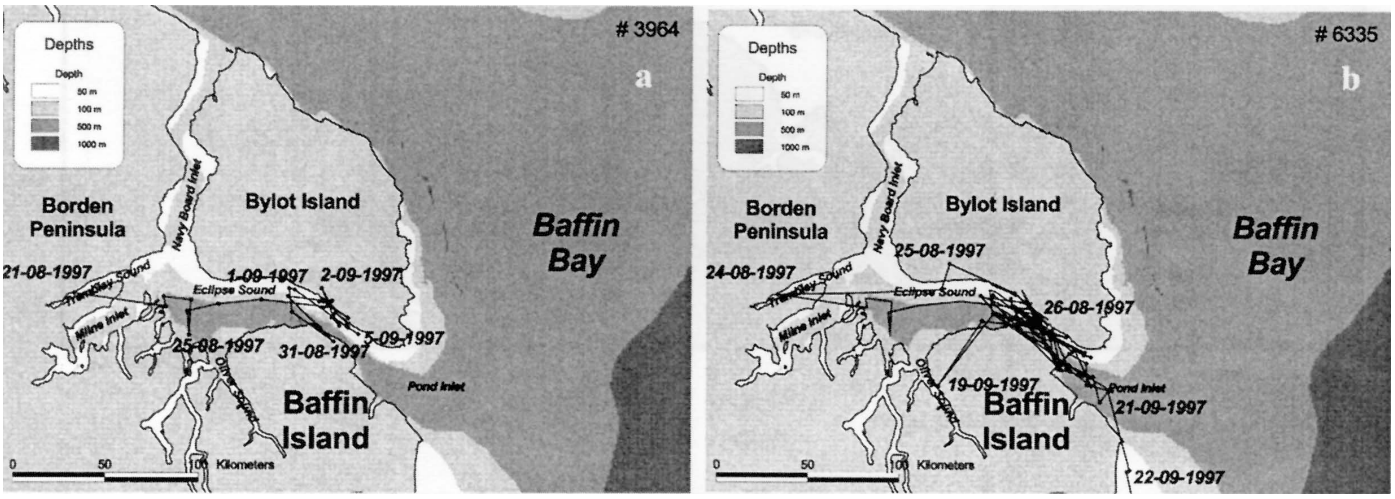

FIG. 3. a: Movements of adult male narwhal #3964 (length: 370 cm, tusk: 63 cm), tracked for 430 km from 21 August through 5 September 1997. b: Close-up of the Bylot Island area movement of adult male narwhal #6335 (length: 440 cm, tusk: 137 cm) from 24 August to 23 September 1997. See Figure 6 for the complete track of this whale. Only good-quality positions (Class 1–3) are shown.

Performance of the Backpack Transmitters

Three backpack transmitters of the second generation were deployed (on #20682 and #20691 in 1997 and on #20692 in 1998), and their average transmitter longevity was 41 days. Although 11 923 transmissions (on average) were sent from each of the three platform transmitter terminals (PTTs), only two Class 1–3 positions and 67 Class 0 positions were obtained in total from these three whales (Table 4).

However, the fourth-generation transmitter (#20696) deployed in 1998 provided three times as many uplinks (33261) on average, resulting in as many as 470 "good" positions (Class 1–3) and 473 positions with unknown accuracy (Class 0). This large difference must be ascribed to the design of the fourth-generation transmitters, which placed the PTT centrally on the saddle (see Fig. 1c). This placement elevated the antennae 3–4 cm higher than on the second-generation transmitters, which had the PTT unit and the battery package on opposite sides of the saddle. We therefore stopped using the second-generation design in subsequent studies on narwhals, as their lack of a protruding dorsal ridge leaves the antennae and saltwater switch too low in the water.

Performance of the Tusk-Mounted Transmitters

As the second- and third-generation transmitters had the same shape and PTT, differing only in the range of the pressure transducer and in colour, we did not compare their longevity. One tusk-mounted transmitter in 1997 (#6335) and two in 1998 (#3961 and #20162) showed fairly good longevity, ranging from 78 to 165 days. But three other tusk transmitters (#3963, #3960, and #3964) transmitted for only 6, 7, and 31 days, respectively: less time than the shortest lasting backpack transmitters. On the basis of the 1997 results, we believed that the small size of the tusks (63–83 cm external lengths) contributed to the premature failure of the tusk-mounted transmitters. However, the failure of #3960 in 1998, after only 7 days, showed that transmitters mounted on a large tusk (148 cm) could fail prematurely as well.

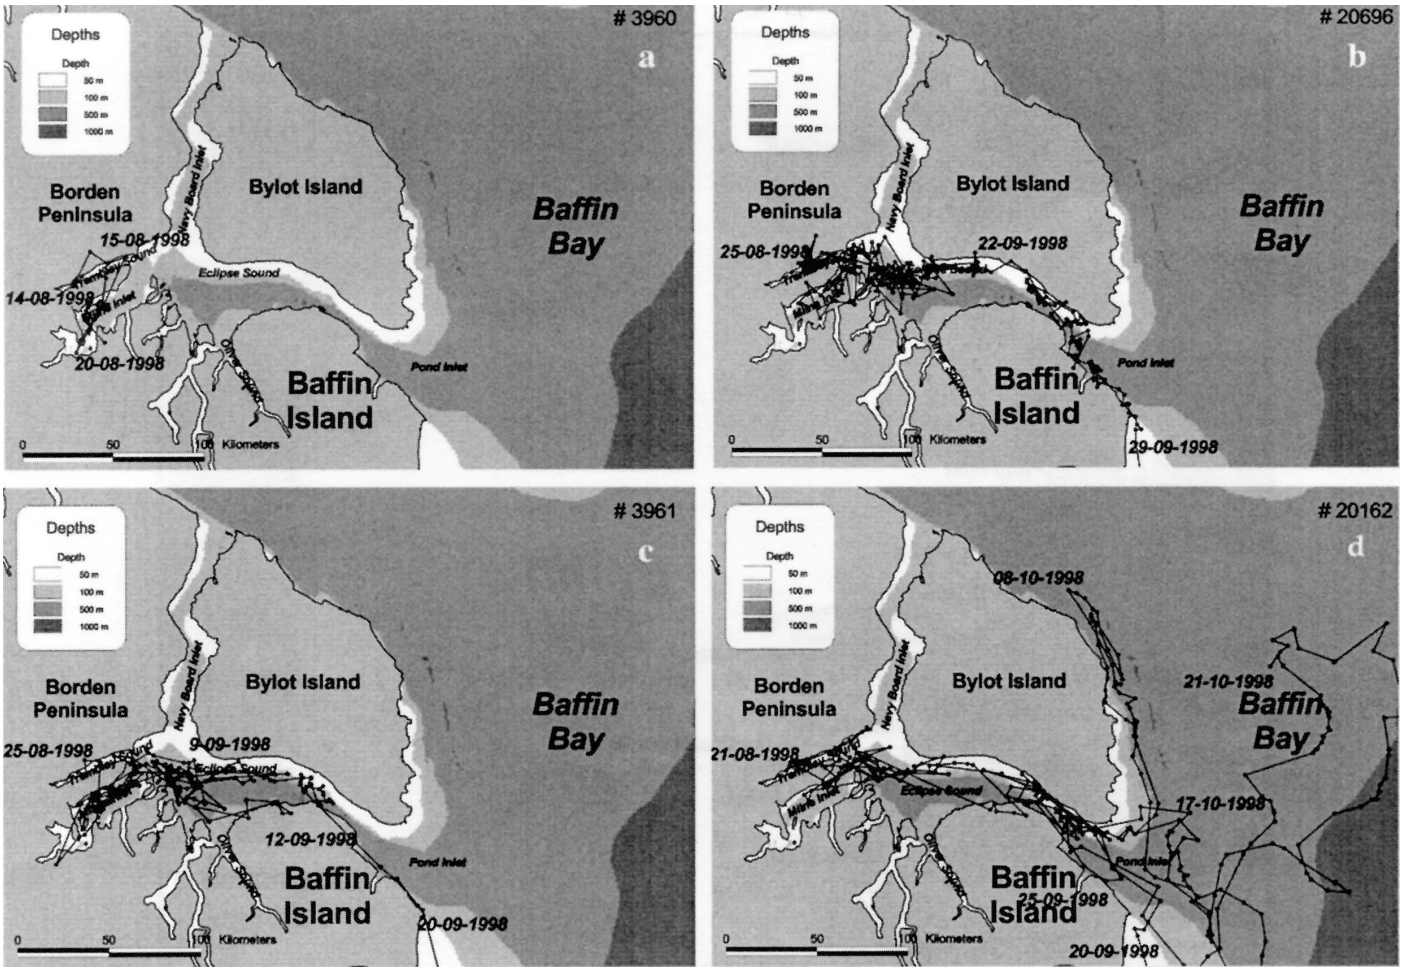

FIG. 4. a: Movements of adult male #3960 (length: 400+ cm, tusk: 148 cm), tracked for 228 km from 14 to 20 August 1998. b: Close-up of the Bylot Island area movement of adult female #20696 (length: 440 cm) from 25 August through 29 September 1998. c: Close-up of the Bylot Island area movement of adult male #3961 (length: 500 cm, tusk: 210 cm) from 25 August through 20 September 1998. d: Close-up of the Bylot Island area movement of adult male #20162 (length: 475 cm, tusk: 190 cm) from 21 August through 22 October 1998. See Figure 6 for complete tracks of whales #20696, #3961, and #20162 (b-d). Only good-quality positions (Class 1–3) are shown.

The fact that a transmitter operated for more than 18 months on a narwhal with a tusk 84 cm long (tagged in 1994) indicates considerable variability in the longevity of the tusk-mounted tags. This information also indicates that the mounting of a PTT on the tusk of a narwhal is not likely to affect the behaviour or survival of the animal. The cause of the transmission failure of the long-lasting transmitters #6335 (76 days), #3961 (78 days), and #20162 (162 days) is also unknown. The climatic conditions at the time of failure (November–February), with low temperatures and up to 10/10 of ice coverage, could have damaged the electronics, the antennae, or the attachment. As no reduction in the monitored voltage was observed, battery failure was not believed to be the cause of the transmission failure.

Backpack Transmitters vs. Tusk-Mounted Transmitters

The tusk-mounted transmitter had greater longevity than the backpack transmitters (61 vs. 43 days) and a larger number of days with good locations (57 vs. 25 days), but the differences were not significant ($p = 0.5869$ and $p = 0.3629$ respectively; unpaired T-test). However, the longevity of the six tusk-mounted transmitters showed greater variability (6–165 days) than that of the four backpack transmitters (32–49 days).

The number of good positions per day (Class 1–3 positions/Good position days) was very poor for the second generation of backpack transmitters (0–0.2 positions/day), intermediate for the tusk-mounted transmitters (0.2–5.4 positions/day) and best for the fourth generation of backpack transmitters (9.6 positions/day). However, data in these three groups were insufficient for a meaningful statistical test.

None of the transmitters showed battery drainage within the period monitored. All ten transmitters showed a higher battery voltage at the end of their operating period compared with the first measurements of voltage. We therefore concluded that none of the units stopped transmitting because of battery failure. It is likely that the backpack transmitters terminated because they fell off as the pins migrated out through the dorsal ridge.

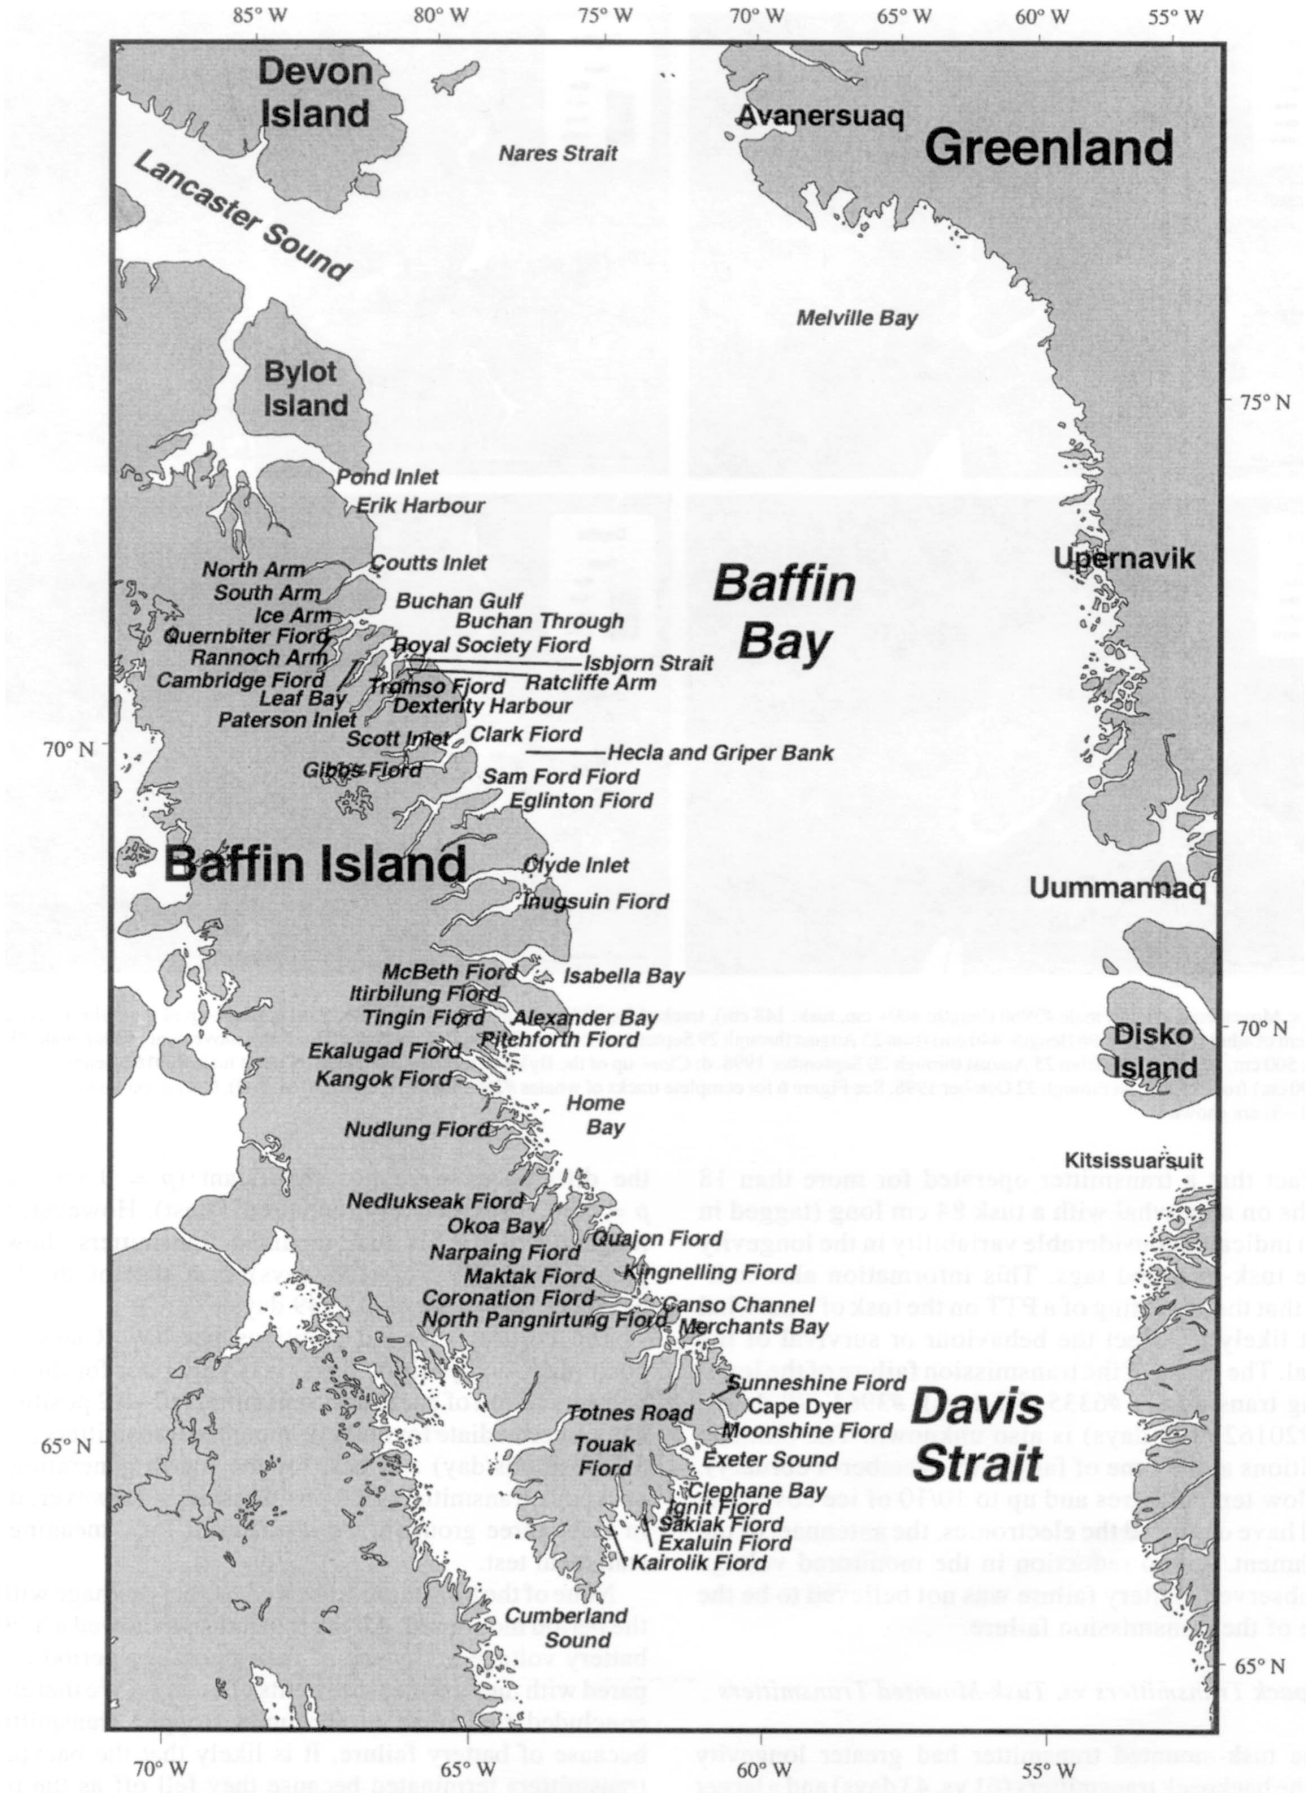

FIG. 3. Map showing place names along Baffin Island.

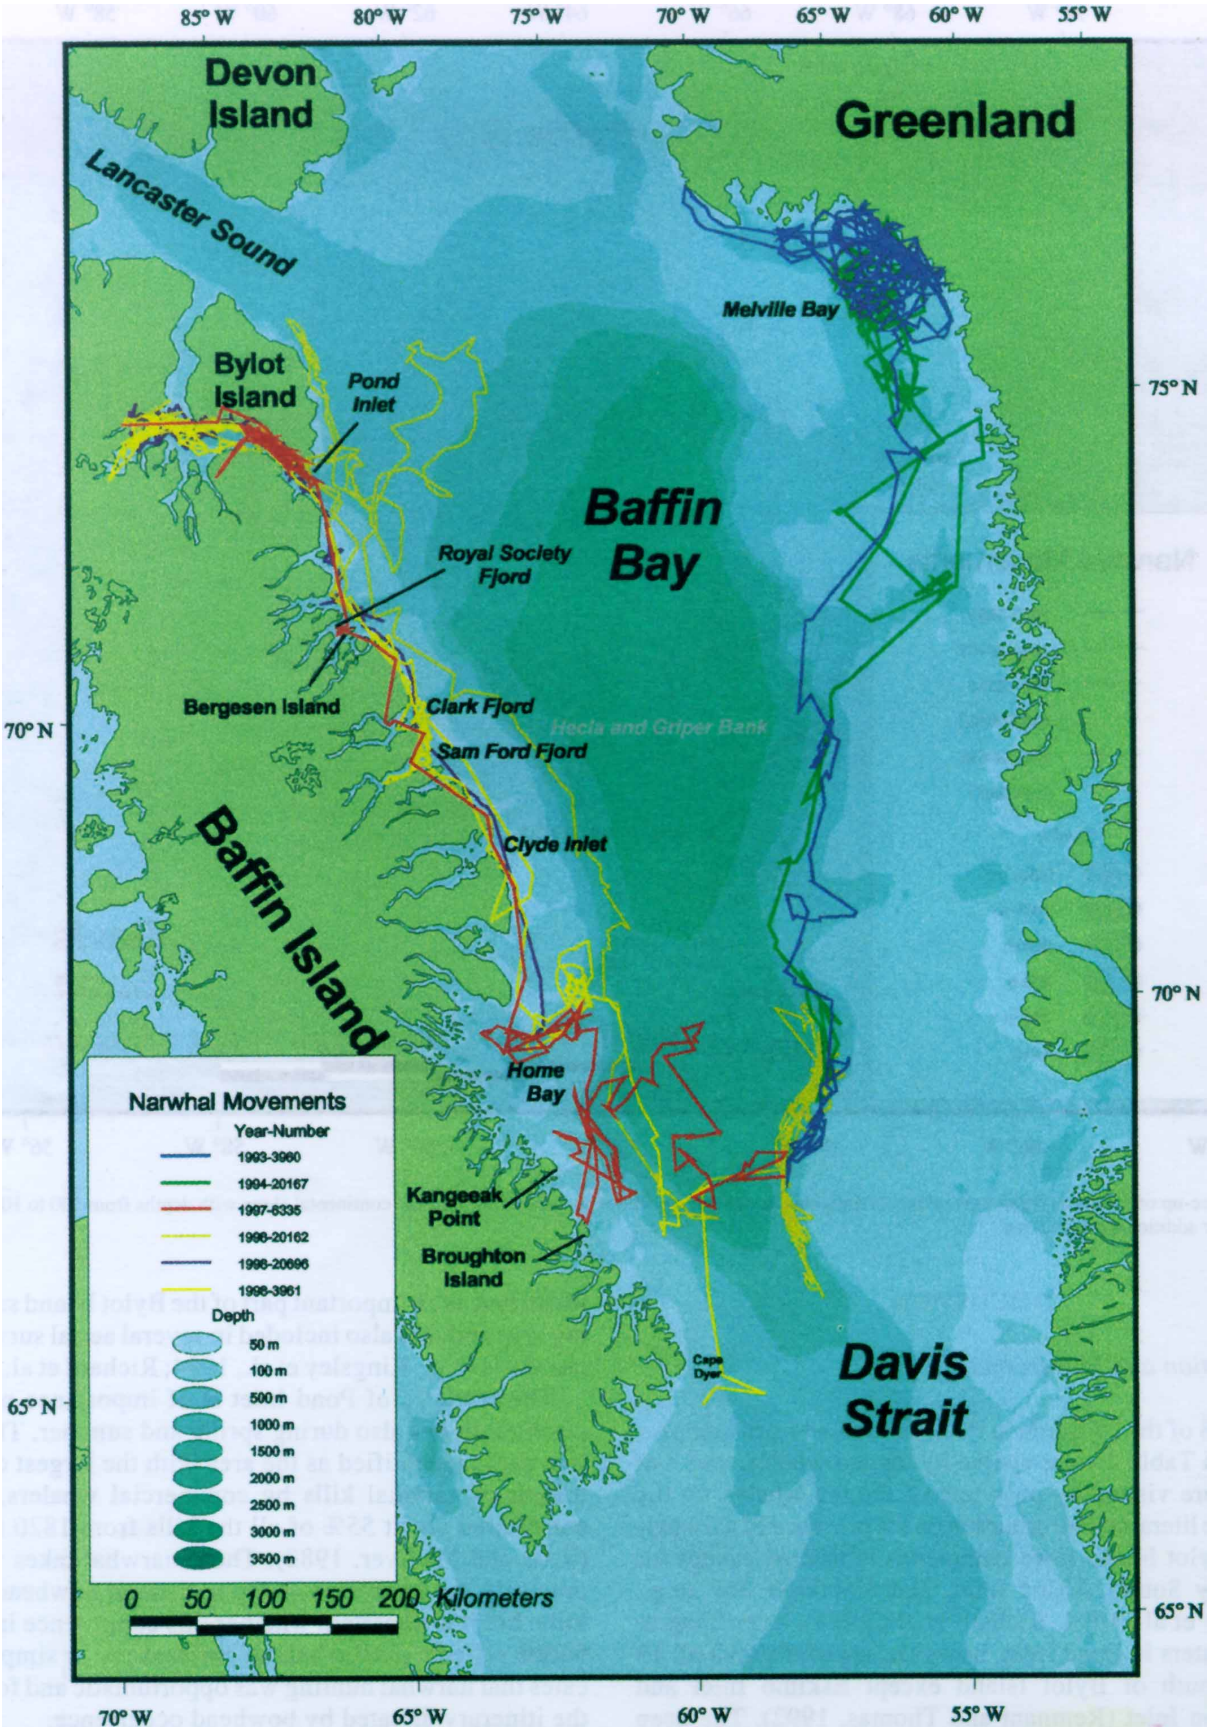

FIG. 6. Autumn movements of three adult narwhal males (#6335; #3961; #20162) and an adult female (#20696) tracked for 4062 km, 4516 km, 7017 km, and 2742 km, respectively, during 1997 and 1998. Also shown are the tracklines of two other male narwhals tracked from Melville Bay in West Greenland in 1993 (#3960) and 1994 (#20167); (see Dietz and Heide-Jørgensen, 1995). Only good-quality positions (Class 1–3) are shown.

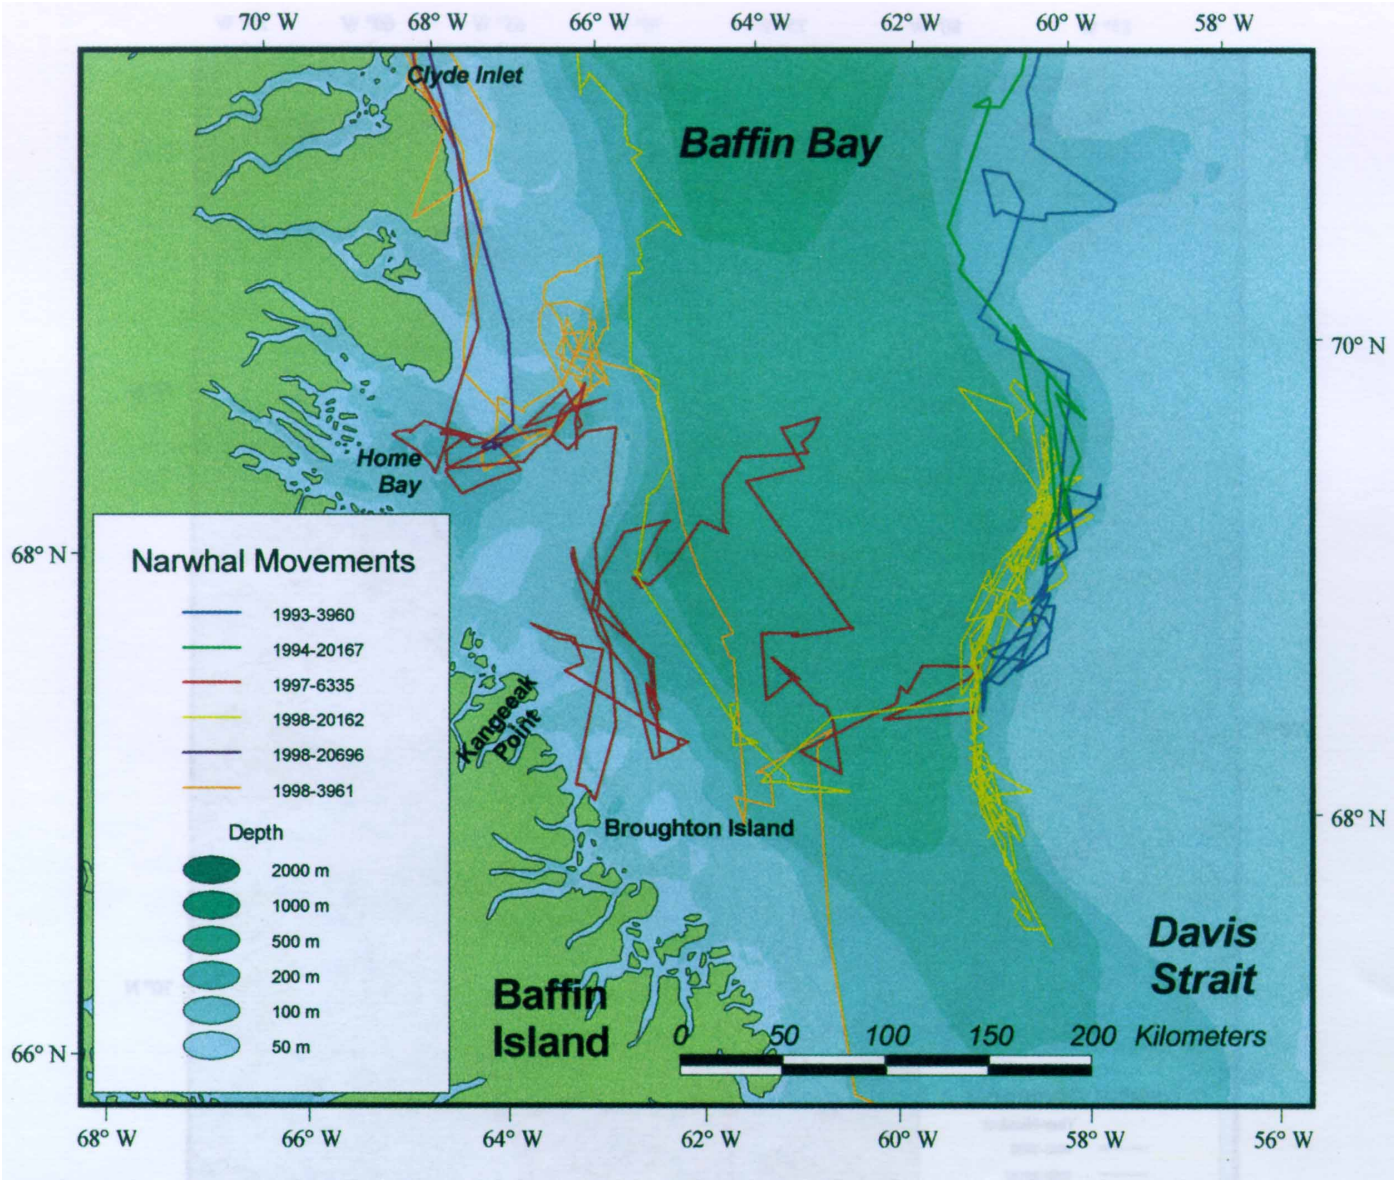

FIG. 7. Close-up of the Davis Strait movements of narwhals from Figure 6, showing their affinity for the continental slope with depths from 500 to 1000 m. See Figure 8 for additional information.

DISCUSSION

Distribution and Movements

Only 8 of the 15 fjords in the Bylot Island fjord complex shown in Table 2 were visited by tagged whales, and 3 of those were visited by only one of the ten whales. In the scientific literature, information on the presence of narwhals in the Bylot Island fjord complexes is limited except for Tremblay Sound, Milne Inlet, and Koluktoo Bay (e.g., Kingsley et al., 1994; Richard et al., 1994). According to Inuit hunters in Pond Inlet, however, narwhals visit all 15 fjords south of Bylot Island except Eskimo Inlet and Stevenson Inlet (Remnant and Thomas, 1992). The deep fjord Tay Sound (to 640 m) has been described as an important summering ground for narwhals (Miller, 1955; J. Mucktar, pers. comm. 1998). Eclipse Sound has also been identified as an important part of the Bylot Island summering area and was also included in several aerial surveys for narwhals (e.g., Kingsley et al., 1994; Richard et al., 1994).

The entrance of Pond Inlet is of importance not only during fall, but also during spring and summer. This area was earlier identified as the area with the largest concentration of narwhal kills by commercial whalers, which constituted about 55% of all the kills from 1820 to 1910 (Ross and MacIver, 1982). These narwhal takes were in precisely the same area as the registered bowhead whale kills, but it is uncertain whether this congruence in distribution reflects similar habitat preferences, or simply indicates that narwhal hunting was opportunistic and followed the itinerary dictated by bowhead occurrence.

In both 1997 and 1998, the tagged whales stayed within the Bylot Island area during the summer, without frequenting Lancaster Sound or the more western summering areas

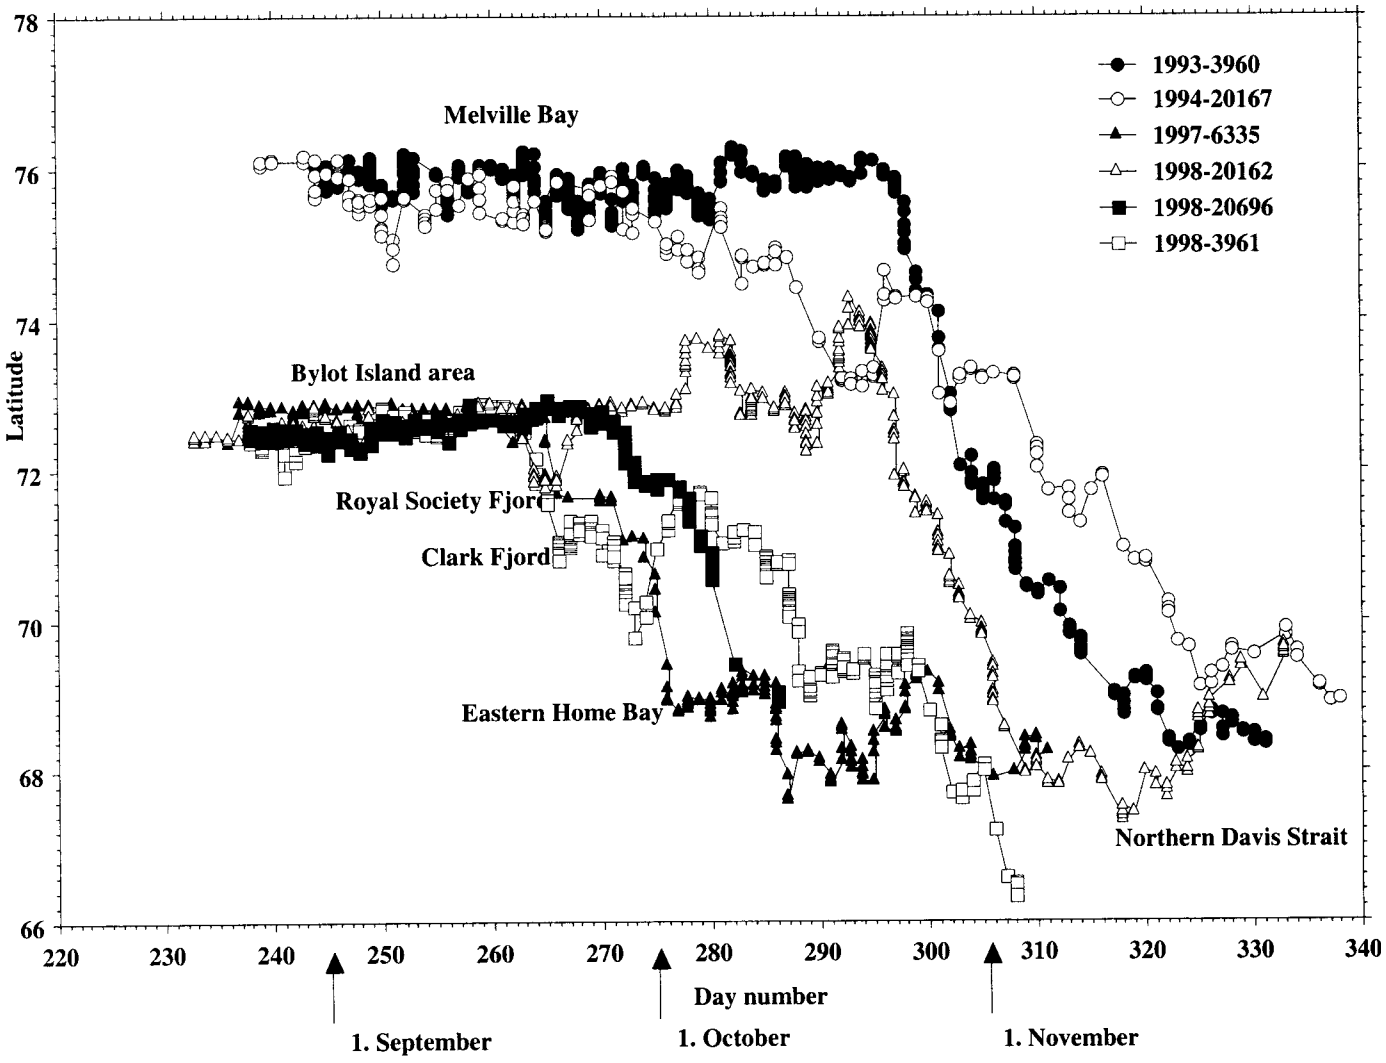

Fig. 8. Comparison of the change in latitudes over time for the narwhals from the Bylot Island area (#6335, #3961, #20162, and #20696) and for two whales from Melville Bay (#20167 and #3960) reported by Dietz and Heide-Jørgensen (1995).

in and around Admiralty Inlet, Prince Regent Inlet, Peel Sound, and the fjords south of Pond Inlet. Five narwhals previously tagged in Tremblay Sound and Milne Inlet also remained within the Bylot Island area without frequenting other summering areas during the monitored period (up to 26 days) in August and early September (Kingsley, 1993; Martin et al., 1994). Inuit hunters indicate that narwhals have a distribution within the Bylot Island area extending from the mouth of Navy Board Inlet to the mouth of Pond Inlet (Remnant and Thomas, 1992). Remnant and Thomas (1992) and Stewart et al. (1995) interviewed hunters from the other Canadian summering areas, but received no reports of summer observations in Lancaster Sound. In those studies, however, the hunters were not specifically asked about the connection between the summering populations. It is therefore not possible to conclude anything from the interview information about the connection between narwhals from the Bylot Island area and those from the other known summering areas around Admiralty Inlet, Resolute, Prince Regent Inlet, or Peel Sound (Remnant and Thomas, 1992; Stewart et al., 1995). Systematic aerial surveys carried out in Lancaster Sound in 1975, 1976, and 1981 likewise resulted in no observations of narwhals there during August and the first part of September (Johnson et al., 1976; Renewable Resources Consulting Services Ltd, 1976; Davis et al., 1978; Smith et al., 1985; Strong, 1988). However, some animals may move between the summering areas.

Even if there is some degree of separation among the summering stocks in and around Admiralty Inlet, Resolute, Prince Regent Inlet, and Peel Sound, most of the whales have to move through Lancaster Sound during their spring and autumn migrations. The exceptions are those narwhals that enter the Bylot Island area through Pond Inlet during the breakup of fast ice. It is possible that narwhals mingle at the entrance to Lancaster Sound in spring, but to what extent this mingling affects their choice of summering habitat and results in genetic exchange is uncertain.

TABLE 3. Eastern Baffin Island fjords, showing depth and length characteristics and visits by narwhals in 1997 and 1998. ? indicates that depth information is not available.

Southeast of Pond Inlet, the hunters of Clyde River indicate the summer presence of narwhals in most of the fjords frequented during the autumn migration, including Scott Inlet, Clark Fiord, Gibbs Fiord, Sam Ford Fiord, Eglinton Fiord, Clyde Inlet, Inugsuin Fiord, McBeth Fiord, the Alexander Bay area, and Ekalugad Fiord (Fig. 5). Coutts Inlet and Buchan Bay were not listed by the 34 Pond Inlet residents interviewed as areas traditionally used by narwhals in summer and autumn (Remnant and Thomas, 1992). However, the Coutts Inlet area and farther south towards Clyde River were designated as "new" sighting areas, where narwhals had increased since the mid-1980s. According to J. Mucktar (pers. comm. 1998), both Buchan Gulf and Coutts Inlet are visited by a considerable number of narwhals in the summer. Buchan Gulf was surveyed between 11 and 15 August 1978, and 300 narwhals were

estimated to have been present there (Koski and Davis, 1994). A large group of narwhals was seen going up Coutts Inlet and moving along the glacier fronts in late August 1984 (R.R. Reeves, pers. comm. 2000). Haller (1967) stated that narwhals were common from Home Bay north to the Clyde River area, where they appeared from summer to early fall. Farther south, the Broughton Island hunters provided information on the summer presence of narwhals in Nudlung Fiord, the mouth of Nedlukseak Fiord, and Merchants Bay, all areas that were not visited by our tagged whales during autumn (Remnant and Thomas, 1992). On present evidence, we can not dismiss the possibility that the narwhals distributed during summer all the way from Peel Sound eastward and southward to Merchants Bay represent one large and widely distributed population. However, it is likely that there are several or many smaller population units, which, even if they mingle during other times of the year, return to specific inlets, embayments, or fjord complexes during the summer.

Exchange is less likely with other summering populations, such as those in Foxe Basin, because of the significant physical land barriers (Mansfield et al., 1975). In early papers, Sergeant (1979a, b) talks of a large northern narwhal component in the Lancaster Sound area and small southern component inhabiting northern Hudson Bay, but it is uncertain whether exchange may occur through Fury and Hecla Strait during summer and whether the segregation persists throughout winter. Small numbers of narwhals may, however, winter in Hudson Strait (McLaren and Davis, 1981; Strong, 1988).

Contact with the Greenland summer populations in Melville Bay and Inglefield Bredning, or with possible populations in the Nares Strait and its associated fjord complexes, is also uncertain. But since not one of the 24 narwhals tagged so far in Canada and Greenland has shown summer movements across country borders, such summer exchange seems unlikely (Kingsley, 1993; Martin et al., 1994; Dietz and Heide-Jørgensen, 1995). Additional tagging and increased tag longevity will certainly shed additional light on these questions.

All evidence points to a southward migration along the east coast of Baffin Island in late September (e.g., Strong, 1988; Remnant and Thomas, 1992). Whales in our study began moving south from the mouth of Pond Inlet around 22–29 September, which is consistent with the observations by Johnson et al. (1976) of eastward movements through Lancaster Sound around 26–28 September. Davis (1980, cited in Strong, 1988) claimed that the autumn migration starts in September or October. The timing of the southward migration at Pond Inlet is also in good accordance with the Inuit information from

this area (Remnant and Thomas, 1992). Koski and Davis (1994) reported departure periods from Admiralty Inlet to be 23–27 September in 1978 and 18–21 September in 1979. Many of the narwhals were reported to follow the coast of Baffin Island southeastward, but some continued moving offshore from SE Devon Island towards Baffin Bay (Koski and Davis, 1994).

Most of the areas visited by the tracked narwhals during their southward migration have also been described as summering areas. For example, Clyde River and Broughton Island residents reported the summer presence of narwhals in all fjords between Scott Island and Home Bay, as well as in the three fjord complexes west of Home Bay and in Merchants Bay south of Broughton Island (Remnant and Thomas, 1992). Wenzel (1991) states that narwhals may appear at any time from mid-August through September around Clyde River. As borders between spring, summer, and autumn are not well defined, at least some of the summer observations may represent late spring or early autumn observations. For example, Home Bay was described as a summering area by Koski and Davis (1994), who surveyed it on 18 September 1979, but this observation could represent an early portion of the southward migration. This "population" was estimated to be more than 95 animals (Koski and Davis, 1994).

According to Koski and Davis (1994), almost 5000 narwhals passed Cape Adair between 29 September and 2 October 1978. This timing agrees well with that of our four tagged narwhals as they moved southward along Baffin Island in 1997–98.

The few autumn kills of narwhal by commercial whalers along the eastern Baffin Island coast might reflect the fact that narwhals migrate southward somewhat later than bowheads (and thus, after the whalers have passed). According to Ross and MacIver (1982), the narwhals appeared after the whalers had cleared Cape Dyer.

The most southern position of our tagged narwhals was just south of Cape Dyer at about 66° N on 6 November 1998. This is consistent with the claim of Strong (1988) that narwhals are seldom seen south of 65° N in the Davis Strait.

The narwhals from Canada showed a preference for deep fjords and for the continental slope (1000–1500 m) along eastern Baffin Island. This same preference was shown by the narwhals from Melville Bay that moved south along the continental slope west of Disko Island (Dietz and Heide-Jørgensen, 1995). We find it remarkable that narwhals are so strongly linked to the narrow bathymetry corridors in Baffin Bay and Davis Strait, which constitute only a small proportion of the total water volume available between Canada and Greenland. A similar preference for a well-defined section (350–975 m isobath) of the continental slope was documented for Risso's dolphin (*Grampus griseus*), another cephalopod predator inhabiting the northern Gulf of Mexico (Baumgartner, 1997). This area constituted only 2% of the surface area of the entire gulf. It was argued that such shelf edges and upper continental slopes are frequently sites for increased biological activity. The upwelling in such areas introduces nutrients from deeper shelf or slope waters into the euphotic zone, stimulating increased primary production and thus supporting secondary production as well. Species with such a specialized distribution, including the narwhal, are particularly susceptible. Disturbance or intense fishing within these areas may force the whales to deeper and less favourable areas, which may negatively affect their foraging. Information on such critical areas can be used in their management and protection to avoid negative impacts from human activities.

The preferred wintering ground observed in this study, with its distinct pattern relative to the bathymetry, has been shown previously only for a few animals tracked from Melville Bay (Dietz and Heide-Jørgensen, 1995). Ours was the first study to document that populations summering in Canada and Greenland share a common wintering area. Our winter observations did not extend beyond 30 January and were restricted to the continental slope between 67°48′ N and 69°36′ N.

Few reliable winter observations of narwhals in Baffin Bay and Davis Strait have been published, but they suggest that wintering occurs in the offshore pack ice with a southern limit from 65° to 70° N. One published winter record is from the account of the North Polar Expedition during the southward drift of the U.S. *Polaris* from northern Baffin Bay to the Labrador Sea between October 1872 and April 1873 (Davis, 1876). Narwhals were seen on 7 February as the ship drifted south of 68°50′ N and then again on March 14 and 15 in latitudes from 64°32′ to 64°19′N, opposite the mouth of Cumberland Sound. No longitudes were given, as chronometers were not available at that time. However, the east coast of Baffin Island, probably Cape Dyer, was visible from the ship on 19 February, as it passed the Arctic Circle on approximately 66°30′N (Davis, 1876). Turl (1987) found large numbers of narwhals in the close pack ice in west and central Davis Strait (between 66°30′ and 68°15′N) in February–March 1976.

Information from aerial surveys in the late winter and early spring (mid-March to late May) suggests that narwhals winter throughout the close pack ice in Davis Strait and southern Baffin Bay down to 68° N, without any clear concentration areas (Heide-Jørgensen et al., 1993; Koski and Davis, 1994).

It is unclear whether this more scattered distribution of narwhals in late winter and early spring represents a reinvasion into the dense pack ice from the more southern winter quarter, or whether other narwhal stocks so far not tracked are using these areas outside the continental slopes as their wintering quarters. Tagging of other summering stocks with transmitters of increased longevity should help to answer these questions.

Stock Identity

The narwhals tracked in this study were almost stationary in the deepwater area of Eclipse Sound and adjacent

fjords for most of August. They moved east to the deep areas in Pond Inlet in early September and stayed there until their southward migration began in late September. From late September, they moved south along Baffin Island and visited a few fjords, possibly selected for their depth, productivity, or glacial activity. They made short stays in these fjords but continued their southward heading towards Davis Strait. The only exception was the individual that, after leaving Pond Inlet, first moved north to an abyss east of Bylot Island then headed south in early October along the continental slope. All of the whales moved east when they reached the southern end of the deep trough in Baffin Bay. They wintered on the eastern slope of the deep trough, together with narwhals that summered on the Greenland side of Baffin Bay.

With the ten animals tracked, we could not document an exchange with narwhals on other summering grounds (e.g., Admiralty Inlet or the eastern coast of Baffin Island) during August. Such an exchange may take place for some animals, in some years, earlier in the season, or between years (i.e., whales could visit different summering grounds in different years). Within the Bylot Island area, our whales seemed to be moving freely among the fjords known to be inhabited by narwhals in summer, so they apparently belong to a common stock. This may also be true of the narwhals in Pond Inlet in September.

During the summering period and the autumn southbound migration, the narwhals visited only 16% of the available fjords. The southbound migrating narwhals used a rather narrow corridor and a specific timing, either traveling along the coast between the few selected fjords or taking an offshore route along the slope of the Baffin Island continental shelf in water 1000–1500 m deep. The tagged animals did not visit the deepest part of Baffin Bay (> 2000 m deep) within the monitored period.

When on the wintering grounds, the narwhals made shorter trips within a restricted area along the north-south oriented slope of the Greenland continental shelf, the same area used by narwhals from Greenland.

These data suggest that some population structure may persist among Baffin Bay narwhals, with specific habitats for summering and wintering grounds and migrations that are well defined both spatially and temporally. In view of these restricted movements and the limited home range during stationary periods, the impact of harvest practices, competing fisheries, and habitat changes should be reviewed.

The mating season of narwhals is uncertain, but likely falls between May and July (Dietz et al., 1994). We have so far no tracking data from that period, but catch and survey data suggest that the narwhals are either still on their wintering grounds or moving towards their summering areas in those months. Large concentrations of narwhals are known to occur at fast-ice edges in both Greenland and Canada, just before the whales move into the summering areas, and this may allow opportunities for mating by animals from different areas. No thorough attempt has been made to investigate genetic differences between whales that use different summering habitats in Canada. Palsbøll et al. (1997) examined 427 narwhals, sampled in five regions, for mtDNA, but only 29 of these were from Canadian waters. The low nucleotide diversity and low number of Canadian samples did not permit internal Canadian comparisons, and no differences were found between the pooled Canadian sample and samples from the Avanersuaq district. However, the homogeneity tests identified five "entities": northern Baffin Bay, Melville Bay and Upernavik, Uummannaq, the 1994 "Sassat" at Kitsissuarsuit, and eastern Greenland (Palsbøll et al., 1997).

Independent of the question of genetic exchange, it is also important to know whether the whales return to the same summering grounds year after year, whether the site fidelity is equally strong for both sexes, and whether narwhals have the ability to re-inhabit localities that are locally depleted.

Performance of the Transmitters

For backpack transmitters, the average attachment period of 43 days for the two years was slightly longer than that obtained from five backpacks deployed on narwhals in Greenland waters in 1993–94, for which the average longevity was 38 days (range: 25–44 days; Dietz and Heide-Jørgensen, 1995). Two first-generation transmitters and three second-generation transmitters were used in the Greenland study. No statistical difference (unpaired t-test) on longevity, location classes, or number of uplinks could be found between first- and second-generation transmitters during the four years of investigation. The fourth-generation transmitter used in the present study certainly showed a considerable improvement on all measured categories; however, with a single unit, sample size was inadequate for a meaningful statistical comparison to previous transmitter generations.

The backpack transmitter longevity of the present study was longer than that for similar mountings on narwhals in Tremblay Sound in 1991 and at Svalbard in 1998 (Martin et al., 1994; Lydersen et al., 1999), but shorter than that for transmitters mounted on belugas (Richard et al., 1998, 2001; Lydersen et al., 1999). The larger dorsal ridge of the belugas—and possibly a stronger epidermis—can explain this difference.

For tusk-mounted transmitters, the average number of days providing good positions (57) in the Canadian study was similar to the average from the Greenland study (64 days; Dietz and Heide-Jørgensen, 1995). Only the transmitter on #20162 in the Canadian study lasted longer (162 days) than the longest-lasting tusk transmitters in the Greenland study, which provided good-quality positions for 87 days in 1993 and 100 days in 1994 (Dietz and Heide-Jørgensen, 1995). No significant differences (unpaired T-test) were found in the longevity, location classes, or number of uplinks between the first tusk-mounted generation used in Melville Bay in 1993 and generations 2 and 3,

used in Melville Bay in 1994 and in Tremblay Sound in 1997 and 1998. This result was due to the small total number (N = 10) in the comparison and to three short-performing transmitters in Tremblay Sound in 1997 and 1998.

Three tusk-mounted units in the Canadian study transmitted for 6, 7, and 31 days: less time than the shortest-performing tusk-mounted transmitter (32 days) in the Greenland study. It remains uncertain why these three Canadian transmitters stopped prematurely. Three of the four transmitters mounted in Greenland terminated because of battery drainage, which was monitored from status messages monitored every 15th uplink (Dietz and Heide-Jørgensen, 1995). None of the transmitters mounted on narwhals in Canada terminated because of battery failure.

In general, the narwhal tusk must be regarded as an ideal substratum for attachment compared to skin penetration. Brear et al. (1993) and Currey et al. (1994), who analyzed the mechanical properties of the narwhal tusk in detail, concluded that the tusk tissues are of low stiffness but very tough, suiting the tusk for loading on impact. The longest-lasting transmitter was on a male narwhal tagged during the Dietz and Heide-Jorgensen study. This transmitter provided scattered uplinks for more than 18 months, indicating that tusks have the potential for long-term attachment. However, the short performances of tusk-mounted transmitters indicate that tusk surface structure and variability of the stainless steel band tension may also produce short-term data series with even shorter longevity than the backpack transmitters.

The termination during winter of the longest-lasting tusk transmitters is likely to be caused by the severe ice conditions that narwhals inhabit at this time of the year. One possibility could be breakage of the antennae, as found on a retrieved walrus transmitter in 2000 in East Greenland (E. Born, pers. comm. 2000). To what extent the ice may cause loosening of the attachment or malfunction of the electronics still remains unknown.

ACKNOWLEDGEMENTS

Four Inuit hunters, Joanie Mucktar, Enookee Killiktee, Joshua Idlout, and Simon Qamarnirq, participated in the capturing and handling of the narwhals over the two years. Sylvain de Guise, Stephane Lair, Hans Christian Schmidt, Eydfinnur Steffanson, and Mehdi Bakhtiari were also part of the tagging teams. The Greenland Institute of Natural Resources, the National Environmental Research Institute, the Department of Fisheries and Oceans, the Nunavut Wildlife Management Board, the Commission for Scientific Research in Greenland, and the Arctic Environmental Program under the Danish Ministry of Environment funded the studies. The Polar Continental Shelf Project supplied logistical support for the fieldwork.

Questions and Responses from June and October Community Information Sessions

TGS NOPEC Geophysical Company ASA, Petroleum GeoServices and Multi Klient Invest AS

Northeastern Canada 2D Seismic Exploration Survey

November 2012

Introduction

This document has been prepared to share information and to continue communication with the communities of Kimmirut, Iqaluit, Pangnirtung, Qikiqtarjuaq, Clyde River and Pond Inlet. The questions in this document were asked in information sessions held in the communities in June and October 2012. Some of the responses were provided during the community sessions, however a few required additional research. All responses are included in this document.

All sources referenced throughout the report will be available at the hamlet office, or provided by email, upon request.

The questions and responses have been grouped into three subject areas:

- The Proposed Project
- Marine Mammals
- Seismic Surveys

The Proposed Project

Question: Who are you? What is the company that is doing this?
Response: We work for a company called NEXUS Coastal Resource Management. Our company was hired by Multi Klient Invest to facilitate dialogue with the communities. Multi Klient Invest AS is the company that will be operating and conducting the proposed 2D Seismic Survey.

Question: How far (depth) is it from the air gun to the ocean floor?
Response: The distance between the air gun and the ocean floor depends on the ocean bathymetry. The project map illustrates the bathymetry of Baffin Bay and Davis Strait. Bathymetry tells us how far away the ocean floor is from the surface. Since the air gun will be relatively near the surface of water (approximately 9 metres, or 27 feet), we can use the bathymetry to tell us how far the air gun will be from the surface. On this map, the darker the colour, going from light purple to dark blue, the further the ocean floor is from the surface. In some areas (dark blue), the air gun will be as far as 5km, roughly 15,000 feet or as close as 500 metres, which is roughly 1500 feet from the ocean floor.

Question: How long will the project take to complete?
Response: The proposed project could be over a span of five years, based on the results of the first year. The survey vessel will only be in operation during the ice-free months.

Question: How much impact will it (the proposed project) have?
Response: The design of the 2D seismic survey includes mitigation measures to lessen the project's impact on the environment. These mitigation measures include a 20 minute ramp up procedure, marine mammal observers, fisheries liaison officers, pollution prevention protocols, and communicating with communities. Past projects have shown that 2D seismic surveys have caused little to no effect to the marine environment.

Question: If and when something goes wrong on the project, is the company held accountable? How?
Response: The Project Proponents are committed to protecting the environment. There are protocols in place to prevent and clean up environmental damage caused by a vessel. These protocols follow international standards and regulations. The Arctic Shipping Pollution Prevention Act (ASPPA) and the Arctic Shipping Pollution Prevention Regulators (ASPPR) develop the protocols for having a vessel in Arctic waters. In addition, the vessel will have contingency plans and safety management systems on board. Also, the vessel will avoid areas of ice, as the survey cannot be completed near ice. This will reduce the chance of collision with an iceberg or ice floe.

Question: Was it the company's strategy to do this last minute so not many people would show up to the meeting?
Response: No, as was explained during the sessions, and in prior communications with the Hamlet, this information session is the first step of the engagement process. It was not the company's intention to have the meeting at the last minute. The purpose of this meeting is to explain the project and to gather community members' questions, concerns and suggestions and bring those questions, concerns and suggestions to the company. Communication with your community will continue. This can be in the form of further meetings, newspaper ads, posters, radio announcements, mail and email. Due to feedback about the meeting time, all future meetings will take into consideration that this is not an ideal time for public meetings.

Question: What happens with the information? Who has access?
Response: The information collected from the 2D seismic survey will be collected and held by the Project Proponent.

Question: What if they notice a lot of algae in the water during the survey? What will happen? Will the survey stop?
Response: This has been researched in the past. Studies have shown that algae are not negatively affected by the sound produced from 2D Seismic Surveys. The survey will not stop.

Question: This information is for the benefit of an oil company? For oil exploration, correct?
Response: The data and information documented throughout the survey can be used in a number of ways. In addition to learning about what's below the ocean floor, information about whales, fish, and the marine environment will be collected. The information collected may influence decisions that are made in the community. For example, we can further our understanding about whale migratory paths. The information collected about what's below the ocean floor is property of the Project Proponent and as such, they can sell that information to other companies.

Question: What type of benefit could a seismic test have (to residents)?
Response: There will be opportunities for residents to work on the project. As we have discussed, Marine Mammal Observers and Fisheries Liaison Officers will be hired from Nunavut. Community members that are trained to be Marine Mammal Observers and Fisheries Liaison Officers will bring new skills and knowledge back to Nunavut.

Question: What will the negative impacts be (from the project)?
Response: The potential impacts from the project may vary but a number of mitigation measures will be implemented to avoid or diminish these impacts. Possible effects of the project

on whales include short term behavioural changes and temporary hearing loss. As we have mentioned, the Project Proponents will be taking precautionary steps to avoid the possible negative effect of the project. These measures include following the 'Canadian Statement of Practice with respect to the Mitigation of Seismic Sound in the Marine Environment', having a Fisheries Liaison Officer to communicate with the fishery, and following the protocols put in place by Arctic Shipping Pollution Prevention Act (ASPPA), safety management systems, contingency plans, and the Arctic Shipping Pollution Prevention Regulators (ASPPR).

Question: Is this not the same project as the other seismic survey in Lancaster Sound that got stopped in 2010?
Response: No, this is not the Lancaster Sound project from 2010. This is a different project in a different area that is funded and operated by a different company.

Question: Will I have a say?
Response: Yes, that is why we are here. We are here on behalf of the Project Proponents to discuss the project with your community and to document your questions, concerns and ideas about this project. The Project Proponents would like to work with communities to so that the project can be mutually beneficial.

Question: What is the research for?
Answer: The research is to better understand the ocean floor for potential resource development

Question: Who is funding the project?
Answer: Multi Klient Invest is funding this project. They are wholly owned subsidiary of Petroleum GeoServices.

Question: Who is buying the data collected?
Answer: At this point in time no one has purchased the data collected. However, potential buyers of such information may include commercial fishery organizations, the Government and industry.

Marine Mammals

Question: Will the sound impact marine mammal migration?
Response: Sound generated by humans has been shown to impact some marine mammal migration. Determining the nature of the impact is a complex subject and depends on a variety of factors including: species, sex, age, presence of offspring, prior experience, time of year, location of the survey, and many others.

Bowhead whales have been shown to alter their migratory route by twenty to thirty kilometers in order to avoid the noise from seismic testing (Richardson, Miller & Greene, 1999). Humpback whales, gray whales and harbour porpoises have shown similar changes in behaviour, while some other species, such as sperm whales, have been shown to be far less deterred by the noise (Weilgart, 2007). However, summering bowheads showed no detectable avoidance of seismic surveys, no change in general activities or call activities (Richardson et al., 2007 in Weilgart, 2007).

While whales seem to generally avoid seismic noise, it has also been shown that some species, such as the humpback whale, will return to follow their normal migration route once they have passed the area of disturbance (McCauley et al. 2000). Determining the effect of man-made noise on migrating marine mammals remains highly uncertain.

Question: Is there research from Greenland that says if whales were harmed?
Response: Currently there are no scientific studies from Greenland looking at the effect of recent seismic survey activity on whales. This year a study was released providing insight into the seasonal presence of background noise in the North Atlantic (Klink et al, 2012). Observed seasonal variations in background noise levels were caused by human activities (seismic surveys, commercial shipping), ocean surface wind and whales communicating. The study did not determine if a seismic survey affected blue, fin and sperm whales. However, sounds from blue, fin and sperm whales were recorded seasonally at both study locations (Klink et al, 2012).

The National Environmental Research Institute of Denmark has also released guidelines for Environmental Impact Assessments in Greenland (Boertmann et al, 2009), which lists beluga, narwhal and bowhead whales, as well as walrus, as species particularly sensitive to seismic surveys (p.22).

Question: Is there an impact on hearing to whales and seals?
Response: It is difficult to know if an animal is negatively impacted as a result of this project. It is not ethical to capture marine mammals and subject them to testing in captivity. The available information on the impact of man-made noise to marine mammals and seals have been from modeling and direct observations during seismic surveys. Several papers have used models to predict the impact of sound intensity, measured in decibels (dB), on the hearing of marine mammals. The 'Canadian Statement of Practice on the Mitigation of Seismic Noise in the Marine Environment' states that at 500m, or 1500 feet, the sound intensity is at a level where no permanent damage would occur to marine mammals (based on what is known about marine mammals).

Question: Will the narwhal conservation area be bothered after this project is completed?
Response: No survey activity will occur within the narwhal conservation area and proposed seismic survey activity surrounding the conservation area is minimal. However, to mitigate any potential effects of the project on narwhal and other marine mammals during the proposed project, the proposed project will adhere to the 'Canadian Statement of Practice on the Mitigation of Seismic Noise in the Marine Environment'. If additional projects were to occur after this proposed 2D Seismic Survey, then Environmental Assessments would need to be completed for each project.

Question: Will the survey impact narwhal?
Response: The potential impacts, if any, on narwhal and other marine mammals will vary. These impacts may include behavioral changes, loss of hearing and the potential for death (if a marine mammal is directly underneath the sound source). However, to our knowledge, no marine mammal deaths have been directly linked to seismic surveys. The effect of seismic surveys on marine mammals will vary depending on the species and individuals within a species.

To limit the potential effect of the proposed project on narwhal and other marine mammals, the project proponent will implement mitigation measures. These mitigation measures include a 20-

minute ramp up procedure, marine mammal observers and passive acoustic monitoring. In addition, the proposed project will adhere to the 'Canadian Statement of Practice on the Mitigation of Seismic Noise in the Marine Environment'.

Question: How can you determine if you have harmed a marine mammal?
Response: In the marine environment, it is difficult to determine if a project has an effect on marine mammals as marine mammals are constantly moving and there are other factors in the environment that can affect marine mammals. These other factors can include ships, earthquakes, and icebergs breaking apart. To limit the potential effect of this project on marine mammals, the project will follow the 'Canadian Statement of Practice with respect to the Mitigation of Seismic Sound in the Marine Environment'.

Question: How would you know that whales are there if they are under water?
Response: Some surveys use passive acoustic monitoring, which will allow the vessel to listen for the whales under water. Passive acoustic monitoring is a technique used to listen for whales under the water. A hydrophone, which is an underwater microphone, is placed in the water and people listen to the hydrophone for sounds that whales make. Passive acoustic monitoring is being researched as a possible option for this project

In addition, there will be Marine Mammal Observers on board the survey vessel looking for whales at the surface of the water.

Question: What will happen if the animals are negatively impacted?
Response: It is difficult to know if an animal is negatively impacted as a result of this project. As we have mentioned, the project will follow the "Canadian Statement of Practice with respect to the Mitigation of Seismic Sound in the Marine Environment". The Canadian Statement of Practice was developed to lessen the potential for seismic survey to effect the marine environment.

Seismic Surveys

Question: If I were beside the air gun in the water would I survive?
Response: Determining the effects of a seismic blast on living creatures is a complex task which is not well understood. This is due to the difference in characteristics of sound in air versus water, different methods of measuring sound intensity and the range of frequencies which are able to be heard by a given creature (Cummings, 2003). While it is not possible to say for certain if a person could survive the blast from an air gun, they would certainly experience negative effects. One report suggests that the lethal zone for marine mammals from a large seismic air gun array is 7 meters (approximately 21 feet) (Parvin, Nedwell & Harland, 2007). Despite the lack of conclusive scientific evidence, the blasts from air guns are still considered "potentially lethal" (Popper and Hastings, 2009). Organisms close to the blast risk organ damage from the potential rupture of gas-filled cavities, such as the lungs or ears (Weilgart, 2007).

Question: Have there been any differences in the sand/mud or microorganisms on the ocean floor from seismic surveys?
Response: Studies have shown that algae and other microorganisms are not negatively affected by the sound produced from 2D seismic surveys.

Question: How far is the after affect going to carry?
Answer: Sound travels further in the water than in the air. Noise from other boats, and natural phenomenon, like earthquakes can be heard throughout the oceans. This constant background noise is present throughout the oceans and whales have begun to adapt to this noise by communicating in higher frequencies.

The effect of the seismic survey in a distance, will contribute to this background noise, but only for a short period of time. It is impossible to determine how far such as 100km or 1000km the sound from the project will travel and be distinguishable from other noises in the environment.

Question: How far does the sound travel under water?
Answer: The sound source will be pointed at the bottom of the ocean. However, there will be some sound that travels outwards from the sound source and sound will bounce off the ocean floor to be reflected back to the survey equipment.

Sound travels further under water than in the air. Noise from other boats and natural occurrences like earthquakes can be heard throughout the oceans. This constant background noise is present throughout the oceans and whales have begun to adapt to this noise by communicating in higher frequencies. It would be difficult to determine how far outwards from the sound source that the sound will travel.

Introduction

1. This section of the **FAO Yearbook of fishery and aquaculture statistics** presents the annual statistics, for a varying series of recent years ending in 2010, on a worldwide basis, on nominal catches of fish, crustaceans, molluscs and other aquatic animals, residues and plants, taken for all purposes (commercial, industrial, recreational and subsistence) by all types and classes of fishing units (fishermen, vessels, gear, etc.) operating both in inland, fresh and brackish water areas, and in inshore, offshore and high seas fishing areas. Beginning with Volume 82 statistics for mariculture, aquaculture and other kinds of fish farming, are excluded from all national, regional and global totals. **Beginning with Volume 90/1, the names and species composition of some groups of the FAO International Standard Statistical Classification of Aquatic Animals and Plants (ISSCAAP) have been revised. See paragraph 3 of the NOTES ON SPECIES ITEMS.**

2. The annual period used is the calendar year (1 January-31 December), with the exceptions of capture data in the Antarctic fishing areas and for some countries, mentioned in the NOTES ON INDIVIDUAL COUNTRIES OR AREAS, for which a split-year is used. Since Volume 94/1, the new fishing season (1 December–30 November) of the Commission for the Conservation of Antarctic Marine Living Resources (CCAMLR) has been adopted. Split-year data are shown under the calendar year in which the split-year ends.

3. Catches are expressed in tonnes, except those for whales, seals and crocodiles which are given in numbers and corals, pearls and sponges which are given in kilograms.

4. Beginning with Volume 48 data on aquatic mammals (tables B-61, B-62 and B-63 expressed in numbers and B-64) and data on aquatic plants (A-6, B-91, B-92, B-93 and B-94) are excluded from all national, regional and global totals. For practice prior to Volume 48, see notes in respective Yearbook. Beginning with Volume 60, data on corals, expressed in kilograms given in table B-82 are also excluded from all national, regional and global totals. Beginning with Volume 62 data on pearls, expressed in kilograms in table B-81 and sponges expressed in kilograms in table B-83 are likewise excluded. Beginning with Volume 66 data on crocodiles expressed in numbers in table B-73 are excluded from all national, regional and global totals.

5. FAO has completed the separation of the aquaculture time series from the capture production time series dating back to 1950. This separation was based on national reporting, when available, and other sources of historical information.

6. Where necessary the data for 1950-2009 published in the preceding issues of the Yearbook of fishery and aquaculture statistics have been revised. Where figures in this issue differ from those previously published, the amended data represent the most recent version. Some statistics provided to FAO by national offices, in particular those for 2010, are provisional and may be amended in future editions, and in other FAO publications.

Introduction

Dans cette section de l'**Annuaire statistique des pêches et de l'aquaculture** figurent, pour diverses périodes récentes prenant fin en 2010, les statistiques établies sur une base mondiale des captures nominales de poissons, crustacés, mollusques et autres animaux aquatiques, résidus et plantes aquatiques, effectuées à toutes fins (commerciales, industrielles, récréatives et de subsistance) par tous les types et catégories d'unités de pêche (pêcheurs, bateaux, engins, etc.) opérant tant dans les eaux continentales, douces et saumâtres, que dans les zones de pêche du littoral, du large et de la haute mer. À partir du Volume 82, les statistiques ayant trait à la mariculture, à l'aquaculture et à d'autres types de pisciculture, sont exclues de toutes les données au niveau national, régional et global. **À partir du Volume 90/1, les dénominations et la composition par espèces de quelques groupes de la Classification statistique internationale type des animaux et des plantes aquatiques (CSITAPA) de la FAO ont subi des révisions. Voir le paragraphe 3 des NOTES SUR LES CATÉGORIES D'ESPÈCES.**

La période annuelle utilisée est l'année civile (1er janvier-31 décembre), sauf pour les données relatives aux captures effectuées dans les zones maritimes de l'Antarctique et pour quelques pays, mentionnés dans les NOTES SUR DIVERS PAYS OU ZONES, pour lesquels on utilise l'année fractionnée. À partir du volume 94/1 on utilise la nouvelle période de pêche (1er décembre-30 novembre) de la Commission pour la conservation de la faune et la flore marines de l'Antarctique (CCAMLR). Les données relatives aux années fractionnées figurent sous l'année civile durant laquelle se termine l'année fractionnée.

Les captures débarquées sont exprimées en tonnes, à l'exception des données relatives aux baleines, phoques et crocodiles qui sont indiquées numériquement et les données sur les coraux, les perles et les éponges qui sont indiquées en kilogrammes.

A partir du volume 48, les données sur les mammifères aquatiques (tableaux B-61, B-62 et B-63 exprimées en nombres et B-64) et les données sur les plantes aquatiques (A-6, B-91, B-92, B-93 et B-94) sont exclues de tous les totaux au niveau national, régional et global. Pour la méthode suivie avant le volume 48, se reporter aux notes de l'Annuaire en question. A partir du volume 60, les données sur les coraux exprimées en kilogrammes indiquées au tableau B-82 sont également exclues de tous les totaux au niveau national, régional et global. A partir du volume 62, les données sur les perles exprimées en kilogrammes indiquées au tableau B-81, et sur les éponges exprimées en kilogrammes indiquées au tableau B-83 sont, de même, exclues. A partir du volume 66, les données sur les crocodiles exprimées en nombre au tableau B-73 sont exclues de tous les totaux au niveau national, régional et global.

La FAO a complété la séparation des séries de production en aquaculture et capture à partir de 1950. Cette séparation a été basée sur des reportages nationaux, si disponibles, et d' autres sources d' information historique.

Le cas échéant, les données relatives aux années 1950-2009 publiées dans les éditions précédents de l'Annuaire statistique des pêches et de l'aquaculture ont été révisées. Lorsque les chiffres indiqués dans l'édition présente diffèrent de ceux déjà publiés, les données modifiées représentent la version la plus récente. Certaines statistiques communiquées à la FAO par les services nationaux sont provisoires, notamment pour 2010, et pourront être modifiées dans les éditions futures ainsi que dans d'autres publications de la FAO.

Introducción

En esta sección del **Anuario estadístico de pesca y acuicultura** se presentan las estadísticas mundiales, para diversas series de los últimos años que terminan en 2010, de las capturas nominales de peces, crustáceos, moluscos y demás animales, residuos y plantas acuáticos, hechas con cualquier fin (comercial, industrial, recreativo y de subsistencia), por unidades de pesca de todos los tipos y categorías (pescadores, barcos, artes, etc.) en aguas continentales, dulces y salobres y en áreas de pesca de bajura, media altura o altura. A partir del volumen 82 las estadísticas correspondientes a maricultura, acuicultura y otros tipos de pisicultura, están excluidas de las cantidades a nivel nacional, regional y global. **A partir del volumen 90/1, las denominaciones y la composición por especies de algunos de los grupos de especies de la Clasificación Estadística Internacional Uniforme de los Animales y Plantas Acuáticos (CEIUAPA) de la FAO fueron revisados. Véase el párrafo 3 en las NOTAS SOBRE LAS PARTIDAS DE ESPECIES.**

El período anual utilizado es el año civil (1 de enero-31 de diciembre), excepto en el caso de las capturas efectuadas en las áreas marítimas del Antártico y para algunos países, mencionados en las NOTAS SOBRE LOS DISTINTOS PAÍSES O ÁREAS, para los que se utiliza el año emergente. Desde el volumen 94/1 se utiliza el nuevo período de pesca (1 de diciembre-30 de noviembre) de la Comisión para la Conservación de los Recursos Vivos Marinos Antárticos (CCRVMA). Los datos correspondientes a los años emergentes se incluyen en el año civil en que termina el año emergente.

Las capturas se expresan en toneladas, excepto en el caso de ballenas, focas y cocodrilos que se dan en número y en el caso de corales, perlas y esponjas que se dan en kilogramos.

A partir del volumen 48 los datos relativos a los mamíferos acuáticos (cuadros B-61, B-62 y B-63 expresados en números y B-64) y los datos relativos a las plantas acuáticas (A-6, B-91, B-92, B-93 y B-94) están excluidos de las cantidades totales a nivel nacional, regional y global. Con respecto a la práctica seguida antes del volumen 48, véanse las notas en el Anuario respectivo. A partir del volumen 60 los datos relativos a los corales expresados en kilogramos que aparecen en el cuadro B-82 están también todos excluidos de las cantidades totales a nivel nacional, regional y global. A partir del volumen 62 los datos relativos a las perlas expresados en kilogramos que aparecen en el cuadro B-81 y a las esponjas expresados en kilogramos que aparecen en el cuadro B-83 están igualmente excluidos. A partir del volumen 66 los datos relativos a los cocodrilos, expresados en números, en el cuadro B-73 están excluidos de las cantidades totales a nivel nacional, regional y global.

La FAO ha completado la separación de las series cronológicas de acuicultura y de producción de captura a partir de 1950. Esta separación se basó en los informes nacionales, cuando eran disponibles, y en otras fuentes de información histórica.

Siempre que ha sido necesario se han revisado los datos correspondientes a 1950-2009 publicados en las ediciones anteriores del Anuario estadístico de pesca y acuicultura. Cuando las cifras que aparecen en esta edición difieren de las publicadas anteriormente, los nuevos datos representan la última versión disponible. Algunas estadísticas facilitadas a la FAO por las oficinas nacionales, en particular las correspondientes a 2010, son provisionales y podrán modificarse en ediciones futuras y en otras publicaciones de la FAO.

Introduction

7. National focal points for fishery statistics, in particular those of countries fishing in more than one major fishing area, report their annual catches to various fishery commissions, as well as to FAO. To eliminate duplication in requests to these national offices, FAO cooperates with regional fishery bodies, particularly through the Coordinating Working Party on Fishery Statistics (CWP), to standardize reporting forms, procedures, definitions, classifications and other related documentation. This system reduces discrepancies between the figures appearing in the Yearbook of Fishery Statistics and those published in the bulletins issued by the commissions. Some discrepancies may still exist, but effort is constantly being made to eliminate them.

8. For the time being, the flag of the vessel is used to assign its nationality unless the wording of chartering and joint operation contracts indicates otherwise.

9. To facilitate use of the Yearbook, a series of notes and lists are included.

10. As usual, government officers and staff of international organizations have made possible the timely publication of this Yearbook by their prompt attention to our requests, and the care they devoted to checking material submitted to them. FAO expresses its thanks to them and welcomes the support of national and international organizations, and of interested individuals, in improving the scope and accuracy of the Yearbook.

11. Great care is taken by FAO in ensuring as far as possible the quality of the data presented in this Yearbook, supplementing data reported by countries with information from other sources, where available, including regional fishery bodies, field projects and independent surveys, specialist literature and fishery-independent sources. However, the accuracy and reliability of world aggregations of fishery statistics ultimately depends upon the quality of national data sources, collection methods, periodicity of updating and reporting. Fishery data quality is known to be very uneven among countries. Although improvements to data quality are made by FAO on a continuing basis, it is clear that many more can be made. Any input from data users in this regard will be most welcome.

Introduction

Les centres nationaux des statistiques des pêches, notamment ceux des pays exploitant plus d'une principale zone de pêche, déclarent leurs captures annuelles aux diverses commissions des pêches, de même qu'à la FAO. Pour éviter que les demandes adressées à ces services nationaux ne fassent double emploi, la FAO coopère avec les organes régionaux des pêches, en particulier par l'entremise du Groupe de travail chargé de coordonner les statistiques des pêches (CWP), pour normaliser les formules de déclaration, les procédures, les définitions, les classifications et toute la documentation connexe. Ce système permet de réduire les divergences entre les chiffres figurant dans l'Annuaire statistique des pêches et ceux des bulletins publiés par les commissions. Certaines de ces divergences demeurent, mais on s'efforce toujours de les éliminer.

Pour le moment, le pavillon du navire est utilisé pour déterminer sa nationalité, à moins que le libellé des contrats d'affrètement et d'opérations conjointes ne l'indique autrement.

Pour faciliter l'emploi de l'Annuaire, on a introduit une série de notes et de listes.

Comme de coutume, c'est grâce à la rapidité et au soin avec lesquels les fonctionnaires des services publics et le personnel des organisations internationales ont répondu à nos demandes et vérifié les matériaux qui leur étaient soumis, que cet Annuaire a pu être publié en temps voulu. La FAO tient à les remercier et se félicite de l'aide que lui apportent les organisations tant nationales qu'internationales et les personnes intéressées, afin d'améliorer l'étendue et la précision de l'Annuaire.

La FAO essaie autant que possible, avec le plus grand soin, d'assurer la qualité des données présentées dans cet Annuaire, en complétant les données communiquées par les pays par des informations provenant d'autres sources telles que: organes régionaux des pêches, projets de terrain, enquêtes indépendantes, documents rédigés par des spécialistes et sources extérieures au secteur des pêches. Néanmoins, la précision et la fiabilité des agrégats mondiaux des statistiques des pêches dépendent en dernière analyse de la qualité des sources nationales de données, des méthodes de collecte, de la périodicité de leur mise à jour et de leur présentation. La qualité des données halieutiques peut être fort inégale d'un pays à l'autre. Même si la FAO s'engage à améliorer constamment la qualité des données, il ne fait pas de doute que nombre d'autres améliorations peuvent être apportées. Toute contribution des utilisateurs des données à cet égard sera la bienvenue.

Introducción

Los centros nacionales de estadísticas pesqueras, en particular los de aquellos países que pescan en más de una de las áreas principales de pesca, comunican sus datos sobre capturas anuales a las diversas comisiones de pesca y a la FAO. Para eliminar duplicaciones en la solicitud de datos a esas oficinas nacionales, la FAO colabora con los órganos regionales de pesca, particularmente mediante el Grupo Coordinador de Trabajo sobre Estadísticas de Pesca (CWP), para uniformar los formularios de comunicación de datos, y los procedimientos, definiciones, clasificaciones, etc. Esto permite además reducir las discrepancias entre las cifras que aparacen en el Anuario Estadístico de Pesca y las publicadas en los boletines preparados por las diversas comisiones. Pueden subsistir aún algunas discrepancias, pero siempre se intenta eliminarlas.

Por el momento, se entiende que el pabellón del barco determina su nacionalidad, a menos que en los contratos de fletes o de operación conjunta se indique otra cosa.

Para facilitar la consulta del Anuario se incluyen una serie de notas y listas.

Igual que en ocasiones anteriores, la pronta publicación de este Anuario ha sido posible gracias a la colaboración de funcionarios estatales y de organizaciones internacionales que han respondido con prontitud a nuestras peticiones y han controlado con atención el material que se les ha presentado. La FAO desea manifestar a todos ellos su reconocimiento y agradece ya desde ahora la ayuda que organizaciones nacionales e internacionales o personas privadas le presten para mejorar el alcance y exactitud de este Anuario.

La FAO presta gran atención a asegurar en la medida de lo posible la buena calidad de los datos que se presentan en este Anuario, complementando los datos comunicados por los países con información de otras procedencias, cuando se dispone, tales como los órganos regionales de pesca, los projectos de campo y encuestas independientes, bibliografía especializada y fuentes que no dependen de la pesca. Sin embargo, la exactitud y fiabilidad del acopio mundial de estadísticas de pesca se basan fundamentalmente en la calidad de las fuentes de datos nacionales, en los métodos de recopilación de los mismos, en la periodicidad de la actualización y la comunicación. Como se sabe, la calidad de los datos pesqueros nacionales puede variar mucho de un país a otro. Aunque la FAO está mejorando constantemente la calidad de los datos, es evidente que se puede mejorar todavía mucho. Cualquier aportación de los usuarios de los datos a este respecto será muy bien recibida.

Notes and lists

Notes et listes

Notas y listas

General notes

1. This section of the **Yearbook of fishery and aquaculture statistics** presents, for the most recent series of calendar years and split-years, annual statistics on NOMINAL CATCHES of freshwater, brackishwater and marine species of fish, crustaceans, molluscs and other aquatic animals and plants, killed, caught, trapped or collected for all commercial, industrial, recreational and subsistence purposes.

2. In view of the importance of recreational fishing regarding some stocks and for certain countries, and the difficulty of distinguishing in many cases between recreational and subsistence fishing (and in accordance with the recommendation of the 16th Session of the Coordinating Working Party on Fishery Statistics - CWP, Madrid, Spain, 20-25 March 1995), data should cover recreational fisheries. However, despite the importance of recreational fishing regarding some species and for certain countries, figures include recreational catches only where available.

3. The NOMINAL CATCHES concept refers to the landings converted to a *live weight* basis; the closely related concept LANDINGS refers to the quantities on a *landed weight* basis. In many fisheries the landed quantities (LANDINGS) are identical to the quantities caught (NOMINAL CATCHES).

4. There are many instances where the catches on board fishing vessels or factory ships are gutted, eviscerated, filleted, salted, dried, etc., or reduced to meals, oil, etc. The data on the LANDINGS of such species and products require conversion by accurate yield rates (conversion factors) to establish the live weight equivalents (nominal catches) at the time of their capture. See diagram on the following pages.

5. Many national statistical publications do not use the terms "landings" and "catches" with their precise meanings as described above. In such publications the term "catches" is used sometimes to refer to quantities on a landed weight basis, i.e. "landings" which might consist of gutted, eviscerated and filleted fish, as well as of meals and oils. However, only where the "primary production" (the phrase "primary production" is used in its economic and not in its biological sense) is landed whole is it correct to describe such landed quantities as "catches".

6. In some national statistics the following terms are in common use to refer to NOMINAL CATCHES, i.e. landings on a live weight basis:

   a) landings on a round, fresh basis;

   b) landings on a round, whole basis;

   c) landings on an ex-water weight basis.

7. For the "primary production" data on seaweeds, pearls, shells, corals, sponges, etc., it is preferable to use the term PRODUCTION which is more appropriate than NOMINAL CATCH. The term CATCH is also more suitable than NOMINAL CATCH in the case of whales and seals, where the "primary production" data for these species are not expressed in weight units but in numbers.

8. Data concerning the nominal catch of fish included within group 36 (tunas, bonitos and billfishes) are generally reviewed in collaboration with the regional agency concerned with tuna statistics (i.e. IATTC, ICCAT, IOTC, and WCPFC). Due to differences in the date by which these agencies require data to be submitted, figures for the most recent year are often subject to significant revision.

Notes générales

Dans cette section de l'**Annuaire statistique des pêches et de l'aquaculture** figurent, pour les plus récentes séries d'années civiles et d'années fractionnées, les statistiques annuelles des CAPTURES NOMINALES de poissons, crustacés, mollusques et autres animaux et plantes aquatiques d'eau douce, d'eau saumâtre et d'eau marine, tués, capturés, piégés ou ramassés à des fins commerciales, industrielles, récréative et de subsistance.

Étant donné que la pêche sportive a une grande incidence sur certains stocks et pour certains pays, qu'il est souvent difficile d'établir une distinction entre celle-ci et la pêche de subsistance (et en conformité avec la recommandation de la seizième session du Groupe de travail chargé de coordonner les statistiques de pêches - CWP, Madrid, Espagne, 20-25 mars 1995), les données doivent concerner la pêche sportive. Toutefois, malgré la grande incidence de la pêche récréative sur certaines espèces et pour certains pays, les chiffres indiqués comprennent les captures de la pêche récréative, seulement lorsque de telles données sont disponibles.

L'expression CAPTURES NOMINALES désigne l'équivalent en *poids vif* des quantités débarquées; l'expression, étroitement apparentée QUANTITÉS DÉBARQUÉES désigne le *poids mis à terre*. Dans de nombreuses pêcheries, les mises à terre (QUANTITÉS DÉBARQUÉES) sont identiques aux quantités capturées (CAPTURES NOMINALES).

Dans de nombreux cas, les captures sont vidées, éviscérées, filetées, salées, séchées, etc., ou réduites, en farine, en huile, etc., à bord des bateaux de pêche ou de navires-usines. Les données sur les QUANTITÉS DÉBARQUÉES de la sorte, à savoir après traitement, doivent être converties à l'aide de taux de rendement précis (coefficients de conversion) afin de déterminer les équivalents en poids vif (captures nominales) au moment de la prise. Voir le diagramme aux pages suivantes.

De nombreuses publications statistiques nationales n'emploient pas les expressions «quantités débarquées» et «captures» avec le sens précis indiqué ci-dessus. Le terme «captures» y sert parfois à désigner les quantités sur la base du poids mis à terre, c.-à-d. les «quantités débarquées» qui peuvent être des poissons vidés, éviscérés et filetés, ainsi que des farines et des huiles. Toutefois, c'est seulement lorsque la «production primaire» (au sens économique et non au sens biologique) est débarquée à l'état entier qu'il est correct de parler de «captures» pour ces mises à terre.

Dans certaines statistiques nationales, on utilise couramment les expressions suivantes pour désigner les CAPTURES NOMINALES, c.-à.-d. l'équivalent en poids vif des quantités débarquées:

a) quantités débarquées sur la base du poisson entier, frais;

b) quantités débarquées sur la base du poids du poisson entier;

c) quantités débarquées sur la base du poids du poisson à sa sortie de l'eau.

Pour les données sur la «production primaire» des algues, perles, coquillages, coraux, éponges, etc., il est préférable d'utiliser le terme PRODUCTION, qui est plus approprié que l'expression CAPTURES NOMINALES. Par ailleurs, le terme CAPTURES convient mieux que l'expression CAPTURES NOMINALES dans les cas des baleines et des phoques où la «production primaire» ne s'exprime pas en unités pondérales mais en nombres.

Les données concernant les captures nominales de poissons appartenant au groupe 36 (thonidés, bonites et marlins) sont en général révisées en collaboration avec l'organisation régionale chargée des statistiques des thonidés (CITT, CICTA, CTOI, et WCPFC). Comme les dates pour lesquelles ces organisations demandent les données ne correspondent pas toujours, les chiffres pour l'année la plus récente sont souvent sujets à des révisions significatives.

Notas generales

En esta sección del **Anuario estadístico de pesca y acuicultura** se presentan, para las más recientes series de años civiles y emergentes, estadísticas anuales de las CAPTURAS NOMINALES de especies de aguas dulces, salobres y marinas, de peces, crustáceos, moluscos y otros animales y plantas acuáticos, matados, capturados, entrampados o cobrados para todo fin de carácter comercial, industrial, pesca de recreo o de subsistencia.

Dada la importancia que la pesca de recreo tiene para algunas poblaciones de pescado y para ciertos países, y la dificultad de distinguir en muchos casos entre dicha pesca y la de subsistencia (y en conformidad con la recomendación de la decimosexta sesión del Grupo Coordinador de Trabajo sobre Estadísticas de Pesca - CWP, Madrid, España, 20-25 de marzo de 1995), los datos deberán incluir la pesca de recreo. Sin embargo, a pesar de la importancia que la pesca recreativa tiene para algunas especies de pescado y para ciertos países, las cifras incluyen las capturas de la pesca recreativa solamente cuando se hallan disponibles.

El concepto de CAPTURAS NOMINALES se refiere a los desembarques expresados en su *peso en vivo*; el concepto DESEMBARQUES íntimamente relacionado, se refiere al *peso descargado*. En muchas pesquerías las cantidades desembarcadas (DESEMBARQUES), son idénticas a las cantidades capturadas (CAPTURAS NOMINALES).

En muchos casos, las capturas a bordo de las embarcaciones de pesca o de los buques factoría se destripan, evisceran, filetean, salan, secan, etc., o se reducen en harina, en aceite, etc. Los datos sobre los DESEMBARQUES de estas especies y productos hay que convertirlos, mediante índices precisos de rendimiento (factores de conversión) para fijar su equivalente en peso en vivo (capturas nominales) en el momento de la captura. Véase el diagrama en las páginas siguientes.

Muchas publicaciones estadísticas nacionales no utilizan los términos «desembarques» y «capturas» con la significación precisa que se describe anteriormente. En tales publicaciones, el término «captura» se emplea algunas veces para referirse a cantidades basadas en el peso desembarcado, es decir «desembarques» que pueden consistir en pescado destripado, eviscerado y fileteado, así como en harinas y aceites. Sin embargo, sólo cuando la «producción primaria» (esta frase «producción primaria» se utiliza en su sentido económico y no en el biológico) se desembarca entera es correcto describir estas cantidades desembarcadas como «capturas».

En algunas estadísticas nacionales son de uso común las siguientes expresiones para referirse a las CAPTURAS NOMINALES, es decir, los desembarques expresados según su peso en vivo:

a) desembarques de pescado fresco, entero;

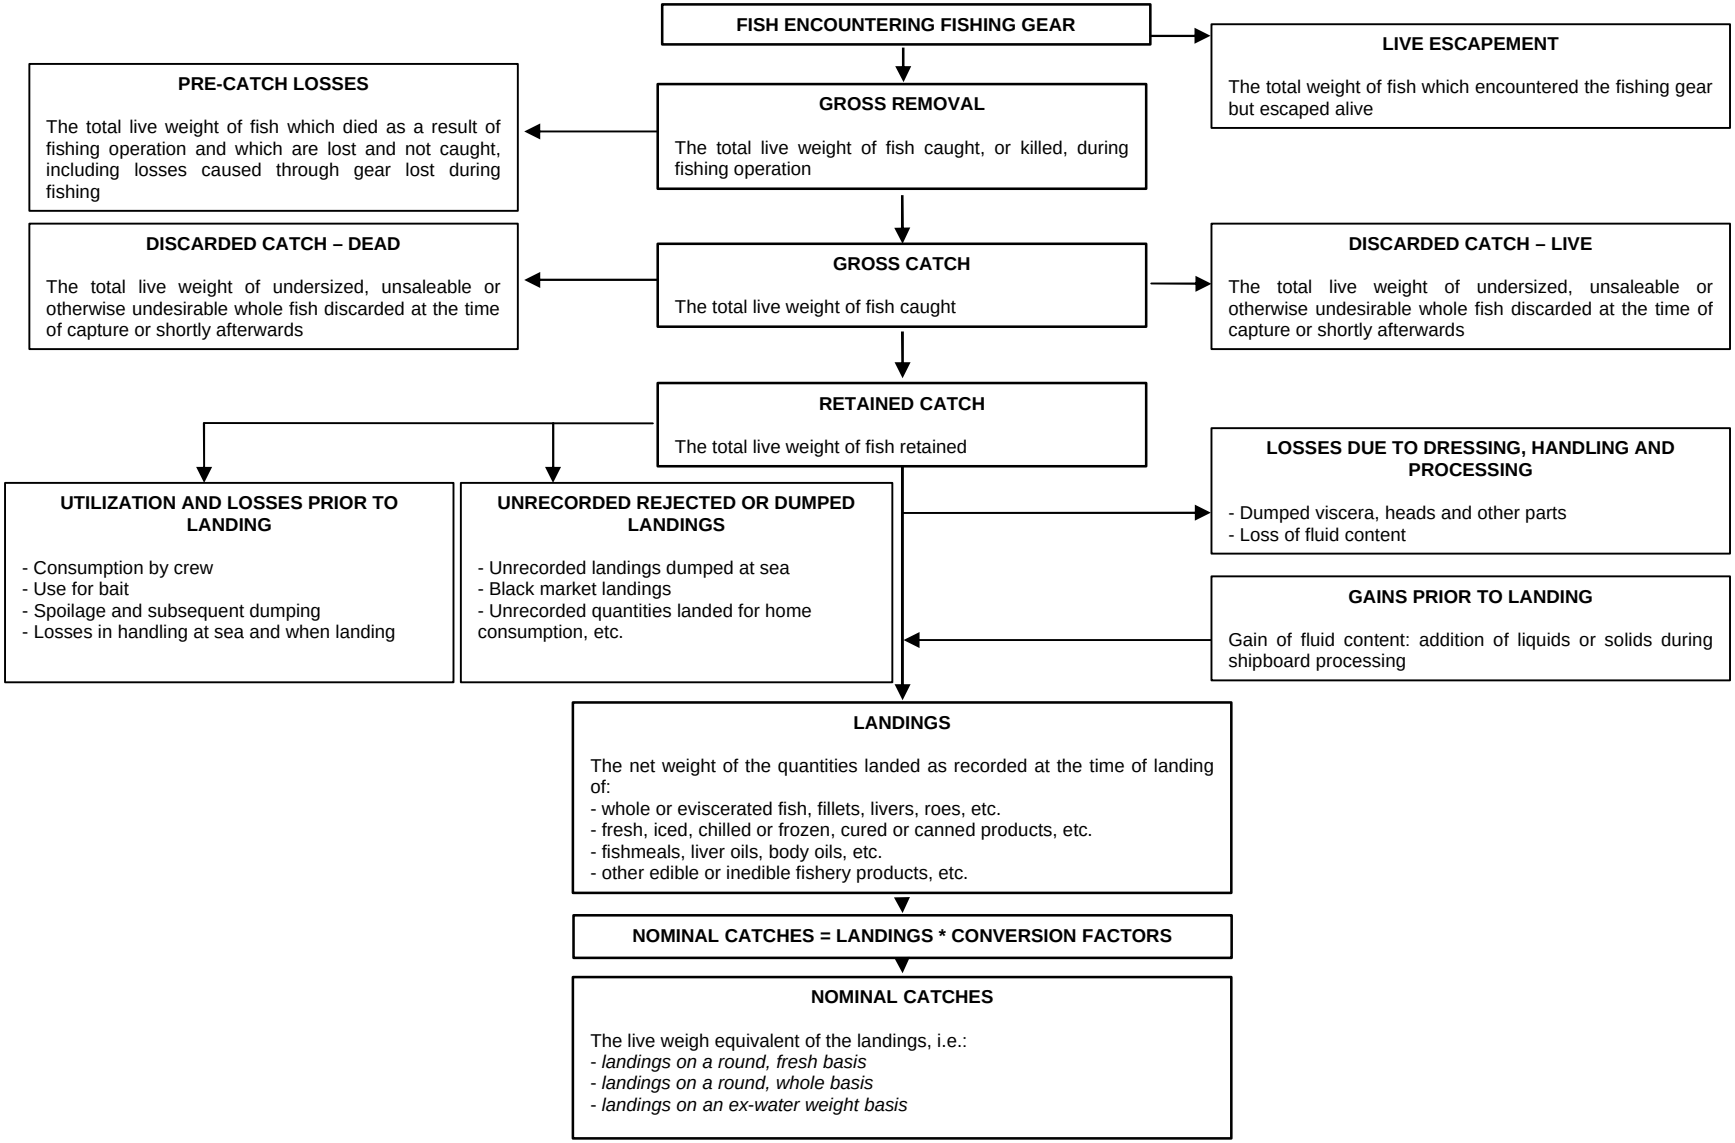
b) desembarques de pescado entero;

c) desembarques según el peso del pescado al sacarlo del agua.

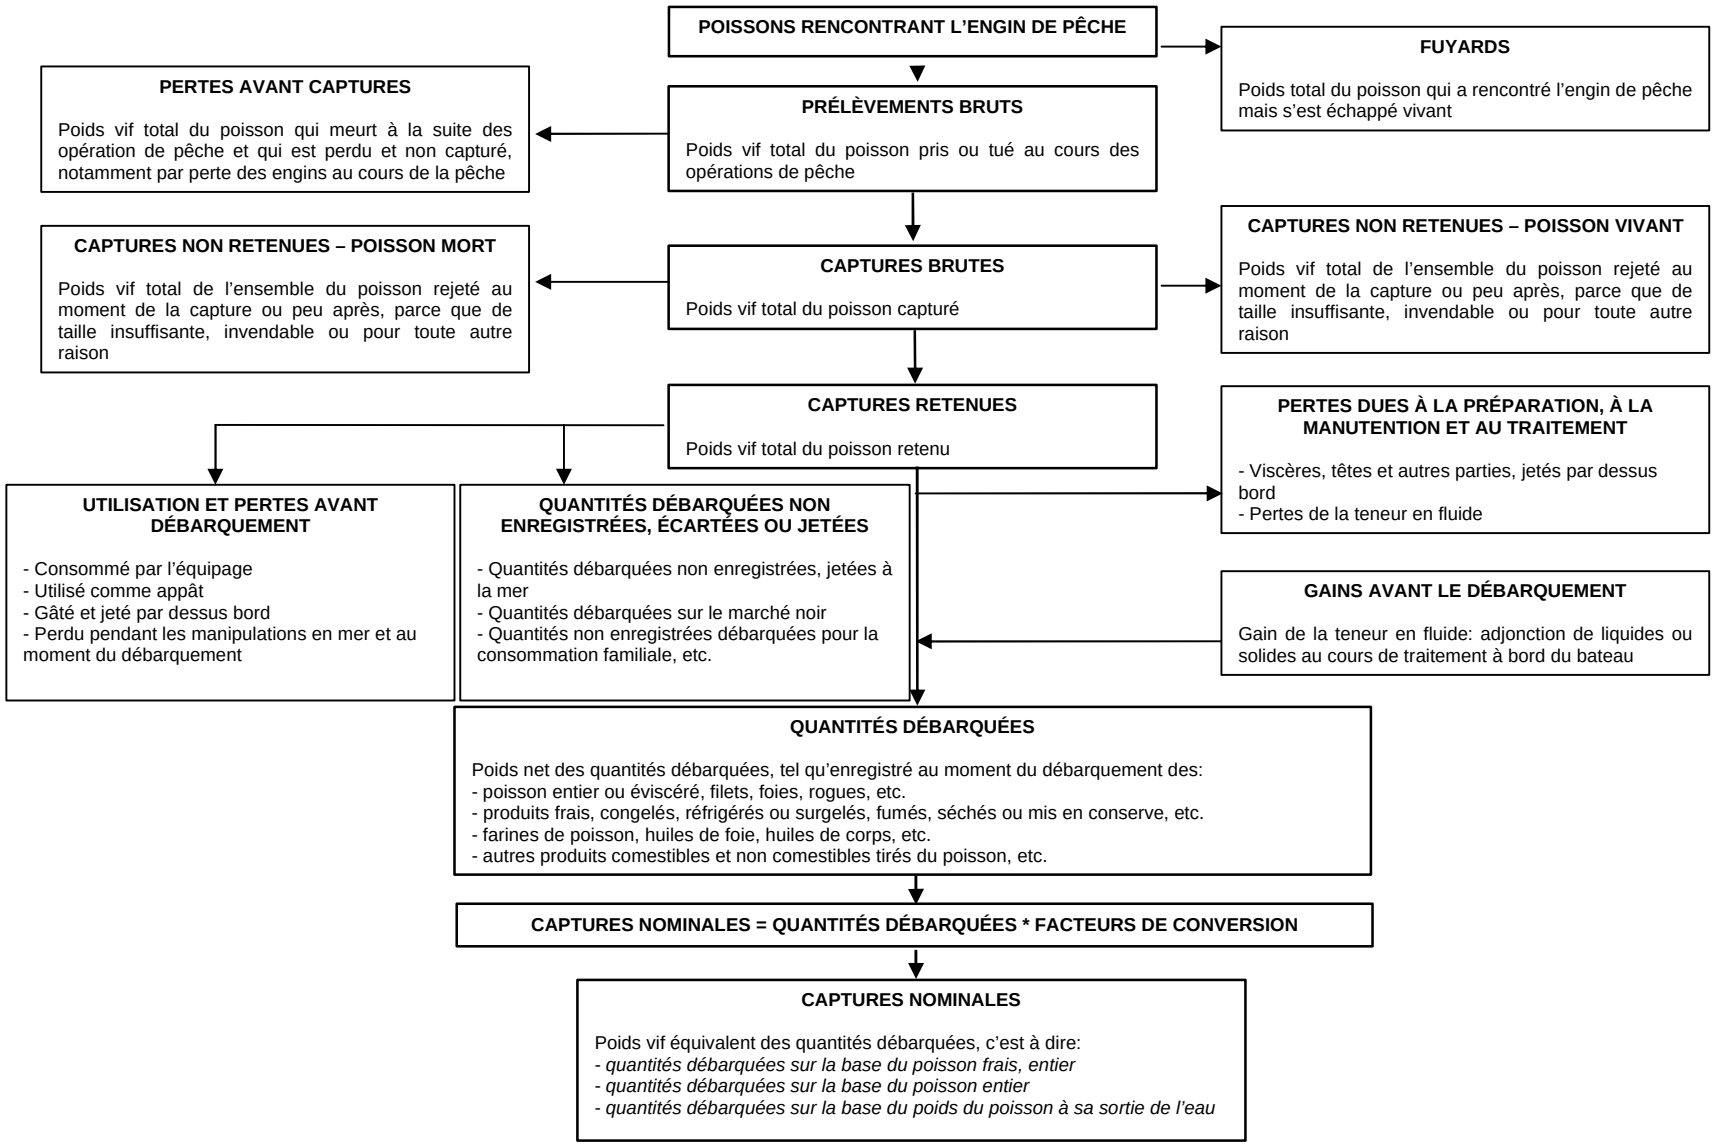
Para los datos de «producción primaria» de algas marinas, perlas, mariscos, corales, esponjas, etc., es preferible usar el término PRODUCCION, ya que es más apropiado que la expresión CAPTURA NOMINAL. El término CAPTURA también es más adecuado que la expresión CAPTURA NOMINAL en el caso de ballenas y focas donde los datos de «producción primaria» para estas especies no se expresan en unidades de peso sino en números.

Los datos relativos a la captura nominal de pescado incluido en el grupo 36 (atún, bonitos y agujas) se revisan generalmente en colaboración con los organismos regionales que se encargan de las estadísticas atuneras (CIAT, CICAA, CAOI, y WCPFC). Debido a las diferentes fechas en que esos organismos necesitan recibir los datos, es frecuente que las cifras correspondientes a los años más recientes se sometan a una considerable revisión.

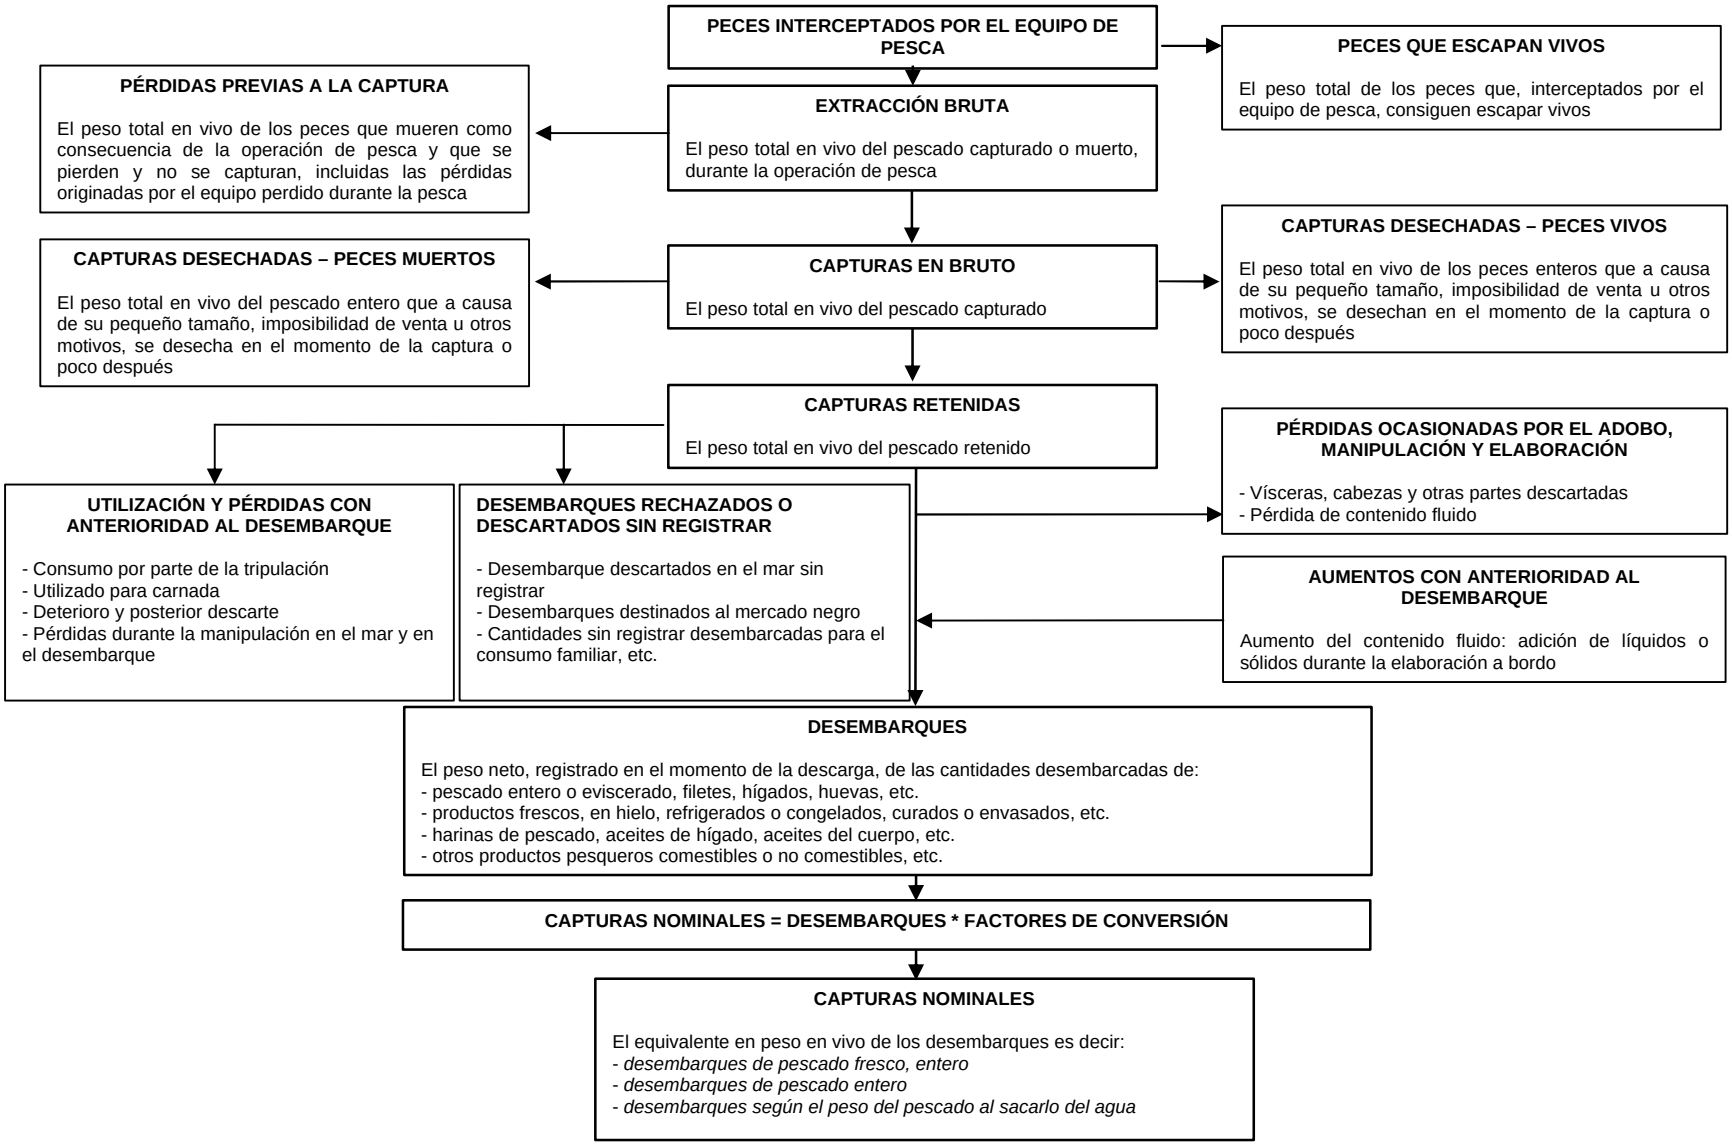
CATCH CONCEPTS: DIAGRAMMATIC PRESENTATION



CONCEPTS RELATIFS AUX CAPTURES: DIAGRAMME EXPLICATIF



CONCEPTOS DE CAPTURA: PRESENTACIÓN DIAGRAMÁTICA



Notes on species items

1. Data available world-wide on nominal catches of aquatic animals and plants, taken in inland and marine waters, for all kinds of commercial, industrial, recreational and subsistence purposes, are at present broken down at either the species, genus, family or higher taxonomic levels into 1875 statistical categories called *species items*.

2. These 1875 *species items* are arranged by FAO within the 50 *groups of species* constituting the nine *divisions* of the FAO "International Standard Statistical Classification of Aquatic Animals and Plants" (ISSCAAP). For these *groups of species* and *divisions* see the ISSCAAP list on the following page. The two-digit group codes shown in this list are reflected in the table numbers in Section B.

3. Following a recommendation of the 19th Session of the Coordinating Working Party on Fishery Statistics - CWP (Nouméa, New Caledonia, 10-13 July 2001) the names and composition of former groups 33, 34 and 37 of the FAO International Standard Statistical Classification of Aquatic Animals and Plants (ISSCAAP) were revised. The species items of the former group 33 "Redfishes, basses, congers" were classified as coastal or demersal fishes and accordingly assigned to the new groups 33 "Miscellaneous coastal fishes" and 34 "Miscellaneous demersal fishes". The species formerly included in group 34 "Jacks, mullets, sauries" were moved to group 37, which was renamed "Miscellaneous pelagic fishes".

4. Each *species item* is identified by means of the following descriptors (subject to constant review and improvement):
   a) FAO English name;
   b) FAO French name;
   c) FAO Spanish name;
   d) scientific name (at the species, genus, family or higher taxonomic levels);
   e) taxonomic code; and
   f) inter-agency 3-alpha code.

5. The taxonomic code descriptors are taken from FAO's **Aquatic Sciences and Fisheries Information System**. The following illustrates the meaning assigned to the different digits of this code:

Main grouping	Order or other taxonomic level	Family	Genus	Species
1,	75	(04)	003,	01

6. In all tables, except A-1(e) (where selected species items of significant commercial importance are listed in the order of 2010 catch size), the species items are arranged in order of their taxonomic codes within their respective ISSCAAP groups.

7. Several countries still report their catches by large groups of species. In these circumstances the catch data presented by individual species items are likely to be underestimated. Therefore, when examining the statistics for a particular species, it should be noted that an unknown proportion of the catches for that species might have been reported by the national office under the generic, family or order name of the species, or even more roughly as 'fishes not identified'. Consequently, **species item totals frequently underestimate the real catch of the individual species**.

Notes sur les catégories d'espèces

Les statistiques disponibles sur une base mondiale des captures nominales d'animaux et de plantes aquatiques effectuées dans les eaux continentales et dans les eaux marines à toutes fins commerciales, industrielles, récréatives et de subsistance sont, à l'heure actuelle, ventilées au niveau de l'espèce, du genre, de la famille ou des niveaux taxonomiques supérieurs dans 1875 catégories statistiques qui sont appelées des *catégories d'espèces*.

Ces 1875 *catégories d'espèces* sont rassemblées par la FAO en cinquante *groupes d'espèces* constituant les neuf *divisions* de la 'Classification statistique internationale type des animaux et des plantes aquatiques' (CSITAPA) de la FAO. Pour ces *groupes d'espèces* et ces *divisions*, on se reportera à la liste de la CSITAPA figurant à la page suivante. Les codes de groupe à deux chiffres indiqués sur la liste se retrouvent dans les numéros des tableaux de la section B.

Sur la base d'une recommandation de la 19ème session du Groupe de travail chargé de coordonner les statistiques des pêches - CWP (Nouméa, Nouvelle-Calédonie, 10-13 juillet 2001), la dénomination et la composition des anciens groupes 33, 34 et 37 de la Classification statistique internationale type des animaux et des plantes aquatiques (CSITAPA) de la FAO ont été révisées. Les catégories d'espèces de l'ancien groupe 33 "Rascasses, perches de mer, congres" ont été classifiées comme espèces côtières ou démersales et réparties sur cette base entre les nouveaux groupes 33 "Poissons côtiers divers" et 34 "Poissons démersaux divers". Les espèces auparavant incluses dans le groupe 34 "Chinchards, mulets, balaous" ont été classées dans le groupe 37 rebaptisé "Poissons pélagiques divers".

Chaque *catégorie d'espèces* est identifiée au moyen des descripteurs suivants (sous réserve de révision et d'amélioration constantes):
   a) nom anglais utilisé par la FAO;
   b) nom français utilisé par la FAO;
   c) nom espagnol utilisé par la FAO;
   d) nom scientifique (de l'espèce, du genre, de la famille ou des niveaux taxonomiques supérieurs);
   e) code taxonomique; et
   f) code interinstitutions alpha-3.

Les descripteurs de code taxonomique proviennent du **Système d'information sur les sciences aquatiques et la pêche** de la FAO. On trouvera ci-après la signification des divers chiffres constituant ce code taxonomique.

Groupe principal	Ordre ou autre niveau taxonomique	Famille	Genre	Espèce
1,	75	(04)	003,	01

Dans tous les tableaux, à l'exception de A-1(e) (où certaines catégories d'espèces ayant une importance commerciale notable sont énumérées selon le chiffre des captures de 2010), les catégories d'espèces sont disposées selon l'ordre du code taxonomique dans leurs groupes CSITAPA, respectifs.

Plusieurs pays continuent à communiquer leurs captures par grands groupes d'espèces. Dans ces circonstances les données des captures par catégories d'espèces individuelles sont donc probablement sous-estimées. Par conséquent, lorsqu'on examine les statistiques d'une espèce donnée, il convient de noter qu'une proportion inconnue des captures de cette espèce peut avoir été consignée par l'organisme national sous le nom du genre, de la famille ou de l'ordre de l'espèce, ou même, plus approximativement dans la catégorie 'poissons non identifiés'. C'est pourquoi **les totaux correspondant aux espèces données sous-estiment souvent la capture réelle de chacune des espèces**.

Notas sobre las partidas de especies

Los datos procedentes de todo el mundo sobre las capturas nominales de animales y plantas acuáticos capturados en aguas continentales y marinas con fines comerciales, industriales, de recreo o de subsistencia se desglosan en la actualidad en unas 1875 categorías estadísticas, denominadas *partidas de especies,* que corresponden a los niveles taxonómicos de especie, género, familia o superiores.

Utilizando esas 1875 *partidas de especies*, la FAO desglosa los cincuenta *grupos de especies* que constituyen las nueve *divisiones* de la Clasificación Estadística Internacional Uniforme de los Animales y Plantas Acuáticos (CEIUAPA) de la FAO. Estos *grupos de especies* y las nueve *divisiones* indicadas pueden verse en la lista de la CEIUAPA que aparece en la página siguiente. Los códigos de dos dígitos que en esa lista identifican a cada uno de los grupos se utilizan luego en los cuadros de la Sección B.

Sobre la base de una recomendación de la 19a sesión del Grupo Coordinador de Trabajo sobre Estadísticas de Pesca - CWP (Noumea, Nueva Caledonia, 10-13 de julio 2001) fue revisada la denominación y la composición de los antiguos grupos 33, 34, y 37 de la Clasificación Estadística Internacional Uniforme de los Animales y Plantas Acuáticos (CEIUAPA) de la FAO. Las partidas de especies del antiguo grupo 33 "Gallinetas, lubinas, congrios" fueron clasificadas como especies costeras o demersales y, de acuerdo con esto, distribuidas entre los nuevos grupos: 33 "Peces costeros diversos" y 34 "Peces demersales diversos". Las partidas de especies anteriormente comprendidas en el grupo 34 "Jureles, lisas, papardas" se incluyeron en el grupo 37, que pasó a denominarse "Peces pelágicos diversos".

Cada una de las *partidas de especies*, se identifica con los siguientes descriptores (que se revisan y mejoran continuamente):
   a) nombre inglés utilizado por la FAO;
   b) nombre francés utilizado por la FAO;
   c) nombre español utilizado por la FAO;
   d) nombre científico (de la especie, género, familia o niveles taxonómicos superiores);
   e) código taxonómico; e
   f) código interinstitucional alfa-3.

Los descriptores del código taxonómico se han tomado del **Sistema de información de las ciencias acuáticas y la pesca** de la FAO. El cuadro siguiente ilustra el significado de los distintos dígitos de dicho código:

Grupo principal	Orden u otro nivel taxonómico	Familia	Género	Especie
1,	75	(04)	003,	01

En todos los cuadros, excepto en el cuadro A-1(e) (en el cual algunas especies de gran importancia comercial aparecen ordenadas según el volumen de sus capturas en 2010), las partidas de especies aparecen por orden de su código taxonómico dentro de los respectivos grupos de la CEIUAPA.

Varios países siguen informando sobre sus capturas por grandes grupos de especies. En estos casos, es probable que aparezcan subestimados los datos sobre la captura de las partidas de especies. Por consiguiente, al examinar las estadísticas de una especie particular, debe tenerse en cuenta que una proporción desconocida de las capturas de esa especie puede haber sido ya comunicada por la oficina nacional con el nombre genérico, el de la familia o el del orden de la especie, o incluso más aproximativamente como 'peces no identificados'. En consecuencia, **los totales de las partidas de especies subestiman frecuentemente las capturas efectivas de la especie individual**.

ISSCAAP		CSITAPA	CEIUAPA
Code Code Código	DIVISION Group of species	DIVISION Groupe d'espèces	DIVISIÓN Grupo de especies
1	Freshwater fishes	Poissons d'eau douce	Peces de agua dulce
11	Carps, barbels and other cyprinids	Carpes, barbeaux et autres cyprinidés	Carpas, barbos y otros ciprínidos
12	Tilapias and other cichlids	Tilapias et autres cichlidés	Tilapias y otros cíclidos
13	Miscellaneous freshwater fishes	Poissons d'eau douce divers	Peces de agua dulce diversos
2	Diadromous fishes	Poissons diadromes	Peces diádromos
21	Sturgeons, paddlefishes	Esturgeons, spatules	Esturiones, sollos
22	River eels	Anguilles	Anguilas
23	Salmons, trouts, smelts	Saumons, truites, éperlans	Salmones, truchas, eperlanos
24	Shads	Aloses	Sábalos
25	Miscellaneous diadromous fishes	Poissons diadromes divers	Peces diádromos diversos
3	Marine fishes	Poissons marins	Peces marinos
31	Flounders, halibuts, soles	Flets, flétans, soles	Platijas, halibuts, lenguados
32	Cods, hakes, haddocks	Morues, merlus, églefins	Bacalaos, merluzas, eglefinos
33	Miscellaneous coastal fishes	Poissons côtiers divers	Peces costeros diversos
34	Miscellaneous demersal fishes	Poissons démersaux divers	Peces demersales diversos
35	Herrings, sardines, anchovies	Harengs, sardines, anchois	Arenques, sardinas, anchoas
36	Tunas, bonitos, billfishes	Thons, pélamides, marlins	Atunes, bonitos, agujas
37	Miscellaneous pelagic fishes	Poissons pélagiques divers	Peces pelágicos diversos
38	Sharks, rays, chimaeras	Squales, raies, chimères	Tiburones, rayas, quimeras
39	Marine fishes not identified	Poissons marins non identifiés	Peces marinos no identificados
4	Crustaceans	Crustacés	Crustáceos
41	Freshwater crustaceans	Crustacés d'eau douce	Crustáceos de agua dulce
42	Crabs, sea-spiders	Crabes, araignées de mer	Cangrejos, centollas
43	Lobsters, spiny-rock lobsters	Homards, langoustes	Bogavantes, langostas
44	King crabs, squat-lobsters	Crabes royaux, galatées	Cangrejos reales, galateidos
45	Shrimps, prawns	Crevettes	Gambas, camarones
46	Krill, planktonic crustaceans	Krill, crustacés planctoniques	Krill, crustáceos planctónicos
47	Miscellaneous marine crustaceans	Crustacés marins divers	Crustáceos marinos diversos
5	Molluscs	Mollusques	Moluscos
51	Freshwater molluscs	Mollusques d'eau douce	Moluscos de agua dulce
52	Abalones, winkles, conchs	Ormeaux, bigorneaux, strombes	Orejas de mar, bígaros, estrombos
53	Oysters	Huîtres	Ostras
54	Mussels	Moules	Mejillones
55	Scallops, pectens	Coquilles St-Jacques	Vieiras
56	Clams, cockles, arkshells	Clams, coques, arches	Almejas, berberechos, arcas
57	Squids, cuttlefishes, octopuses	Encornets, seiches, poulpes	Calamares, jibias, pulpos
58	Miscellaneous marine molluscs	Mollusques marins divers	Moluscos marinos diversos
* 6	Whales, seals and other aquatic mammals	Baleines, phoques et autres mammifères aquatiques	Ballenas, focas y otros mamíferos acuáticos
* 61	Blue-whales, fin-whales	Baleines bleues, rorquals communs	Ballenas azules, rorcuales
* 62	Sperm-whales, pilot-whales	Cachalots, globicéphales	Cachalotes, calderones
* 63	Eared seals, hair seals, walruses	Otaries, phoques, morses	Lobos marinos, focas, morsas
* 64	Miscellaneous aquatic mammals	Mammifères aquatiques divers	Mamíferos acuáticos diversos
7	Miscellaneous aquatic animals	Animaux aquatiques divers	Animales acuáticos diversos
71	Frogs and other amphibians	Grenouilles et autres amphibies	Ranas y otros anfibios
72	Turtles	Tortues	Tortugas
* 73	Crocodiles and alligators	Crocodiles et alligators	Cocodrilos y aligatores
74	Sea-squirts and other tunicates	Ascidiens et autres tuniciers	Ascidias y otros tunicados
75	Horseshoe crabs and other arachnoids	Limules et autres arachnoïdés	Límulos y otros arácnidos
76	Sea-urchins and other echinoderms	Oursins et autres échinodermes	Erizos de mar y otros equinodermos
77	Miscellaneous aquatic invertebrates	Invertébrés aquatiques divers	Invertebrados acuáticos diversos
* 8	Miscellaneous aquatic animal products	Produits divers d'animaux aquatiques	Diversos productos de animales acuáticos
* 81	Pearls, mother-of-pearl, shells	Perles, nacres, coquilles	Perlas, madreperlas, conchas
* 82	Corals	Coraux	Corales
* 83	Sponges	Éponges	Esponjas
* 9	Aquatic plants	Plantes aquatiques	Plantas acuáticas
* 91	Brown seaweeds	Algues brunes	Algas pardas
* 92	Red seaweeds	Algues rouges	Algas rojas
* 93	Green seaweeds	Algues vertes	Algas verdes
* 94	Miscellaneous aquatic plants	Plantes aquatiques diverses	Diversas plantas acuáticas

ISSCAAP = International Standard Statistical Classification of Aquatic Animals and Plants.

* In order to obtain the same aggregates presented in the Summary Tables for capture production, the ISSCAAP groups marked should be excluded.

CSITAPA = Classification statistique internationale type des animaux et des plantes aquatiques.

* Pour obtenir les mêmes agrégats que ceux qui sont présentés dans les Tableaux Résumés relatifs aux Captures, il faut exclure les groupes de la CSITAPA qui sont marqués d'un astérisque.

CEIUAPA = Clasificación Estadística Internacional Uniforme de los Animales y Plantas Acuáticos.

* Para obtener las mismas agregaciones que se presentan en los Cuadros Resúmenes para las Capturas, se deben excluir los grupos CEIUAPA que están marcados con un asterisco.

Notes on countries or areas

1. The designations employed and the presentation of material in this publication do not imply the expression of any opinion whatsoever on the part of the Food and Agriculture Organization of the United Nations concerning the legal or development status of any country, territory, city or area or of its authorities, or concerning the delimitation of its frontiers or boundaries.

2. The term *country or area* as used in the stubs and the column headings of the tables also covers territories, cities, land areas, as well as provinces, districts, enclaves, exclaves and other parts of territories or combinations of countries or areas such as economic or customs unions.

3. In all tables a country or area entry is designated by a multilingual code of not more than 12 characters. This code is keyed in the LIST OF COUNTRIES OR AREAS to the other descriptors for each country or area entry - the names in English, French and Spanish, the ISO's 3-alpha and 2-alpha codes, the UN's three-digit numerical code, etc.

4. Country or area names and designations are subject to nationally announced changes. Name changes announced after 31 December 2011 have not necessarily been incorporated in this issue but will be reflected in future ones.

5. The flag of the vessel performing the essential part of the fishing operation should be considered the paramount indication of the nationality assigned to the catches.

   The flag State of the vessel performing the essential part of the fishing operation should be responsible for the provision of catch data.

   Where a foreign flag vessel is fishing in the waters under the national jurisdiction of another State, the flag State of the vessel should have at all times the responsibility to provide relevant catch and landing data. The only exceptions to this shall be:

   (a) where the vessel undertakes fishing under a charter agreement or arrangement to augment the local fishing fleet, and the vessel has become for all practical purposes a local fishing vessel of the host country;

   (b) where the vessel undertakes fishing pursuant to a joint venture or similar arrangement in waters under the national jurisdiction of another State and the vessel is operating for all practical purposes as a local vessel, or its operation has become, or is intended to become, an integral part of the economy of the host country.

   In any situation where there is uncertainty as to the application of these criteria, any agreement, charter, joint venture or other similar arrangement should contain a provision setting out clearly the responsibility for reporting catch and landing data, which should be reported to the flag State and, where relevant, to any coastal State in whose waters fishing operations are to take place or competent subregional, regional or global fisheries organization or arrangement.

6. National data cover all quantities caught by fishing craft flying the flag of the reporting country and landed not only in the domestic harbours of the reporting country but also in foreign harbours. National catch excludes quantities caught by foreign fishing craft and landed in domestic ports.

7. Final data have been provided by many national offices; others submitted provisional figures only. Whenever national offices failed to report their annual catch statistics in time for publication, FAO has estimated the quantities to reflect more realistic catch data (F designated figures).

Notes sur les pays ou zones

Les appellations employées dans cette publication et la présentation des données qui y figurent n'impliquent de la part de l'Organisation des Nations Unies pour l'alimentation et l'agriculture aucune prise de position quant au statut juridique ou au stade de développement des pays, territoires, villes ou zones, ou de leurs autorités, ni quant au tracé de leurs frontières ou limites.

Le terme *pays ou zone* employé dans les talons et les têtes de colonne des tableaux, doit s'entendre également des territoires, villes, zones terrestres, ainsi que des provinces, districts, enclaves, parties détachées d'un État, autres parties de territoires ou regroupements de pays ou zones, tels qu'unions économiques ou douanières.

Dans tous les tableaux, les entrées des pays ou zones sont désignées par un code multilingue n'excédant pas douze espaces typographiques. Dans la LISTE DES PAYS OU ZONES ce code est associé aux autres descripteurs, c'est-à-dire aux noms en anglais, français et espagnol, aux codes ISO alpha-3 et alpha-2, au code numérique à trois chiffres des Nations Unies, etc.

La liste des appellations des pays ou zones est sujette de temps à autre à des modifications annoncées par les pays ou zones. Les modifications de noms survenues après le 31 décembre 2011 n'ont pas toujours été incorporées dans l'édition présente, mais il en sera tenu compte dans celles futures.

Le pavillon du navire effectuant la partie essentielle de l'opération de pêche devrait être considéré comme le facteur déterminant du pays ou zone auquel sont attribuées les captures.

L'État du pavillon du navire effectuant la partie essentielle de l'opération de pêche devrait fournir les données sur les captures.

Lorsqu'un navire battant pavillon étranger pêche dans des eaux placées sous la juridiction nationale d'un autre État, l'État du pavillon du navire devrait fournir à tout moment les données pertinentes sur les captures et les débarquements. Les seules exceptions à ce principe sont les suivantes:

(a) lorsque le navire pêche au titre d'un contrat ou d'un arrangement d'affrètement visant à compléter la flottille de pêche locale et que le navire est devenu à toutes fins utiles un navire de pêche local du pays d'accueil;

(b) lorsque le navire pêche dans le cadre d'une opération conjointe ou d'arrangements similaires dans des eaux placées sous la juridiction nationale d'un autre État et que le navire opère à toutes fins utiles en tant que navire local ou que ses activités font, ou sont appelées à faire, partie intégrante de l'économie du pays d'accueil.

Dans toute situation où il existe une incertitude quant à l'application de ces critères, l'accord, le contrat, l'opération conjointe ou tout autre arrangement similaire devrait contenir une disposition fixant clairement les responsabilités en matière de notification des données sur les captures et les débarquements. Celles-ci devraient être notifiées à l'État du pavillon et, le cas échéant, à tout État côtier dans les eaux duquel les opérations de pêche ont lieu ou à tout organisme ou accord de pêche sous-régional, régional ou mondial compétent.

Sont comprises dans les données nationales toutes les quantités capturées par les bateaux de pêche battant le pavillon du pays déclarant et débarquées non seulement dans les ports du pays déclarant, mais aussi dans des ports étrangers. Ne sont pas comprises dans les captures nationales, les quantités capturées par des bateaux étrangers et débarquées dans des ports nationaux.

De nombreux services nationaux ont communiqué des données définitives; d'autres n'ont fourni que des chiffres préliminaires. Chaque fois que les services nationaux n'ont pu déclarer leurs statistiques de captures annuelles en temps utile pour la publication, la FAO procédé à des estimations pour arriver à des chiffres de captures plus proches de la réalité (chiffres désignés par F).

Notas sobre los países o áreas

Las denominaciones empleadas en esta publicación y la forma en que aparecen presentados los datos que contiene no implican, da parte de la Organización de las Naciones Unidas para la Agricultura y la Alimentación, juicio alguno sobre la condición jurídica o nivel de desarrollo de países, territorios, ciudades o zonas, o de sus autoridades, ni respecto de la delimitación de sus fronteras o límites.

En los encabezamientos de las columnas o renglones de los cuadros, el término *país o área* puede referirse también a territorios, ciudades, zonas terrestres, provincias, distritos, enclaves, exclaves, otras partes de territorio o grupos de países o áreas, como uniones económicas o aduaneras.

En todos los cuadros, los países o áreas se indican con un código multilingue que no utiliza más de doce espacios. En la LISTA DE PAISES O AREAS dicho código aparece acompañado de otros descriptores - los nombres en inglés, francés y español, los códigos ISO alfa-3 y alfa-2, y el código numérico de tres dígitos de las Naciones Unidas, etc.

Los países o áreas anuncian en algunas ocasiones cambios de sus nombres y denominaciones. En la presente edición no se han incorporado todos los cambios de nombres anunciados después del 31 de diciembre de 2011, pero se tendrán presentes en las futuras.

El pabellón del barco que efectúa la parte principal de las operaciones de pesca debería considerarse como indicación decisiva para establecer a qué país o área hay que asignar las capturas.

El Estado del pabellón del barco que efectúa la parte principal de las operaciones de pesca debería ser el responsable de facilitar datos sobre capturas.

Cuando un barco de pabellón extranjero faene en aguas sometidas a la jurisdicción nacional de otro Estado, el Estado del pabellón de ese barco debería tener en todo momento la responsabilidad de facilitar datos pertinentes sobre capturas y desembarques. Las únicas excepciones a esto serán:

(a) cuando el barco faene con arreglo a un acuerdo de fletamento o como medida para aumentar la flota pesquera local, y el barco se ha convertido a todos los efectos prácticos en un barco pesquero local del país hospedante;

(b) cuando el barco emprenda las operaciones pesqueras en virtud de un acuerdo de empresa mixta o análogo en aguas sometidas a la jurisdicción nacional de otro Estado y faene a todos los efectos prácticos como un barco local, o sus operaciones se hayan convertido, o se tenga intención de que se conviertan, en parte integrante de la economía del país hospedante.

En cualquier situación en que haya incertidumbre respecto de la aplicación de estos criterios, cualquier acuerdo, fletamento, empresa mixta u otro acuerdo similar debería contener una disposición por la que se establezca claramente la responsabilidad de la presentación de datos sobre capturas y desembargues que deberían notificarse al Estado del pabellón y, según proceda, a cualquier Estado ribereño en cuyas aguas se vayan a realizar operaciones pesqueras o a cualquier organización o acuerdo pesquero subregional, regional o mundial competente.

Los datos nacionales incluyen todas las cantidades capturadas por embarcaciones pesqueras que enarbolan el pabellón del país que comunica los datos y desembarcadas en los puertos del país en cuestión o en puertos extranjeros. Las capturas nacionales no incluyen las cantidades capturadas por embarcaciones pesqueras extranjeras y desembarcadas en puertos del país al que se refieren los datos.

Muchas oficinas nacionales han facilitado datos difinitivos; otras, en cambio, sólo han presentado cifras provisionales. Cuando las oficinas nacionales no han comunicado a tiempo sus estadísticas nacionales de captura, la FAO ha estimado las cantidades para que reflejaran más objetivamente los datos de captura (cifras designadas F).

Notes on countries or areas

8. The NOTES ON INDIVIDUAL COUNTRIES OR AREAS list the few national exceptions to the standards described above and also to those standards specified in other NOTES in this Yearbook.

9. Users are reminded that, although data are shown to the nearest tonne, they are not necessarily of this degree of accuracy.

10. Countries included in the low-income food-deficit countries (LIFDCs) grouping are those classified (i) by the World Bank as low-income in terms of GNP per capita, and (ii) by FAO as having a trade deficit for food in terms of calorie content. Countries which have formally objected to being included in the grouping are excluded.

Notes sur les pays ou zones

Les quelques exceptions nationales à ces normes ainsi qu'aux normes indiquées dans les autres NOTES figurant dans le présent Annuaire sont indiquées dans les NOTES SUR DIVERS PAYS OU ZONES.

Il est rappelé aux utilisateurs que les chiffres sont arrondis à la tonne la plus proche, mais qu'ils n'ont pas nécessairement un tel degré de précision.

Les pays inclus dans le groupe pays à faible revenu et à déficit vivrier (PFRDV) sont ceux classifiés (i) par la Banque mondiale comme ayant un revenu par habitant bas en termes de PIB, et (ii) par la FAO comme ayant un déficit commercial alimentaire en termes de contenu en calories. Les pays qui se sont formellement opposés à leur inclusion dans ce groupe n'y figurent pas.

Notas sobre los países o áreas

En las NOTAS SOBRE LOS DISTINTOS PAISES O ÁREAS pueden verse algunas excepciones nacionales a estas normas; véanse también las que aparecen en otras NOTAS de este Anuario.

Se recuerda a los usarios que, si bien los datos están redondeados a la tonelada más próxima, no tienen necesariamente ese grado de precisión.

Los países incluidos en el grupo países de bajos ingresos y con déficit de alimentos (PBIDA) son aquellos clasificados (i) por el Banco Mundial como teniendo una renta per cápita baja en términos de PNL, y (ii) por la FAO como teniendo un déficit comercial alimentario en términos de contenido en calorías. Los países que se han formalmente opuesto a su inclusión en este grupo no están incluidos.

Column A = FAO multilingual country or area code (maximum 12 characters) used for statistical purposes.

Column B = Alpha-3 country or area code: ISO (International Organization for Standardization).

Column C = Alpha-2 country or area code: ISO (International Organization for Standardization).

Column D = Three-digit UN numerical country or area code as published in the "STANDARD COUNTRY OR AREA CODES FOR STATISTICAL USE" Statistical Papers, Series M., No. 49; United Nations, New York (http://unstats.un.org/unsd/methods/m49/m49.htm).

Column E = Continents:
- 002 = Africa
- 019 = Americas
- 142 = Asia
- 150 = Europe
- 009 = Oceania

Column F = Country or area names in English (maximum 24 characters).

Column G = Country or area names in French (maximum 24 characters).

Column H = Country or area names in Spanish (maximum 24 characters).

Colonne A = Noms de pays ou zone en code multilingue FAO (n'excédant pas 12 lettres) utilisés à des fins statistiques.

Colonne B = Code Alpha-3 des pays ou zones: ISO (Organisation internationale de normalisation).

Colonne C = Code Alpha-2 des pays ou zones: ISO (Organisation internationale de normalisation).

Colonne D = Code numérique à trois chiffres pour les pays ou zones des Nations Unies, tel que publié dans "STANDARD COUNTRY OR AREA CODES FOR STATISTICAL USE" (Code type pour les pays ou les zones des Nations Unies à des fins statistiques), Statistical Papers, Series M., No. 49; United Nations, New York (http://unstats.un.org/unsd/methods/m49/m49.htm).

Colonne E = Continents:
- 002 = Afrique
- 019 = Amériques
- 142 = Asie
- 150 = Europe
- 009 = Océanie

Colonne F = Noms de pays ou zone en anglais (n'excédant pas 24 espaces typographiques).

Colonne G = Noms des pays ou zone en français (n'excédant pas 24 espaces typographiques).

Colonne H = Noms de pays ou zone en espagnol (n'excédant pas 24 espaces typographiques).

Columna A = Nombres multilingües de los países o áreas utilizados por la FAO para fines estadísticos (máximo, 12 espacios).

Columna B = Código Alfa-3 de los países o áreas: ISO (Organización Internacional de Normalización).

Columna C = Código Alfa-2 de los países o áreas: ISO (Organización Internacional de Normalización).

Columna D = Código numérico de tres dígitos atribuido al país o área en cuestión por las Naciones Unidas, tal como aparece en la publicación "STANDARD COUNTRY OR AREA CODES FOR STATISTICAL USE" (Código estándar por los países o áreas de las Naciones Unidas para fines estadísticos), Statistical Papers, Series M., No. 49; United Nations, New York (http://unstats.un.org/unsd/methods/m49/m49.htm).

Columna E = Continentes:
- 002 = África
- 019 = Américas
- 142 = Asia
- 150 = Europa
- 009 = Oceanía

Columna F = Nombres de los países o áreas en inglés (máximo, 24 espacios).

Columna G = Nombres de los países o áreas en francés (máximo, 24 espacios).

Columna H = Nombres de los países o áreas en español (máximo, 24 espacios).

Notes on major fishing areas

1. The 26 *major fishing areas*, internationally established for fishery statistical purposes, consist of:

   a) seven major inland fishing areas, covering the inland waters of the continents;

   b) nineteen major marine fishing areas, covering the waters of the Atlantic, Indian, Pacific and Southern Oceans with their adjacent seas.

2. The list of these 26 areas appears on the following page facing the world map on which the boundaries of the various major fishing areas are shown together with their identifying two-digit codes. These two-digit area codes are reflected in the table numbers in Section C.

3. The major fishing areas, inland and marine, are identified in all tables by two kinds of descriptors: their FAO names and/or two-digit codes. Space restrictions require the use in column headings of the word *fishing area* when referring to *major fishing areas*.

4. Breakdown of catch statistics by subareas, divisions, subdivisions, etc., within these major fishing areas, are not given in this yearbook. These details appear in statistical bulletins issued regularly by various regional fishery organizations, councils, commissions, committees, etc., e.g. CECAF, GFCM, ICCAT, ICES, NAFO, etc.

5. Changes have been made in some of the boundaries between major fishing areas. The catch statistics for all areas and all years in this issue have been adjusted in accordance with the boundaries as now shown in the world map.

   The fishing area 07 ("Former USSR area – Inland waters") referred to the area that was formerly the Union of Soviet Socialist Republics. Since 1988, information for each new independent Republic is shown separately with the exception of capture data in the Antarctic fishing areas for which separate data begin in 1991. The new independent Republics are: Armenia, Azerbaijan, Georgia, Kazakhstan, Kyrgyzstan, Tajikistan, Turkmenistan, Uzbekistan (statistics now assigned to the fishing area "Asia – Inland waters") and Belarus, Estonia, Latvia, Lithuania, Republic of Moldova, Russian Federation, Ukraine (assigned to the fishing area "Europe – Inland waters").

   Since 1981, fishing area 41 includes the waters lying between 55° and 60° South latitude and between 50° and 60° West longitude which during the 1970-80 period were included in the fishing area 48.

   Division of catches between fishing areas 57 and 71 was estimated following boundary change in the Strait of Malacca in 1986.

   Beginning with the 1989 data, catches have been adjusted in accordance with the boundary change between fishing areas 87 and 81; and between 87 and 77.

   Boundary between fishing areas 51 and 57 was modified starting with the 1999 data. As a consequence data for Sri Lanka have been moved from area 51 to area 57.

   Boundary between fishing areas 57 and 71 in the Australian-Indonesian region was modified starting with the 2001 data.

6. Freshwater species are usually recorded as caught in inland waters. Small quantities of several freshwater species are caught regularly in parts of some seas with low salinities; these catches are included in the statistics of the appropriate marine area. Similarly, the catches of diadromous (anadromous and catadromous) species are shown in either the marine or inland area where caught.

Notes sur les principales zones de pêche

Les 26 *principales zones de pêche* établies au plan international à des fins statistiques, comprennent:

a) sept principales zones de pêche continentales, couvrant les eaux des continents;

b) dix-neuf principales zones de pêche maritimes, couvrant les eaux des océans Atlantique, Indien, Pacifique et Austral et leurs mers limitrophes.

La liste de ces 26 zones figure à la page suivante faisant face à la carte mondiale sur laquelle on a porté les limites des principales zones de pêche avec les codes à deux chiffres qui les identifient. Ces codes à deux chiffres se retrouvent dans les numéros des tableaux figurant à la Section C.

Les principales zones de pêche, tant continentales que maritimes, sont identifiées dans tous les tableaux par deux types de descripteurs: leur nom FAO et/ou leur code à deux chiffres. Faute d'espace, il a fallu utiliser le terme *zone de pêche* dans les têtes de colonne pour indiquer les *principales zones de pêche*.

Les ventilations des statistiques des captures par sous-zones, divisions, sous-divisions, etc., au sein de ces principales zones de pêche ne sont pas données dans cet annuaire. Ces détails figurent dans les bulletins statistiques qui sont publiés périodiquement par les divers organismes régionaux de pêche, conseils, commissions ou comités des pêches, par exemple, COPACE, CGPM, CICTA, CIEM, NAFO, etc.

Des modifications ont été apportées à certaines des limites tracées des principales zones de pêche. Les statistiques des captures relatives à toutes les zones de pêche et à toutes les années incluses dans l'édition présente ont été ajustées de manière à correspondre aux limites qui sont maintenant indiquées sur la carte mondiale.

La zone de pêche 07 (Zone de l'ex-URSS – Eaux continentales) correspondait au territoire de l'ancienne Union des Républiques socialistes soviétiques. Depuis 1988 les renseignements sont donnés séparément pour chaque république indépendante sauf pour les données relatives aux captures effectuées dans les zones maritimes de l'Antarctique pour lesquelles les données séparées commencent en 1991. Les nouvelles Républiques indépendantes sont: Arménie, Azerbaïdjan, Géorgie, Kazakhstan, Kirghizistan, Tadjikistan, Turkménistan, Ouzbékistan (statistiques maintenant attribuées à la zone de pêche Asie - Eaux continentales) et Bélarus, Estonie, Lettonie, Lituanie, République de Moldova, Fédération de Russie, Ukraine (statistiques attribuées à la zone de pêche "Europe - Eaux continentales").

Depuis 1981 la zone de pêche 41 comprend les eaux situées entre 55° et 60° de latitude sud et entre 50° et 60° de longitude ouest qui durant la période 1970-80 étaient incluses dans la zone de pêche 48.

La répartition des captures entre les zones de pêche 57 et 71 était estimée après changement apporté en 1986 à la limite relative au détroit de Malacca.

A partir des données de 1989 les captures ont été ajustées de manière à correspondre à la modification apportée aux limites entre les zones de pêche 87 et 81, et entre les zones 87 et 77.

La limite entre les zones de pêche 51 et 57 a été modifiée à partir des données de 1999. En conséquence les données pour le Sri Lanka ont été portées de la zone de pêche 51 à la zone de pêche 57.

La limite entre les zones de pêche 57 et 71 dans la région australien-indonésienne a été modifiée à partir des données de 2001.

Les poissons d'eau douce sont d'ordinaire enregistrés comme captures faites dans les eaux continentales. De petites quantités de poissons d'eau douce de plusieurs espèces sont couramment capturées dans certaines mers dont la salinité est faible; ces captures figurent dans les statistiques relatives à la zone maritime appropriée. De même, les captures de poissons d'espèces diadromes (anadromes et catadromes) apparaissent dans les statistiques ayant trait soit aux zones maritimes, soit aux zones continentales où elles ont été effectuées.

Notas sobre las áreas principales de pesca

Las 26 *áreas principales de pesca* establecidas internacionalmente con fines estadísticos se dividen en:

a) siete áreas principales de pesca continental, que cubren las aguas de los continentes;

b) diecinueve áreas principales de pesca marítimas, que cubren las aguas de los océanos Atlántico, Índico, Pacífico y Austral así como las de sus mares adyacentes.

La lista de estas 26 áreas de pesca puede verse en la página siguiente opuesta a la carta mundial, en la que se indican los límites de las distintas áreas principales de pesca con los códigos de dos dígitos correspondientes a cada área de pesca. Estos dos dígitos se utilizan luego en los números de los cuadros de la Sección C.

Las áreas principales de pesca, continentales y marinas, se identifican en todos los cuadros con dos tipos de descriptores: su nombre FAO y/o código de dos dígitos. Por razones de espacio, en los encabezamientos de las columnas se utiliza el término *área de pesca* para designar las *áreas principales de pesca*.

En esto anuario no se desglosan las estadísticas de captura por subáreas, divisiones, subdivisiones, etc., dentro de las áreas principales de pesca. Esos desgloses pueden verse en los boletines estadísticos publicados regularmente por las distintas organizaciones regionales de pesca, consejos, comisiones, comités, etc., como el CPACO, la CGPM, la CICAA, el CIEM, la NAFO, etc.

Los límites de algunas de las áreas principales de pesca han sido modificados en los años pasados. Las estadísticas de captura de todas las áreas y años que figuran en esta edición se han ajustado en consecuencia, teniendo en cuenta los límites que ahora aparecen en la carta mundial.

El área de pesca 07 (Área de la ex URSS – Aguas continentales) correspondía a la antigua Unión de Repúblicas Socialistas Soviéticas. A partir de 1988 la información de cada una de las nuevas repúblicas independientes se expone por separado excepto en el caso de las capturas efectuadas en las áreas marítimas del Antártico para las cuales los datos separados comienzan en 1991. Las nuevas repúblicas independientes de la ex URSS son: Armenia, Azerbaiyán, Georgia, Kazajstán, Kirguistán, Tayikistán, Turkmenistán, Uzbekistán (los datos han sido atribuidos al área de pesca Asia - Aguas continentales) y Belarús, Estonia, Letonia, Lituania, República de Moldova, Federación de Rusia, Ucrania (datos atribuidos al área de pesca "Europa – Aguas continentales").

Desde 1981 la área de pesca 41 incluye las aguas comprendidas entre 55° y 60° de latitud Sur y entre 50° y 60° de longitud Oeste que durante el período 1970-80 eran incluidas en la área de pesca 48.

La distribución de las capturas entre las áreas de pesca 57 y 71 fue una estimación debida a la modificación hecha en 1986 al límite relativo al estrecho de Malaca.

A partir de datos de 1989 las capturas se han ajustado teniendo en cuenta las modificaciones hechas a los límites entre las áreas de pesca 87 y 81, y entre las áreas 87 y 77.

El límite entre las áreas de pesca 51 y 57 ha sido modificado a partir de datos de 1999. Consecuentemente se cambiaron los datos por Sri Lanka desde la área de pesca 51 a la 57.

El límite entre las áreas de pesca 57 y 71 en la región australiana-indonesia ha sido modificado a partir de datos de 2001.

Las especies de agua dulce se consignan de ordinario considerando que se han capturado en aguas continentales. Pequeñas cantidades de varias especies de agua dulce se capturan regularmente en algunas zonas marítimas de poca salinidad; dichas capturas se incluyen en las estadísticas correspondientes al área marítima en cuestión. De igual forma, las capturas de especies diadromas (anádromas y catádromas) se incluyen en el área marítima o continental en que se han capturadas.

These countries or areas are those with capture production of 200 000 tonnes or more in 2010.

(1) See note on China in NOTES ON INDIVIDUAL COUNTRIES OR AREAS.

Ces pays ou zones sont ceux dont les captures ont été de 200 000 tonnes ou plus en 2010.

(1) Voir la note sur la Chine dans les NOTES SUR DIVERS PAYS OU ZONES.

Estos países o áreas son referentes a los que totalizan unas capturas de 200 000 toneladas o más en 2010.

(1) Véase la nota sobre China en las NOTAS SOBRE LOS DISTINTOS PAÍSES O ÁREAS.

The data in this A-6 table and in tables B-91, B-92, B-93 and B-94 refer to the annual production of seaweeds and other aquatic plants (expressed in tonnes and on a wet-weight basis) through harvesting of wild stocks.

See paragraph 5 of the INTRODUCTION.

Les données présentées dans les tableaux A-6 et B-91, B-92, B-93 et B-94 se rapportent à la production annuelle d'algues marines et autres plantes aquatiques (exprimée en tonnes et en poids vert) fournie par la récolte des espèces sauvages.

Voir le paragraphe 5 de l'INTRODUCTION.

Los datos de este cuadro A-6 y de los cuadros B-91, B-92, B-93 y B-94 se refieren a la producción anual de algas marinas y otras plantas acuáticas (expresada en toneladas y peso en húmedo) obtenida mediante la recolecciòn de plantas silvestres.

Véase el párrafo 5 en la INTRODUCCIÓN.
