[a] Starting with the 1998 issue ("Capture production 1996"), the nominal catch statistics include only the production from capture fisheries with the exclusion of aquaculture production.
[a] À partir de l'édition de 1998 («Captures 1996»), les statistiques des captures nominales comprennent uniquement la production des pêches de capture à l'exclusion de la production aquacole.
[a] A partir de la edición de 1998 («Capturas 1996»), las estadísticas de las capturas nominales incluyen únicamente la producción de la pesca de captura con exclusión de la producción de acuicultura.

[b] Aquaculture production statistics were combined with those of capture fisheries and published jointly in the "FAO Yearbook. Fishery statistics. Catches and landings" until volume 80. The 1984-97 data were formerly published yearly as "FAO Fisheries Circular No. 815 Aquaculture production statistics".
[b] Les statistiques de production de l'aquaculture étaient confondues avec celles de la production de pêche et publiées dans «FAO annuaire. Statistiques des pêches. Captures et quantités débarquées» jusqu'au volume 80. Auparavant, les données 1984-97 étaient publiées sur base annuelle dans la «Circulaire de la FAO sur les pêches n° 815: Statistiques de la production de l'aquaculture».
[b] Las estadísticas de producción de acuicultura estaban incluidas en la producción de pesca y publicadas juntas en «FAO anuario. Estadísticas de pesca. Capturas y desembarques», hasta el volumen 80. Anteriormente los datos desde 1984 hasta 1997 se publicaron anualmente en la «Circular de Pesca de la FAO N° 815: Estadísticas de la producción de acuicultura».

[c] Starting with the 2008 issue ("Fishery and Aquaculture Statistics 2006"), the FAO yearbooks of fishery and aquaculture statistics are published in a revised format consisting in a booklet, containing general notes and summary tables, accompanied by a CD-ROM with the complete yearbooks package of statistical tables.
[c] À partir de l'édition de 2008 («Statistiques des pêches et de l'aquaculture 2006»), les annuaires statistiques des pêches et de l'aquaculture adoptent un format révisé, consistant en un fascicule, avec les notes générales et les tableaux résumés, accompagné d'un CD-ROM, contenant tous les tableaux statistiques.
[c] A partir de la edición de 2008 («Estadísticas de pesca y acuicultura 2006»), los anuarios FAO de Estadísticas de pesca y acuicultura se publican con la presentación revisada que incluye un volumen, con las notas generales y los cuadros resúmenes, y un CD-ROM con todos los cuadros estadísticos.

[d] Starting with the 2009 issue ("Fishery and Aquaculture Statistics 2007"), the FAO yearbook of fishery and aquaculture statistics includes the section "Fish and fishery products – World apparent consumption statistics based on food balance sheets". Formerly published as "FAO Fisheries Circular No. 821".
[d] À partir de l'édition de 2009 («Statistiques des pêches et de l'aquaculture 2007»), l'annuaire statistique des pêches et de l'aquaculture de la FAO inclut la section «Poissons et produits de la pêche – Statistiques sur la consommation mondiale apparente, fondées sur les bilans alimentaires». Autrefois publiée comme «FAO Circulaire sur les pêches n° 821»
[d] A partir de la edición de 2009 («Estadísticas de pesca y acuicultura 2007»), el anuario FAO de Estadísticas de pesca y acuicultura incluye la sección «Pescado y productos pesqueros – Estadísticas sobre consumo mundial aparente, basadas en las hojas de balance de alimentos». Anteriormente publicado como «FAO Circular de Pesca N° 821».

ARCTIC
VOL. 41, NO. 3 (SEPTEMBER 1988) P. 239-240

Maximal Feeding Depth of Walruses

F.H. FAY[1] and J.J. BURNS[2]

(Received 26 November 1986; accepted in revised form 26 April 1988)

ABSTRACT. Walruses (*Odobenus rosmarus*) feed mainly on benthic invertebrates in waters less than 80 m deep, and they have been presumed to be incapable of diving to greater depths. Reported here are seven walruses whose stomachs contained significant amounts of benthic sediments and food, some of which must have been ingested in waters more than 100 m deep. Walruses may be able to dive to depths much greater than 100 m, but they usually have little reason to do so, since their benthic prey are most abundant in shallower waters.

Key words: walrus, *Odobenus*, diving, feeding, Bering Sea

RÉSUMÉ. Les morses (*Odobenus rosmarus*) mangent surtout des benthiques invertébrés dans les eaux qui ne dépassent pas 80 m de profondeur et l'on suppose qu'ils sont incapables de plonger plus bas. Nous rendons compte ici de la prise de sept morses ayant dans leurs estomacs des quantités importantes d'aliments et de sédiments benthiques, dont une certaine quantité a dû être ingérée à une profondeur de plus de 100 m. Les morses sont peut-être capables de plonger à des profondeurs qui dépassent 100 m, mais il y a très peu de raison qu'ils le fassent à cause du manque de proie à cette profondeur.

Mots clés: morse, *Odobenus*, plongée, alimentation, Mer de Bering

Traduit par V. Pelletier, l'Université d'Alaska-Fairbanks.

РЕЗУМЕ. Моржи (Odobenus rosmarus) питаются главным образом бентическими беспозвоночными в водах мельче 80 м, и полагалось что они не имели способности нырять ниже. Здесь предоставляем доклад о семи моржах, в чьих желудках было значительное количество бентоса и бентонного гравия, которое добивалось в водах глубже 100 м, где моржи наверно питались некоторым количеством этих материалов. Возможно что моржи имеют нырять глубже 100м, но мало причин почему бы им нырять в такие глубины, так как пища становится самая обильная в более мелких водах.

Ключевые слова: морж, Odobenus, нырание, питание, Берингово море

Перевод по С. Лекомт, Университет Аляски-Фэрбанкс.

Walruses, *Odobenus rosmarus* (Linnaeus), reside mainly in seasonally ice-covered seas of the Arctic and Subarctic. Because they feed primarily on bivalve mollusks (Chapskii, 1936; Tsalkin, 1937; Nikulin, 1941; Brooks, 1954; Loughrey, 1959), they must dive to the bottom of the sea for most of their food. Walruses are not known to bottom-feed in waters deeper than 80 m, which has led some observers to hypothesize that either the walruses are incapable of diving to greater depths (Vibe, 1950, 1956; Mansfield, 1958) or their preferred foods are scarce in deeper waters (Brooks, 1954; Loughrey, 1959). They do venture occasionally into areas of deeper water (Vibe, 1950; Loughrey, 1959; Fay, 1982; Finley and Renaud, 1980), but they are believed to subsist there by preying on pelagic organisms, particularly phocine seals (Vibe, 1950).

In March 1985, we had an opportunity to examine the stomachs from 13 walruses that were killed on ice floes over waters 102-117 m deep in the central Bering Sea. Six of those stomachs were nearly empty, containing only trace amounts of digesta from a previous meal, but four contained partly digested food, and the last three contained food that was very fresh (undigested), along with associated benthic sediments. The presence of fresh, undigested prey, which consisted of infaunal and epifaunal mollusks (fleshy parts only; walruses usually do not ingest the shells) and crustaceans (Table 1), indicates that at least the last three animals had fed very recently, probably in the immediate vicinity of the floes where they lay when killed. The partly digested food in the other four stomachs was of the same kind as that in those three, but it evidently had been eaten some time earlier, possibly a few km away. The nearest waters 80 m and less in depth were at least 50-95 km away from the location where the animals were killed. At the normal swimming speed of walruses (up to about 10 km·h^{-1}; Fay, 1982), those shallow waters were at least 5-9 h distant. Had the walruses eaten their

last meal there, 5-9 h earlier, the digestion of it in their stomach certainly would have been completed before they were captured. Pinnipeds digest their food rapidly (Gurova and Pastukhov, 1974; Parsons, 1977; Miller, 1978; Murie and Lavigne, 1986), and the walrus's digestion is thought to be exceptionally rapid (Murie, 1871).

The bivalves on which walruses feed are abundant in northern seas mainly at depths between 10 and 100 m (Thorson, 1934; Belyaev, 1960; Neiman, 1960; Thompson, 1982). In the Bering Sea, the production of macrobenthos in that range (middle shelf) is an order of magnitude higher than it is on the outer shelf at depths of 100-200 m (Walsh and McRoy, 1986). This is a result of partitioning of primary production to the pelagic food web seaward of the 100 m isobath and to the benthic food web shoreward of 100 m (Cooney and Coyle, 1982).

Judging from our findings, walruses are capable of diving and feeding to depths greater than 100 m in that region, but they probably do not do so very often, because they gain less from it than from feeding in shallower waters. Their geographic distribution, therefore, may be limited less by their diving ability than by the bathymetric distribution of their food.

ACKNOWLEDGEMENTS

This work was done with support from the University of Alaska and the Alaska Department of Fish and Game, with logistic accommodation by the Soviet All-Union and Pacific Research Institutes of Fisheries and Oceanography under the aegis of the Marine Mammal Project (V.6), US-USSR Agreement in the Field of Environmental Protection. We thank Captain Victor Yagupov and his crew on the ZRS *Zakharovo* and Chief Scientist A.A. Kibal'chich for their generous hospitality. Nora Foster, of the University of Alaska-Fairbanks Museum, assisted us by identifying some of the invertebrates from the walrus stomachs, and B.P. Kelly, C.P. McRoy, H.M. Feder, and two anonymous reviewers kindly read and commented on earlier drafts of the manuscript.

Summer Diet of the Bearded Seal (*Erignathus barbatus*) in the Canadian High Arctic

K.J. FINLEY[1] and C.R. EVANS[1]

ABSTRACT. Stomach contents of 34 bearded seals taken in three High Arctic localities (Grise Fiord, Pond Inlet and Clyde) during the summers from 1978-1980 were examined. At least 12 species of fish were present but sculpins (Cottidae) and arctic cod (*Boreogadus saida*) comprised the bulk of the diet. Eelpouts (*Lycodes* spp.) and polar cod (*Arctogadus glacialis*) were also ingested in considerable amounts. In 15 of 19 stomachs containing >1 kg food, fish contributed >90% of the wet weight. The whelk *Buccinum* and the shrimp *Sclerocrangon boreas* accounted for most of the invertebrate component of the diet. Clams, cephalopods, anemones, sea cucumbers, polychaete worms and other invertebrates occurred in small amounts. The largest measured weight of stomach contents was 7.6 kg from a seal that had fed heavily on arctic cod. There were no significant differences amongst the three localities in the amount of food ingested; however, the proportions of arctic cod and sculpins varied considerably among localities. Bearded seals fed on the available size range of arctic cod but were limited to the smaller sculpins (<200 g), eelpouts (<200 g) and polar cod (<350 g).

Key words: bearded seals, Canadian High Arctic, diet

RÉSUMÉ. On a examiné le contenu de l'estomac de 34 phoques barbus pris à trois centres du nord de l'Arctique (Grise Point, Pond Inlet et Clyde) au cours des étés de 1978 à 1980. Au moins douze espèces de poissons s'y trouvaient mais le chabot (Cottidae) et le saida (*Boreogadus saida*) formaient la majeure partie du régime alimentaire. Les lycodes (*Lycodes* spp.) et la "morue polaire" (*Arctogadus glacialis*) furent aussi consommées en quantité considérable. Le poisson comptait pour >90% du poids mouillé dans 15 des 19 estomacs contenant plus de 1 kg de nourriture. Le buccin *Buccinum* et la crevette *Sclerocrangon boreas* comportaient la majeure partie des invertébrés du régime. Les clams, les céphalopodes, les anémones, les concombres de mer, les vers polychètes et d'autres invertébrés s'y trouvaient aussi en petites quantités. Le poids maximal mesuré pour le contenu d'un estomac était de 7.6 kg pour un phoque qui s'était gavé de saida. L'étude n'a indiqué aucune différence marquée dans la quantité de nourriture consommée entre les trois centres. Cependant, la proportion de saida et de chabot variait de façon importante entre les trois centres. Les phoques barbus s'étaient nourris de saidas de la taille disponible mais avaient dû se satisfaire de mets de taille inférieure quant aux chabots (<200 g), aux lycodes (<200 g) et aux "moreus polaires" (<350 g).

Mots clés: phoques barbus, nord de l'Arctique canadien, régime alimentaire

INTRODUCTION

The bearded seal, *Erignathus barbatus*, is a large, solitary seal with continuous circumpolar distribution in arctic and subarctic waters (Mansfield, 1967; Benjaminsen, 1973). It is most abundant in areas where it can reach the sea bottom to feed (i.e. generally <200 m — Burns and Frost, 1979) and where it has access to ice pans upon which to haul out (Fig.1). Since the bearded seal has only a limited capability to maintain breathing holes in solid ice, it is excluded from areas of fast ice and is found among pack ice where openings are continually formed (Burns *et al.*, 1981). In many areas, bearded seals are quite sedentary and undertake only local movements in response to ice conditions (Vibe, 1950; McLaren, 1962; Fedoseev, 1973) although in the Bering Sea, bearded seals undertake considerable north-south movements in response to seasonal changes in ice conditions (Burns and Frost, 1979).

The bearded seal is primarily a benthic feeder with a diverse diet that varies with location and time of year (for reviews see Chapskii, 1938; Kosygin, 1971; Davis *et al.*, 1980; Lowry *et al.*, 1980). Most studies of the diet of bearded seals have been conducted in the shallow Bering and Chukchi seas which provide "the largest continuous area of favorable bearded seal habitat in the world" (Burns and Frost, 1979:12). In a comprehensive study and review of the diet of the bearded seal in the Bering and Chukchi seas, Lowry *et al.* (1980) found that it consisted mainly of crabs, shrimps and clams. Fish, they concluded, were of minor importance in the diet.

In the Kara and Barents seas of the western Soviet Arctic, Chapskii (1938) concluded that shrimp, particularly *Sclerocrangon boreas*, and molluscs were the basic food of the bearded seal, though fish, particularly arctic cod (*Boreogadus saida*), were thought to be important when they occurred in

large concentrations. Pikharev (1941) found that bearded seals of the Sea of Okhotsk fed on fish when they could not reach the bottom. Vibe (1950) stated that arctic cod were of major importance in areas of NW Greenland where bearded seals could not reach the bottom; in coastal waters they fed on various benthic fishes, crustaceans, gastropods, holothurians, gephyreans, cephalopods and polychaetes. Like Chapskii (1938), Vibe (1950) noted the preference of bearded seals for whelks, *Buccinum* spp.; he and others wondered how the bearded seal managed to remove the snails from the shells without ingesting the shells.

Very little is known about the bearded seal in the Canadian Arctic (Davis *et al.*, 1980). It is taken in relatively small numbers in virtually all coastal communities and is thought to be most abundant in Hudson Strait, Foxe Basin and along the west coast of Hudson Bay (Mansfield, 1967). Bearded seals are excluded by fast ice from large areas of the High Arctic Archipelago during much of the year, but during the summer they are found widely distributed in small numbers throughout much of the archipelago. In the eastern Canadian High Arctic, bearded seals are hunted in fiords, primarily from July to October. The feeding habits of these seals are examined in this paper.

METHODS

Stomachs were obtained from 36 bearded seals taken by hunters from the communities of Grise Fiord, Pond Inlet and Clyde (Fig. 2) during 1978-80. Hunters provided the stomachs along with jaws, reproductive organs and a tag with the date and location of each seal kill. Most seals were taken from July to October (Table 1) and almost all were taken within fiords near the communities.

The stomachs were weighed on a triple-beam balance and all contents were removed and frozen for later processing. In the laboratory all whole organisms were individually weighed and measured. The remaining digested material was sorted into fish, crustaceans, gastropods, cephalopods, clams, etc., and these components, along with whole specimens, were weighed in order to determine composition by weight. Digested material was then further sorted by differential specific gravity in a water bath. Food items were sorted to the lowest possible taxonomic level using published keys and reference collections. In many cases, the number of individuals in each taxon was determined from counts of characteristic hard parts such as the otoliths of fish, beaks of cephalopods, jaws of polychaetes, carapaces of shrimps, and opercula of gastropods.

Fish otoliths are valuable in the interpretation of feeding habits of marine mammals (Fitch and Brownell, 1968; Frost and Lowry, 1981; Finley and Gibb, 1982; in press). Otoliths reveal the identity of the taxon ingested; since the teleost fish has two sagittal otoliths, the number of fish ingested can be estimated as half the number of otoliths within mm length categories. Length distributions of otoliths for certain fish were sometimes determined from subsamples (of one quarter) when the numbers of otoliths in a stomach exceeded 500. Because there are close relationships among otolith length, fish length and fish weight it is possible to estimate the size and weight of fish ingested. Such equations have been developed for *Boreogadus saida* and *Arctogadus glacialis* from the Canadian High Arctic (Finley and Gibb, in press) but are not known for most benthic species of fish that were consumed by bearded seals.

The percent occurrence of food organisms is of limited value in understanding their dietary importance. However, back calculation of weights from diagnostic hard parts provides an important means of estimating the actual biomass contribution of a particular species consumed, particularly since percent occurrence values, as used in many studies of marine mammal diets, are often quite misleading (Frost and Lowry,

1980; Finley and Gibb, in press). The differential retention and digestion of calcareous (otoliths) or chitinous (beaks, operculae) material poses some problems in terms of reconstruction of the recent dietary intake. Finley and Gibb (1982) conducted simple experiments to demonstrate the resistance and retention of chitinous parts. They and Frost and Lowry (1980) considered that otoliths were indicative of food (fish) intake within the previous 24-h period, whereas chitinous beaks were probably retained and were not necessarily indicative of recent ingestion (see also Pitcher, 1980). To compensate for the differential retention Finley and Gibb (1982) included only identifiable remains of cephalopods or beaks with attached flesh as being representative of recent intake. We have taken the same approach in evaluating the relative biomass contribution of various taxa in the bearded seal diet. In addition, we have used the actual wet weight composition of major taxa (i.e. fish, crustaceans, gastropods, clams) to evaluate their relative biomass.

Our samples were too small to permit detailed analysis of food habits by sex and age classes for each of the three areas. Lowry *et al.* (1980) found no differences in the diets of male and female bearded seals but found that older seals (i.e. ≥3 yr) consumed more clams than did younger seals. Our samples consisted of equal numbers of males (18) and females (18). Reproductive organs indicated that 66% of the seals were mature (maturity is reached at about age 5-6 yr in females and 6-7 yr in males — McLaren, 1958; Burns, 1967). Variability in diet is probably more a function of locality than of sex or age (Lowry *et al.*, 1980), so we combined all ages and both sexes for each of the three localities (Table 1).

RESULTS

Diet Composition

All except two of the 36 stomachs contained food, often in considerable amounts. The diet included a remarkable variety of fishes and invertebrates. The following presentation of data is organized by general categories of food organisms; detailed information on species composition is given in Tables 2 and 3.

Fish. Fishes were found in most of the bearded seal stomachs and comprised 85% of all organisms ingested. At least 12 species of fishes, mostly benthic inhabitants, were identified from whole specimens or characteristic remains in the seal stomachs. Arctic cod, *Boreogadus saida*, were especially abundant (52% of all organisms) in the diet of seals from Grise Fiord, whereas sculpins were the most frequent items (49% and 44%, respectively) at Pond Inlet and Clyde. Many of the sculpin otoliths and identifiable remains appeared to be those of *Myoxocephalus scorpius* and *Gymnocanthus tricuspis*. Eelpouts, particularly *Lycodes polaris*, were also found frequently in the stomachs and comprised 6% of all organisms ingested. Polar cod, *Arctogadus glacialis*, comprised 4% of all organisms ingested. Other fish were, in decreasing order of abundance, seapoachers (*Agonus decagonus*), fish doctors (*Gymnelis* sp.), and seasnails (*Liparis* sp.). Fish constituted >90% of the weight in 15 of 19 stomachs that contained >1 kg of food.

Crustaceans. At least 10 species of benthic shrimps were found in the stomachs of bearded seals but the crangonids, especially *Sclerocrangon boreas*, predominated. Crustaceans comprised only 3% of all organisms ingested (Table 3). Their

[a] Numbers in parentheses indicate indigestible material such as squid beaks that were not considered representative of recent intake.
[b] Denominator also includes fish in Table 2.
[c] Includes *Colus* spp. and a few *Acmaea* sp.
[d] Primarily *Sclerocrangon boreas*; also *S. ferox*, *Sabinea septemcarinata* and *Argis dentata*.
[e] Includes *Lebbeus polaris*, *Spirontocaris spinus* and *Eualus fabricii*.
[f] *Hymenodora* sp. and one pandalid.
[g] *Clinocardium ciliatum*, *Astarte borealis*, *A. montagui*, *Mya truncata*, *Musculus niger*, *Macoma* sp. and *Mytilus* sp. from whole specimens or shell fragments.
[h] Probably *Thyonidium* sp.
[i] Genus *Harmothoë*.
[j] Includes various amphipods, one brittlestar, one lampshell, one leech and algae in trace (—) amounts.

wet weight contribution to the stomach contents was always <200 g and in stomachs with >1 kg of food, crustaceans always accounted for <10% of the weight.

Snails. The operculae of snails, particularly *Buccinum* spp., were found in almost all bearded seal stomachs but this indigestible material probably was retained and was not necessarily representative of recent intake. Counts of identifiable bodies of snails showed that they comprised at least 7% of all recently-ingested organisms. Their wet weight contribution never exceeded 200 g in any stomach and comprised <10% of the weight in all 19 stomachs containing >1 kg of food.

Clams. Clams were infrequent in bearded seal stomachs (Table 3). Almost all of the clams enumerated in Table 3 were from a seal taken at Grise Fiord; this individual had fed almost exclusively (600+ g) on *Serripes groenlandicus*.

Cephalopods. Chitinous beaks of the octopod *Bathypolypus arcticus* and an unidentified squid of the genus *Gonatus* were found in many bearded seal stomachs but this indigestible material probably was retained and was not representative of recent intake (*cf.* Finley and Gibb, 1982). Small amounts of soft tissue and a few semi-intact specimens of cephalopods were found in 24% of the stomachs. They comprised <1% of all organisms ingested (Table 3) and <5% of the weight in all 19 stomachs that contained >1 kg of food.

Polychaetes. Small numbers of chitinous jaws of polychaetes, all *Harmothoë*, were found in 41% of the stomachs. The chitinous jaws may not be representative of recent ingestion as no other identifiable remains of polychaetes were found.

Sea cucumbers and anemones. All 109 sea cucumbers found were in the stomach of a single bearded seal, an adult female taken at the Pond Inlet floe edge in July 1979. In this individual, they comprised 34% of the weight of the stomach contents (3.3 kg). Thirteen anemones were found in two stomachs.

Feeding Capacity

The feeding rate of bearded seals is unknown. If the rate is 3-8% of body weight per day, as in some other phocid seals (Sergeant, 1973; Parsons, 1977; Ashwell-Erickson and Elsner, 1981), then an average adult bearded seal (240 kg

— Burns and Frost, 1979) would ingest about 7-19 kg of food per day. The maximum weight of stomach contents that we recorded was 7.6 kg, found in an immature male from Grise Fiord which had fed almost exclusively on arctic cod.

The mean weight of contents for 29 stomachs was 2.0 kg; there were no significant differences in amounts in seals from the three localities (Table 4, Kruskal-Wallis H ≥ 0.30, df = 2, $p > 0.8$). Six of 29 stomachs contained >3 kg of food; in contrast, Kosygin (1971) reported a maximum weight of 2.7 kg in a sample of 565 seals from the Bering Sea, and Lowry *et al.* (1980) recorded an average volume of 670 ml (essentially equivalent to wet weight in g — Pitcher, 1981) in a sample of 50 adult seals from the Bering Sea.

TABLE 4. Average and maximum weights of stomach contents from bearded seals from three arctic localities, 1978-1980[a]

	Grise Fiord $n = 12$	Clyde $n = 7$	Pond Inlet $n = 10$
Range of weights (kg)	0.3 - 7.6	0.6 - 4.1	0.3 - 3.7
Average weights (kg) ± SD	2.18 ± 2.10	2.00 ± 1.17	1.56 ± 1.31

[a] Five of the 34 stomachs that contained food also contained considerable amounts of blood or sea water that had been ingested at the time of death. These were excluded.

Prey Size and Estimated Biomass Contribution

The teeth of the bearded seal are too degenerate to be used for shearing/biting, so the species is limited to prey that it can swallow whole (Vibe, 1950; Burns, 1967). Bearded seals are able, however, to remove the shells of clams and snails before ingesting them. Lowry *et al.* (1980) thought that the bearded seal grasped the exposed foot of a *Serripes* clam in its mouth and somehow tore it from the shell. Vibe (1950) believed that the bearded seal removed *Buccinum* snails from their shells by a sucking action, removing the body along with the opercula. Indeed, freshly-ingested snails do retain the opercula, but our frequent finding of the columella within the snail body suggests that the seal removed the shell by crushing it and ejecting the fragments. The shells of both *Buccinum* snails and *Serripes* clams can be crushed easily with hand pressure. Whatever the means, the energetic return to the bearded seal is not large; the maximum weight of a shelled snail was only 8 g, and that of a clam was only 6 g.

The largest whole fish that we found in bearded seal stomachs were sculpins, *Myoxocephalus scorpius*; the largest individual weighed 190 g. The average weight of 17 *M. scorpius* from seal stomachs was 73 g and that of nine *Gymnocanthus tricuspis* was 69 g. *M. scorpius* is highly sexually dimorphic; for example, a netted sample of 11 females averaged 470 g ± SD 180, whereas 12 males averaged 182 g ± SD 57 (Pond Inlet, 23 December 1979). It is apparent that bearded seals were feeding on the smaller individuals of the sculpin population, and a disproportionate fraction of these probably were males. It appears that the seals would be physically unable to swallow the larger spiny females. A maximum of 1717 otoliths representing at least 858 small sculpins were found in the stomach of one seal.

The frequency distribution of otolith sizes indirectly reveals the size range of arctic cod that were ingested by bearded seals (Fig. 3). The average otolith size (5.5 mm ± SD 1.80) of arctic cod ingested by bearded seals corresponded to a 13.2-cm fish (calculated as per Finley and Gibb, in press). The average wet weight of ingested arctic cod was 30 g. The largest calculated wet weight intake of *B. saida* was estimated at 18.9 kg from 1740 otoliths in the stomach of a bearded seal from Grise Fiord. The size range (maximum size about 22 cm and 80 g) of arctic cod ingested by bearded seals encompassed the size range of arctic cod found around N. Baffin Island (Finley, pers.obs.) and other arctic localities (Hognestad, 1968; Frost and Lowry, 1981; Craig *et al.*, 1982) and the size distribution shows emphasis on the 12-16 cm fish — also the sizes most commonly taken in nets in nearshore areas (Craig *et al.*, 1982; Finley, pers.obs.).

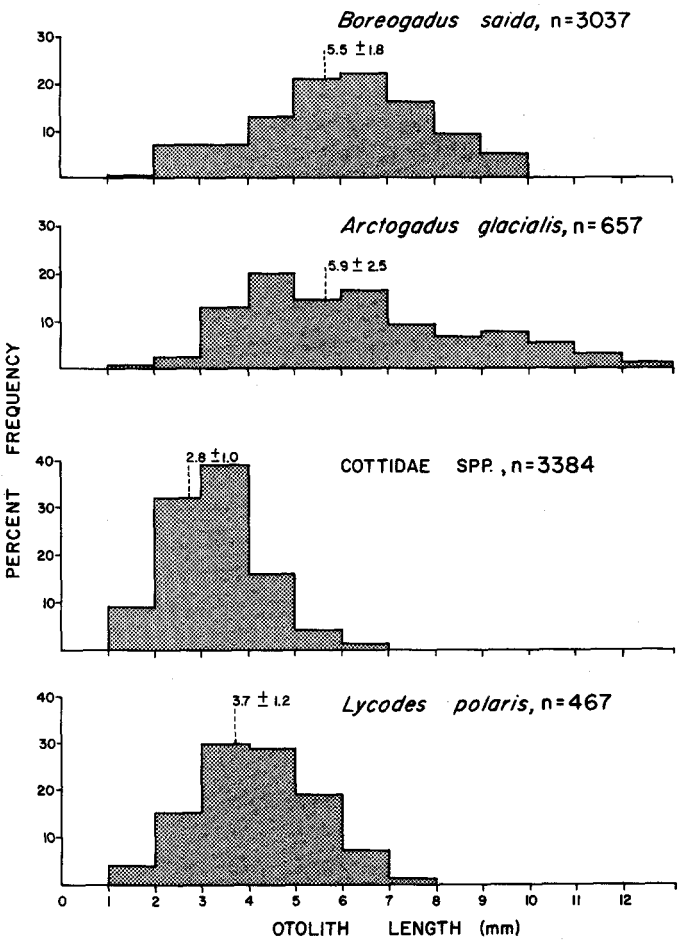

FIG. 3 Frequency distribution of otolith sizes of important fishes found in bearded seals taken in three arctic localities. Sample sizes, means and standard deviations of otolith lengths are given.

Bearded seals ingested a large size range of polar cod (Fig. 3); the average otolith size (5.9 mm ± SD 2.5) corresponded to a 14-cm fish. The average wet weight of an ingested polar cod was 85 g and the largest otoliths indicated that bearded seals had ingested a few individuals up to 340 g in weight (calculated as per Finley and Gibb, in press). The polar cod taken by bearded seals were considerably smaller than those (373 g ± SD 121, $n = 110$ — Finley and Gibb, in press) taken by hook in coastal waters of N. Baffin Island.

Only one intact specimen (108 g) of eelpout (*Lycodes polaris*) was found in a bearded seal stomach. The otoliths of this fish were 5-6 mm long, which is above the average size of eelpout otoliths that we found in bearded seal stomachs (Fig. 3). There are no otolith length-to-wet-weight conversion equations for eelpouts in the Canadian Arctic, but application of a conversion equation developed for the similarly-shaped *L. palearis* in Alaskan waters (Frost and Lowry, 1980) to the otolith size of our specimen shows good agreement between the actual (108 g) and estimated (118 g) weight. From this it appears that the largest specimens of eelpouts (otolith size 7-8 mm, Fig. 3) would not exceed about 200 g wet weight. Bearded seals would be unable to ingest some of the larger specimens of eelpouts such as a 510-g *Lycodes mucosa* that we collected near Pond Inlet in August 1978. A maximum of 234 otoliths representing at least 117 eelpouts were found in a bearded seal stomach.

Other fish in the bearded seal diet were small benthic species such as seasnails, seapoachers and fish doctors. Of these, the seapoachers, *Agonus decagonus*, were the largest specimens (maximum 12 g) that we found in the stomachs. An adult male bearded seal taken in late July at Pond Inlet contained fresh remains of many seapoachers and otoliths that represented at least 112 individuals. The presence of many ripe eggs with the fish bodies indicated that this particular seal had encountered a spawning aggregation.

The invertebrates consumed by bearded seals were generally small. The bottom-dwelling crangonid shrimps *Sclerocrangon boreas* were the largest crustaceans (maximum 30 g) ingested by bearded seals but it should be noted that a proportion of the weight consists of indigestible chitinous exoskeleton. The largest measurable cephalopod, *Bathypolypus arcticus*, weighed about 50 g.

It has already been shown that fish were the major component by weight of the semi-digested stomach contents of the bearded seal, but it is not evident which species or groups dominated. By back calculation from otolith size to wet weight it is possible to derive the wet weight composition of certain species (Frost and Lowry, 1980; Finley and Gibb, in press) but such conversion equations are not available for some species (e.g., sculpins and eelpouts) ingested by bearded seals. However, by substituting average weights of ingested organisms it is possible to roughly approximate the relative composition by weight of the various food organisms (Table 5). This exercise again demonstrates the importance of fish relative to invertebrates in the bearded seal diet, and it emphasizes the greater relative biomass contribution of larger fish such as polar cod and eelpouts (Table 5).

TABLE 5. Summary of occurrence and estimated wet weight of food items from 34 bearded seals taken in the Canadian High Arctic

	Percent occurrence (/34 stomachs)	Percent of food items	Average weight of ingested item (g)[a]	Percent estimated wet weight[b]
Fish	97	85	—	98
Arctic cod	94	36	30	24
Polar cod	47	4	85	8
Sculpin	88	35	70	55
Eelpout	82	6	80	11
Fish doctor	29	<1	5	<1
Seapoacher	29	<1	8	<1
Seasnail	35	<1	10	<1
Unidentified	97	3	10	<1
Invertebrates	100	15	—	2
Snail	82	7	3	<1
Shrimp	88	3	17	1
Clam	26	3	3	<1
Cephalopod	82	<1	20	<1
Polychaete	41	<1	1	<1

[a] Average weights were determined from otolith length - fish weight conversion equations (Frost and Lowry, 1980; Finley and Gibb, in press) or were approximated from actual weights of whole or partial organisms taken from seal stomachs.

[b] Approximate values only.

DISCUSSION

The results of this study provide further documentation of the diverse diet of the bearded seal within its large circumpolar range. Few other seals exhibit such a degree of consumer opportunism. Although bearded seals feed on a wide variety of benthic (both epifaunal and infaunal) invertebrates and demersal fish, they are also capable of exploiting schooling (pelagic and demersal) fish such as arctic cod. This ability to switch from benthic to pelagic feeding was noted by Vibe (1950) in northern Baffin Bay. Recent aerial surveys in late winter showed that some bearded seals do occupy offshore pack ice over deep water (>500 m) in northern Baffin Bay (Finley and Renaud, 1980) and other aerial surveys conducted in association with this study found bearded seals widely distributed in low densities over much of the offshore pack ice of Baffin Bay in June (Koski and Davis, 1979). Presumably they depend on a pelagic food source in Baffin Bay when they are excluded by fast ice from coastal areas.

In coastal waters of the Canadian High Arctic where the bearded seal can reach the bottom, it feeds heavily on benthic fish such as sculpins or takes advantage of schooling fish such as arctic cod. This stands in marked contrast to the situation in the Bering and Chukchi seas where fish are of minor importance in the bearded seal diet (Lowry *et al.*, 1980). Whether this reflects differences in prey availability or in predator selection cannot be evaluated since little is known about the abundance of fish and invertebrates in arctic epibenthic communities.

Most species of arctic fish are found in close association with the bottom. They are generally found under rocks, in

macrophyte beds, or partly buried in soft substrate; they are rarely found on exposed bottom away from cover (Thomson and Cross, 1980). Remotely-employed sampling devices such as otter trawls provide only a rough approximation of the abundance of some species. Trawl sampling and SCUBA diver collections in coastal areas of northern Baffin Island produced 14 species of fish of which the two sculpins, *Myoxocephalus scorpius* and *Gymnocanthus tricuspis*, were the most common species (Thomson and Cross, 1980). The two sculpins were also the most common species found in bearded seal stomachs from northern Baffin Island. Although lumpsuckers (*Eumicrotremus* spp.) were taken in trawl collections they were not found in bearded seal stomachs. Seapoachers (*Agonus decagonus*) were not found in diver and trawl collections. Gill-net catches, although highly selective, also indicate that sculpins, particularly *M. scorpius*, are a dominant component of High Arctic benthic communities. For example, a 24 h set of a 30 m gill-net in 10 m of water at Grise Fiord in September 1979 produced 88 sculpins, primarily *M. scorpius*. A 24 h set of a 50 m gill-net in 40 m of water at Pond Inlet in December 1978 produced 14 *M. scorpius*, 2 *M. scorpioides* and 2 *G. tricuspis* (Finley, pers.obs.).

Burns and Frost (1979) believed that geographic variation in the diet of bearded seals in the Bering and Chukchi seas was a reflection of local faunal differences. This variation was apparent only in the relative amounts of shrimp, crabs and clams that were ingested; fish were always of minor importance. Qualitatively, our results most closely resemble those of Vibe (1950) from nearby NW Greenland, and suggest that the food of bearded seals in these areas reflects the importance of benthic fishes in the composition of benthic communities. An experienced hunter from Grise Fiord, formerly from Port Harrison on Hudson Bay, commented that one of the major differences that he noted in bearded seals from the two areas was that those in Hudson Bay fed on shrimps and clams almost exclusively. Further regional studies on the diet of the bearded seal may provide interesting insight into the composition, distribution and utilization of arctic epibenthic communities.

ACKNOWLEDGEMENTS

This research was funded by Petro-Canada Exploration Inc. as part of a multi-disciplinary research effort, the Eastern Arctic Marine Environmental Studies (EAMES) program. We thank G. Glazier, G. Koenig, W. Speller and B. Veldhoen of Petro-Canada for their support and encouragement.

O. Akeagok of Grise Fiord, P. Aglak of Pond Inlet, and I. Angutijuak of Clyde organized the collection of samples. B. Wooley, N.W.T. Dept. of Fish and Game, provided much support at Clyde. K.J. Frost and L.F. Lowry, Alaska Dept. of Fish and Game, assisted in otolith identification and provided many helpful comments on the manuscript. D.H. Thomson and W.E. Cross of LGL Ltd. assisted in invertebrate identification. F.A. Aldrich and C. Morris, Memorial University of Newfoundland, assisted in octopod identification. J.A. Fournier, Invertebrate Zoology Division, Museum of Natural Sciences, Ottawa, identified the polychaete jaws. R.A. Davis and W.J. Richardson of LGL Ltd. provided constructive comments on the manuscript. We gratefully acknowledge all these people and the many hunters in all three communities who cooperated in this study.

Summer diet of the narwhal (*Monodon monoceros*) in Pond Inlet, northern Baffin Island

K. J. FINLEY AND E. J. GIBB[1]

LGL Limited, Environmental Research Associates, Suite 414, 44 Eglinton Avenue West, Toronto, Ont., Canada M4R 1A1

Received March 29, 1982

FINLEY, K. J., and E. J. GIBB. 1982. Summer diet of the narwhal (*Monodon monoceros*) in Pond Inlet, northern Baffin Island. Can. J. Zool. **60**: 3353–3363.

Stomach contents of 73 narwhals (*Monodon monoceros*) taken in Pond Inlet during June to September 1978–1979 were examined. Arctic cod (*Boreogadus saida*) and Greenland halibut (*Reinhardtius hippoglossoides*) comprised 51% and 37%, respectively, of the diet by weight. Arctic cod contributed 57% in 1978 but only 29% in 1979. Squid (*Gonatus fabricii*) beaks were abundant but not representative of recent intake. Deepwater fish (halibut, redfish (*Sebastes marinus*), and polar cod (*Arctogadus glacialis*)), found primarily in male narwhals, indicate a deep diving (>500 m) capability. The largest measured weight of stomach contents was 10.1 kg and weights projected from otoliths did not exceed 19.6 kg. No selection of prey items by size was evident amongst various sex and age groups of narwhals. Feeding was most intensive at the ice edge and ice cracks but little feeding took place in the fiords during late summer. Blubber thickness declined in females but not in males during the summer. The significance of traditional summering areas appears to be related to calving requirements and not to feeding opportunities.

FINLEY, K. J., et E. J. GIBB. 1982. Summer diet of the narwhal (*Monodon monoceros*) in Pond Inlet, northern Baffin Island. Can. J. Zool. **60**: 3353–3363.

Les contenus stomacaux de 73 narvals (*Monodon monoceros*) de Pond Inlet, recueillis de juin à septembre en 1978–1979, ont été analysés. La saïda (*Boreogadus saida*) constitue 51% de la diète et le flétan du Groenland (*Reinhardtius hippoglossoides*), 37%. Les becs de seiches (*Gonatus fabricii*) sont abondants dans la diète, mais n'en constituent pas les éléments consommés depuis peu. Les poissons d'eau profonde (flétan, le sébaste (*Sebastes marinus*) et la morue polaire (*Arctogadus glacialis*) se retrouvent surtout dans la diète des mâles et reflètent leur aptitude à plonger en eau profonde (>500 m). Le contenu stomacal le plus lourd qui ait été pesé avait une masse de 10,1 kg et la masse maximale, déterminée par l'examen des otolithes, ne pouvait dépasser 19,6 kg. Il ne semble pas y avoir de sélection des proies en fonction de la taille chez les différents groupes d'âge et de sexe. L'activité alimentaire est intense surtout en bordure des glaces et dans les fentes, mais elle est minime dans les fjords à la fin de l'été. L'épaisseur de la couche de graisse diminue à la fin de l'été chez les femelles, mais pas chez les mâles. L'existence de territoires traditionnels d'été semble reliée aux besoins de la reproduction plutôt qu'à l'alimentation.

[Traduit par le journal]

Introduction

The narwhal (*Monodon monoceros*) is a gregarious odontocete whale that inhabits arctic seas bordering the Atlantic Ocean. It is most numerous in Baffin Bay – Davis Strait and adjacent waters of the eastern Canadian arctic (Davis et al. 1980). The narwhal undertakes seasonal migrations from wintering grounds in Davis Strait – Baffin Bay to traditional summering areas in the eastern Canadian high arctic and in northwest Greenland. In summer it concentrates in the fiord complexes of Admiralty Inlet and Eclipse Sound, northern Baffin Island.

Male narwhals (and very rarely females) have a single long tusk. There has been much speculation about the possible role of the narwhals' tusk in feeding (e.g., Vibe 1950) although Scoresby (1820) reasoned that it could not serve such a function as females did well without it. Scoresby (1820, p. 491) concluded that "the tusk is principally, if not solely, a sexual distinction," a hypothesis that is supported by Silverman and Dunbar (1980). Best (1981) reviews the function of the tusk and concurs.

There have been no systematic, quantitative studies of narwhal feeding although anecdotal accounts indicate that it feeds on fish, squid, and shrimp. Scoresby (1820) believed that the principal food was cephalopods. During voyages to the Greenland Sea, Gray (1889) found that narwhal stomachs contained numerous beaks and other remains of a small squid, *Gonatus fabricii*, and, in July, the pelagic shrimps *Pasiphaea tarda* and *Hymenodora glacialis*. In northwest Greenland the summer diet of the narwhal was found to consist mainly of arctic cod (*Boreogadus saida*) with some halibut (*Reinhardtius hippoglossoides*) and shrimp (Vibe 1950). Brown (1868, p. 552) noted that a female narwhal killed in Pond Inlet, northwest Baffin Island, in August 1861 "contained crustaceans, bones of fish, and an immense quantity of the horny mandibles of some species of Cephalopod." Degerbøl and Freuchen (1935) stated that narwhals in Pond Inlet fed on arctic cod, halibut, decapod shrimp, and arctic char (*Salve-*

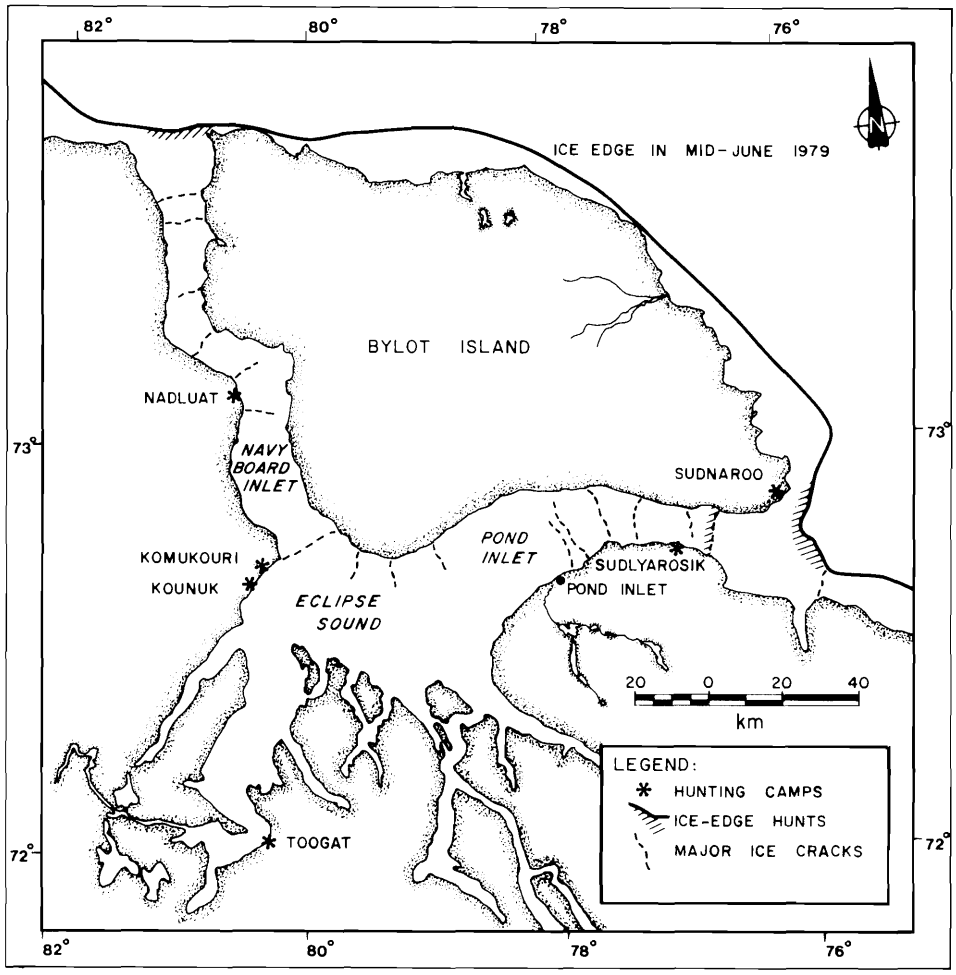

FIG. 1. Pond Inlet area showing positions of ice edges, ice cracks, and hunting areas in 1979. See Finley et al. (1980) for 1978 ice features.

linus alpinus). However, Mansfield et al. (1975) noted that, in spite of large runs of anadromous char in Eclipse Sound near Pond Inlet, no char were found in the stomachs of 62 narwhals netted there in late summer. In fact, they found very little food in the 62 stomachs; identifiable remains consisted only of arctic cod and squid beaks. Observations on the feeding habits of the narwhal have been limited to a rather brief period during the summer and nothing is known of their winter diet.

Narwhals are hunted intensively during the summer by Inuit from northwest Baffin Island (Finley et al. 1980; Finley and Miller 1982). In Pond Inlet, the hunt is conducted in three seasonal phases: at the floe edge, in ice cracks during break up, and during the open water season (Finley et al. 1980; Finley and Miller 1982). The three phases vary in duration depending on ice conditions but generally narwhals are hunted from the ice edge across the eastern entrance of Pond Inlet from mid-June to mid-July, in ice cracks in Pond Inlet briefly during mid-July, and by boat in open water in western Eclipse Sound during August and early September (Fig. 1; see also Finley et al. 1980; Finley and Miller 1982 for details). Specimens killed during the hunt in Pond Inlet – Eclipse Sound from June to September of 1978 and 1979 provided the basis for the present study.

Herein we present a quantitative description of the narwhal diet relative to seasonal changes in ice conditions and movements of the narwhal. We attempt to reconstruct the diet on the basis of the relative biomass contribution from the important dietary components; this approach avoids some of the biases that arise when numerical abundance of different prey items is the only basis of interpretation. Finally we examine blubber thickness as an indicator of condition which may reflect proximate feeding conditions.

Methods

Stomach collection

Narwhals were taken in the same general areas during the same hunting seasons in 1978 and 1979. In both years the

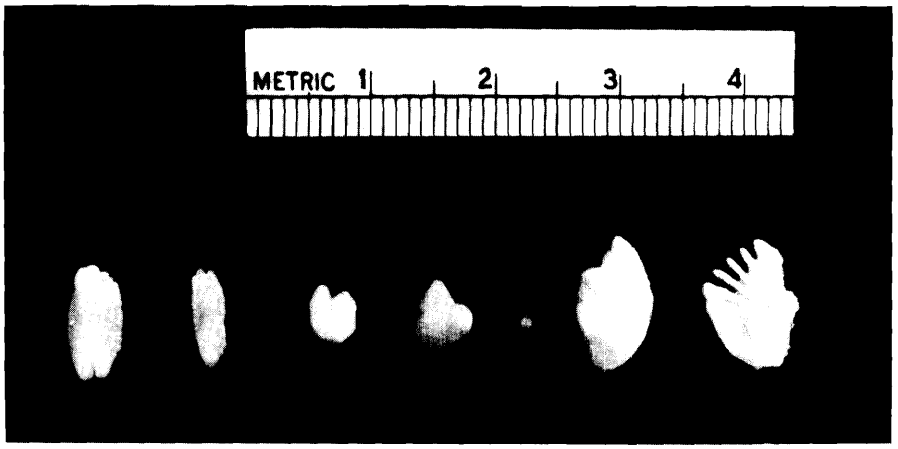

FIG. 2. Fish otoliths from narwhal stomachs. From left to right: *Arctogadus glacialis*, *Boreogadus saida*, *Lycodes mucosus*, *Lycodes polaris*, *Liparis* sp., *Sebastes marinus*, and *Reinhardtius hippoglossoides*.

position of the ice edge was similar (Fig. 1) and all animals that we sampled were taken in areas where the water depth was >500 m. In the Pond Inlet narrows, where the ice crack hunt is conducted, the coast is precipitous and water depth is >500 m in most areas where the narwhals were taken. During the open water season most of the narwhal samples came from the vicinity of Kounuk in Eclipse Sound; water depths in the area were generally <100 m.

Stomachs were excised from narwhals within 1 h after death. All contents were obtained from the forestomach and the epithelium was rinsed for residual matter. We also examined the main and pyloric stomachs but rarely found any identifiable material. Whenever possible the contents of the forestomach were weighed with a spring scale (± 100 g) and then frozen.

Standard measurements (e.g., length, axillary and maximum girths) were taken from all narwhals and the reproductive condition was examined. Measurements and reproductive data were used to differentiate adults from immatures. Mature males were generally >390 cm in length, had a tusk >100 cm long, and a single testicle weight >400 g. Mature females showed indications of ovulation and were >340 cm in length. Blubber thickness (excluding dermis) was measured from a slit cut midlaterally approximately 1.2 m behind the eye.

Laboratory analysis

Stomach samples were thawed and all whole organisms were removed from the sample and then weighed and measured. The remainder of the contents were separated through differential specific gravity in a water bath; denser material such as fish otoliths and squid beaks settled, whereas crustaceans and soft tissues were decanted off. All squid flesh was sorted and weighed.

Fish otoliths are valuable in the interpretation of feeding habits of marine mammals (Fitch and Brownell 1968; Frost and Lowry 1980, 1981; Finley and Gibb 1982). Otoliths reveal the identity of the taxon ingested (Fig. 2). Since the teleost fish has two sagittal otoliths, the number of fish ingested was estimated as half the number of otoliths within millimetre length categories. Because there are close relationships among otolith length, fish length, and fish weight it is possible to estimate the size and weight of fish ingested (Fitch and Brownell 1968). Length and weight equations for two important fish, arctic cod (*Boreogadus saida*) and polar cod (*Arctogadus glacialis*), were determined by Finley and Gibb (1982). Such equations were not available for the Greenland halibut, so we used the average weight (1962 g) of six whole specimens (lengths, 45–61 cm) that we took from narwhal stomachs. This estimated weight is consistent with the weight of 50- to 60-cm halibut from west Greenland (Lear 1968).

Whole crustaceans from narwhal stomachs were identified, counted, and measured. However, crustaceans were usually found in a disarticulated condition and in such cases counts of identifiable heads and telsons were used to estimate the number of each species present. Since there are close relationships among telson length – total length – wet weight, it was possible to estimate wet weight intakes from telsons. We used 27 whole specimens of *Hymenodora glacialis* (50–110 mm in length) from narwhal stomachs to derive conversion equations: total length (in millimetres) = 3.02 (telson length in millimetres) + 0.22, and wet weight (in grams) = 1.63×10^{-6} (total length in millimetres)$^{3.37}$.

All cephalopod beaks were identified (Clarke 1962; Akimushkin 1963) and counted but only beaks with attached muscle were used as an indication of recent ingestion (see below). In all cases the ventral mandibles of the beaks were more numerous than the dorsal mandibles and thus only the former were used to derive total numbers. However, the length of the dorsal mandible was used to estimate the length and weight of ingested squid based on equations developed by Clarke (1962) for squid in the family Gonatidae.

Digestibility of food items

Digestion in odontocete whales is rapid (Shapunov 1971; Gaskin 1978). Indigestible material such as the chitinous beaks of cephalopods, crustacean carapaces, fish bones, and eye lenses are often the only evidence that an organism has been ingested. The chitinous beaks of cephalopods, in particular, appear to be retained for long periods in the stomachs of marine mammals (Clarke and Kristensen 1980; Pitcher 1980). This differential digestibility and retention poses a problem in attempting to reconstruct the composition of the recent diet.

Total stomachs with contents	25	10	20	7	4	7

[a]Numbers in parentheses represent empty stomachs.

We attempted to assess this problem by conducting two simple experiments.

In the first experiment we used HCl to simulate a range (pH 0.9–2.4) of acidic conditions that would be expected in a mammalian stomach and examined the rate of dissolution of fish otoliths, crustacean carapaces, and squid beaks over a period of 24 h. As expected this demonstrated the resistance of chitinous material to acidic conditions while the calcareous otoliths underwent considerable dissolution.

In a second *in vivo* experiment we examined relative digestion and retention of soft and hard tissues of fish, squid, and shrimp in the stomachs of pigs. Two pigs were fed large otoliths from polar cod, squid beaks, and large amphipods (*Anonyx nugax*) 15 and 12 h, respectively, before they were killed and examined. The same pigs were fed whole arctic cod, commercial squid, and decapod shrimps 5 and 2 h, respectively, before they were killed. This demonstrated a nearly equal rate of digestion of soft tissues of fish, squid, and shrimp that had been ingested within the previous 2–5 h. By 5 h little soft tissue remained but otoliths, shrimp carapaces, and squid beaks were still intact. Of the hard parts ingested 12–15 h previously, only a few squid beaks remained.

Thus, in the following presentation of results we assume that soft tissues of prey are digested at nearly similar rates and should reflect, in relative proportions, the prey species most recently ingested. Squid beaks are not necessarily indicative of recent ingestion and we have included in our calculations of dietary contribution only squid beaks with attached muscle as an indication of recent ingestion. Otoliths are considered to be indicators of recent ingestion (probably within the previous 24 h); however, otoliths from larger fish such as halibut may be retained longer than those from smaller fish because the former would not be released as rapidly by digestive processes. Thus, estimates of the biomass contribution of halibut may slightly overestimate the importance of halibut in the narwhal diet.

Results

Diet composition

Table 1 presents the seasonal distribution of 49 stomach samples taken in 1978 and 24 in 1979. Food items were found in 85% of 86 narwhal stomachs examined. All (13) of the empty stomachs were taken during the open water season of 1979. Hereafter all precent occurrence values are related to the 73 stomachs that contained food. Detailed information on the occurrence and numbers of prey items is given in Table 2. The following account is organized by the major prey groups.

Fish

Fish remains were found in 92% of the narwhal stomachs examined in 1978 and 1979 and comprised 93% of the calculated wet weight of contents. Arctic cod were found in 88% of the stomachs. Other teleost fishes, including polar cod, snailfishes (*Liparis* spp.), Greenland halibut, redfish (*Sebastes marinus*), sculpins (Cottidae), and eelpout (*Lycodes* spp.), occurred less frequently and in relatively small numbers compared with arctic cod (Table 2). Arctic cod and Greenland halibut were by far the dominant component of the diet in terms of wet weight.

Cephalopods

Squid (*Gonatus fabricii*) beaks were found in 88% of the narwhal stomachs. However, soft tissue, indicative of recent ingestion, was found in only 33% of the stomachs. Only two entire specimens of *Gonatus fabricii* were found in all of the stomachs examined. Relative to the weight of other stomach contents (mainly fish), squid flesh was insignificant; in no stomach did it exceed 5% by weight of the total stomach contents. Based on beak measurements, we estimated (probably liberally) that squid flesh comprised approximately 7% of wet weight at ingestion.

Although squid was not a dominant food item during the period of study (June–September), it may have much more importance at other times. A total of 10 840 squid beaks was enumerated in 73 stomachs. One additional sickly narwhal that we did not include in our analysis contained about 39 000 squid beaks that had

undoubtedly accumulated over considerable time. There was differential retention of the upper and lower beaks of the squid in narwhal stomachs. Ventral beaks were always more numerous and often were stacked within one another, presumably reflecting prolonged retention and considerable physical activity in the narwhal stomach.

Octopus beaks (*Bathypolypus arcticus*) were found in 16% of the narwhal stomachs but they occurred only in small numbers and no octopus flesh was found.

Crustaceans

Pelagic crustaceans (decapods and mysids) were found frequently in narwhal stomachs but occurred in small numbers and contributed less than 1% of the wet weight intake. Their importance would be considerably overestimated if percent occurrence or numerical abundance were the only method of analysis, as in most previous studies.

Other stomach items

Single gastropod opercula were found in two narwhal stomachs and a limpet shell was found in another. The remains of a skate (probably *Raja hyperborea*), two egg capsules and cartilaginous skeletal material, were found in a mature male narwhal. Small bits of grit were found in 20–30% of the stomachs.

Age- and sex-related variability in the diet

Since hunters strongly select for adult narwhals and for those with tusks (Finley et al. 1980), the majority (76%) of our samples were from adults and 61% of these were males (Table 1). Sample sizes by season and by sex and age were generally too small to permit extensive comparisons, nevertheless some differences in the diet were apparent. All sex and age groups of narwhals fed on arctic cod, squid, and crustaceans but the 35 adult males contained most of the deeper-dwelling fishes. Redfish (in seven individuals) and skate (from one individual) were found exclusively in the stomachs of adult males and 83% of all polar cod otoliths and 84% of all halibut were found in adult males. However, most of the halibut and polar cod came from stomachs taken during the ice crack hunt in 1978 when only three adult female stomachs were examined. None of these 3 females contained halibut and 2 contained polar cod but 8 of 15 males taken during the ice crack hunt contained halibut and 7 of 15 contained polar cod.

Where sample sizes permitted we looked for relationships between narwhal sex or age and the sizes or numbers of arctic cod in their stomachs. In seven adult males and seven adult females taken during the 1978 ice-edge hunt, sizes and numbers of arctic cod were similar (respective mean otolith lengths = 4.2 and 4.8 mm, Mann–Whitney $U = 12$; $n = 7$ and 7; $p = 0.46$; respective mean numbers = 66 and 54, $U = 18$; $p = 0.280$). Nor did we find any differences in sizes of cod consumed between the same adult females and five immature females taken during the 1978 ice-edge hunt (respective mean otolith lengths = 4.8 and 5.1 mm, $U = 13$; $n = 7$ and 5; $p = 0.53$; respective mean numbers of cod = 167 and 100, $U = 16$; $n = 7$ and 5; $p = 0.88$).

We also looked for evidence of differential size selection of squids by various ages (i.e. length intervals) of narwhals but found none.

Temporal variability in diet and feeding intensity

Seasonal variability

During June to September the narwhals moved westward from the floe edge through Pond Inlet into western Eclipse Sound (Fig. 1). In both 1978 and 1979, estimated average weights of stomach contents declined markedly from the ice edge and ice crack seasons to the open water season (Table 3).

In both years, but especially in 1978, arctic cod were most important in the diet of narwhals taken at the ice edge. In both years the estimated wet weight intake of arctic cod decreased (significant difference in 1978) from the ice edge to ice crack period (Table 3). Relatively few arctic cod were taken by narwhals during the open water period in 1978 and very few were taken during this period in 1979. There were no major seasonal changes in the average size of arctic cod ingested, although in 1978 there was a slight but significant decrease in the average size of otoliths from the ice edge to ice crack period (4.76 mm ± SD 1.12 vs. 4.29 mm ± SD 1.08, Mann–Whitney $Z = 2.06$, $p < 0.05$).

In contrast to arctic cod, more polar cod by weight were taken by narwhals moving through the ice cracks than at the ice edge (Table 3). Few polar cod were taken during the open water season in 1978 and none were taken during this period in 1979.

In 1978, halibut predominated in the narwhal diet as they moved through the ice cracks (Table 3). Only 13 halibut were found in narwhals in 1979 and 6 of these were found in one individual taken at the ice edge. The ice crack period in 1979 was of such short duration that little can be said about the importance of halibut during this period compared with 1978. No halibut were taken by narwhals during the open water season of 1978 or 1979.

In both 1978 and 1979, the amount of squid in the diet decreased from the ice edge period to the open water season. There was no evidence of recently ingested squid in the open water diet although beaks were still retained, presumably from feedings earlier in the summer.

There were no apparent seasonal differences in the amount of crustaceans ingested. Small amounts of crustaceans were found in narwhal stomachs throughout the three seasons.

TABLE 3. Seasonal variation in estimated weight contribution of various food organisms in narwhal diet, 1978 and 1979

Period	No. of stomachs	Estimated mean wet weight (g) ± SD				
		Boreogadus	*Arctogadus*	*Reinhardtius*	*Gonatus*	Decapods
1978

Pooled 1979	24	685±1600	326±1351	1062±3612	296±525	15±55
Pooled 1978 and 1979	73	1598±2563	175±782	1156±3082	223±436	14±50

NOTE: For each taxon and year, a Kruskal–Wallis test was used to test for differences in weights within the three seasons. The estimated weight of a particular food item in each stomach was taken as a unit of observation. Significant seasonal differences were found in the 49 samples from 1978 for *Boreogadus* ($H = 6.47$, $p < 0.05$), *Arctogadus* ($H = 6.11$, $p < 0.05$), *Reinhardtius* ($H = 12.86$, $p < 0.01$) and *Gonatus* ($H = 11.56$, $p < 0.01$). Dunn's Multiple Comparison was then used to compare weights for each of these four taxon among the three possible combinations of seasons in 1978. Significant differences were found for *Boreogadus* ($TS = 2.53$, $p < 0.05$), *Reinhardtius* ($TS = 2.42$, $p < 0.05$) and *Gonatus* ($TS = 2.55$, $p < 0.05$) for the ice edge vs. ice crack season.

TABLE 4. Average sizes and numbers of cod and squid ingested by narwhals in the Pond Inlet vicinity, 1978 and 1979

	Year			
	1978 ($n = 49$)	1979 ($n = 24$)	Test statistic Z	P
Boreogadus saida				
Mean otolith length (mm) ± SD	4.6±1.1	4.1±1.3	−1.87	NS
Mean no. fish (and range)	199 (0–1259)	64 (0–590)	−3.19	<0.001
Arctogadus glacialis				
Mean otolith length (mm) ± SD	6.2±0.9	6.8±0.8	−0.29	NS
Mean no. fish (and range)	2 (0–21)	12 (0–214)	−0.72	NS
Gonatus fabricii				
Mean beak length (mm) ± SD	2.8±0.5	3.0±0.5	−3.62	<0.001
Mean no. squid (and range)	170 (0–1392)	106 (9–976)	−2.03	0.04

NOTE: n denotes the number of analyzed stomachs that contained food items. In the Mann–Whitney U-test, the mean otolith/beak length or number in each stomach was taken as a unit of observation. NS, not significant.

Annual variability

The stomachs of narwhals examined in 1979 contained much less food, especially arctic cod, than during the previous year (Table 3). Although the size of arctic cod ingested did not differ significantly between the two years, an average stomach contained significantly more cod in 1978 than in 1979 (Table 4). Considering only the stomachs that contained food items, the mean number of cod per stomach was higher during each of the three seasons in 1978 than during the corresponding periods in 1979. Furthermore, all empty stomachs (13) that we found came from the open water period of 1979.

The average number of squid beaks in narwhal stomachs did not differ significantly between 1978 and 1979 although the squid ingested in 1979 were slightly, but significantly, larger than those taken in the previous year (Table 4).

Feeding capacity and size of prey

Sergeant (1969) estimated that the daily feeding rates of several captive odontocetes, including the white whale *Delphinapterus leucas*, which is closely related to the narwhal, are 4–6% of body weight. It is not known whether feeding rates of odontocetes in captivity can be

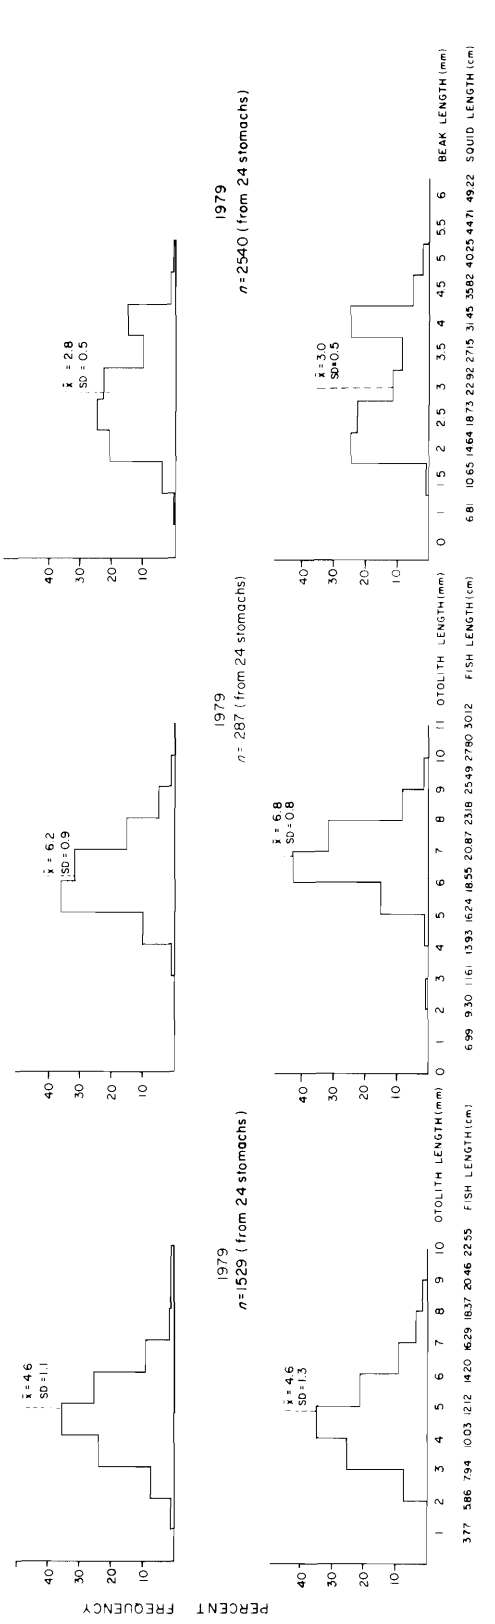

FIG. 3. Size distribution of *Boreogadus saida*, *Arctogadus glacialis*, and *Gonatus fabricii* ingested by narwhals in 1978 and 1979.

applied to the wild state since activity levels, energy requirements, and food availability may be quite different. If these rates do apply to free-ranging narwhals, daily intake would be 45–80 kg assuming weights of 900 kg for an adult female and 1600 kg for a large male (Mansfield et al. 1975).

In 1979 the largest amount of food that we found in any narwhal stomach was 10.1 kg in an adult male and 8.6 kg in an adult female (total weights of stomach contents were not obtained in 1978). In most cases, digestion was well advanced in the forestomach and we found no recognizable remains in the main or pyloric stomachs. Based on the numbers and sizes of otoliths and other remains present, the estimated weight of food items at the time of ingestion never exceeded 19.6 kg. Thus, it is apparent that the stomach contents at any one time represented only a portion of the expected daily intake.

Narwhals consumed arctic cod of similar sizes in 1978 and 1979 (Fig. 3). The average otolith length (4.6 mm) corresponded to a fish with length 11.3 cm and wet weight 9.2 g. The largest wet weight intake of arctic cod was estimated at 13.9 kg from 2500 otoliths in the stomach of an adult male that had fed exclusively on arctic cod at the ice edge in 1978.

Polar cod otoliths from narwhal stomachs were also of a similar size and size range in 1978 and 1979 (Fig. 3). However, the polar cod were much larger than arctic cod taken by narwhals; the mean otolith size (6.5 mm) of the polar cod corresponds to a fish of length 18.6 cm and wet weight 68 g. The largest polar cod taken by narwhals was about 30 cm long. The polar cod taken by narwhals were considerably smaller than those in a sample taken by hook in nearby Arctic Bay in late June 1976 (fork length 309 mm + 28.2 (SD); weight 373 g + 121 (SD); $n = 110$). The largest wet weight intake of polar cod was estimated at 16.6 kg based on 420 otoliths in the stomach of an adult male narwhal taken during the ice crack hunt in 1979. This amount was exceptional; the next largest wet weight contribution of polar cod was 6.5 kg.

The largest whole halibut that we found in a narwhal stomach was 61 cm long and weighed 2378 g. Other whole halibut taken by narwhals were 45–60 cm long. One male narwhal taken at the Pond Inlet ice edge contained two whole and four semidigested halibut weighing 10.1 kg in all. The estimated weight at time of ingestion of these six halibut was 11.8 kg, the maximum estimated amount of halibut in any one narwhal.

The size distribution of squid ingested by narwhals was similar in 1978 and 1979, although the size distribution appeared to be more bimodal in 1979 (Fig. 3). The only whole specimen of squid from a narwhal stomach was 21 cm long and weighed 130 g. Excluding a sick narwhal with 39 000 squid beaks, stomachs contained an average of 170 squid beaks; the maximum for a "normal" individual was 1392 beaks.

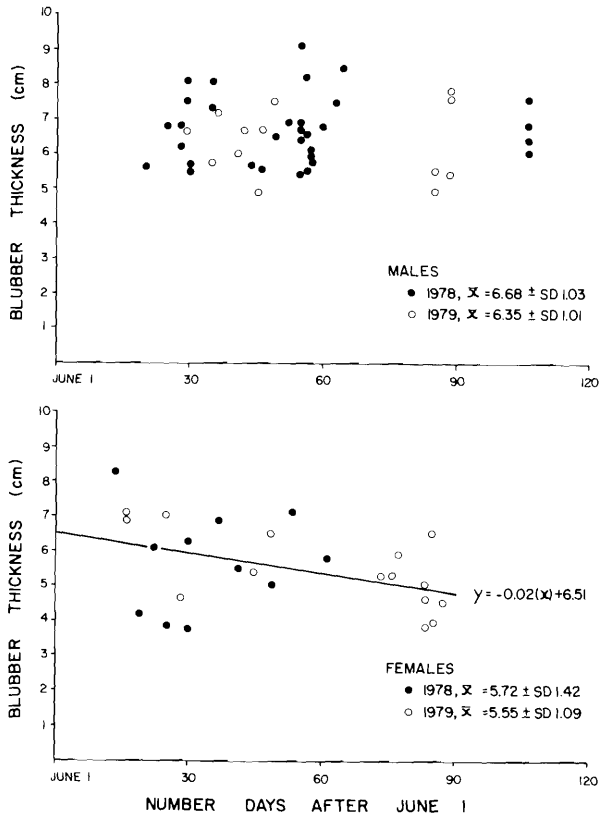

FIG. 4. Variation in blubber thickness of male and female narwhals during the summer seasons of 1978 and 1979.

Some of the crustaceans, especially *Boreomysis* sp., found in narwhal stomachs were of such a small size (30–50 mm) that we wondered whether they had been intentionally ingested or whether they had been released from digested fish stomachs. However, the presence of these crustaceans in samples with few fish remains indicated that they had been purposely ingested.

Blubber thickness

Blubber thickness in whales can be used as a simple index of proximate feeding conditions (Gaskin 1978). In addition to blubber thickness, we also examined a condition index based on maximum girth/length but found that simple regressions of girth to length for 1978 specimens and 1979 specimens showed considerable variation in measurements between the two collections (e.g., $r = 0.26$ for 1978 males, $r = 0.65$ for 1979 males) suggesting inconsistencies in the measuring technique. Blubber thickness showed poor correlation with body length ($r = 0.26$, $p > 0.09$ for males, $r = 0.29$, $p > 0.14$ for females) indicating that it is not a sensitive growth parameter but more purely a condition factor. During the period of sampling in 1978 and 1979, blubber thickness of males remained the same ($r = 0.00$, $p > 0.99$) but that of females decreased significantly ($r = -0.403$, $p < 0.05$; Fig. 4). These results may reflect reduced feeding intensity and (or) additional demands on females with suckling calves.

Discussion

Feeding behavior of the narwhal is not easy to observe and we can only draw inferences based on their stomach contents and their limited activity at the surface, combined with limited knowledge about the distribution and behaviour of prey species.

Feeding at the ice edge in spring

In 1978 and 1979, the occurrence of the narwhals at the Pond Inlet ice edge was sporadic and often they were disturbed by hunters. When undisturbed, their movements were generally parallel to the ice edge but were often interrupted by circling movements and dives that were directed toward the fast ice. Virtually all deep dives (identified by the distinctive flukes-up posture at the onset) were directed toward the fast ice from a distance of usually <10 m; the narwhals moved rapidly downward and disappeared beneath the ice edge. Silverman (1979) described the behaviour of narwhals at ice edges in more detail and reported the average duration of 10 "deep dives" to be 15 ± 7 min. The stomach contents of narwhals taken along the ice edge indicate that they were feeding primarily on arctic cod.

On only one occasion (6 July 1978) did we observe what appeared to be organized feeding activity by narwhals and in this case it was centred about 200–300 m off the ice edge. The group of about 100 appeared to be composed primarily of males organized into several compact units each diving in unison with the distinctive "deep dive" posture. The activity, which lasted about 1 h, was concentrated and quickly attracted an attendant flock of feeding northern fulmars (*Fulmarus glacialis*) and glaucous gulls (*Larus hyperboreus*). A male narwhal killed in the immediate area <1 h after feeding had ceased, contained large amounts of arctic cod. Finley and Gibb (1982) described similar avian–marine mammals "feeding frenzies" that they believed always involved concentrations of arctic cod.

Although narwhals do feed on arctic cod along ice edges there is no evidence that their presence in late June – early July can be attributed to special or favourable feeding opportunities provided by ice edges, as such, or an epontic food chain associated with the undersurface of the fast ice as suggested by Bradstreet and Cross (1982). Indeed during their study, scuba divers at the Pond Inlet ice edge found arctic cod associated with the undersurface of the ice but they were small, widely dispersed and usually inaccessible in crevices along inverted ice ridges (Bradstreet 1982). It is unlikely that narwhals could use this food source. It is possible that arctic cod are more accessible to narwhals in coastal areas (and thus ice edges) but too little is known about

For personal use only.

their distribution for this to be evaluated. Alternatively, we suggest that ice edges act primarily as barriers to movements of narwhals into their traditional summering areas around northern Baffin Island.

Feeding during breakup

As soon as ice breakup begins in July, narwhals move west through ice cracks and enlarged seal holes toward traditional summering areas in Eclipse Sound. Males tend to precede females and their young, and the hunters exercise strong selection for the males (Finley and Miller 1982). In 1978 the breakup was more prolonged than usual and a large number of males were taken. Although our sample is limited largely to males and to the 1978 season, the diet appears to shift to halibut as the narwhals move through Pond Inlet. This indicates a deep diving capability of the narwhal since the inlet is deep (400–1000 m) and Greenland halibut are usually most abundant (in other areas) at depths of 400–800 m (Andriyashev 1964; Nizovtsev 1968). Because of the difficulties of working on the ice during breakup, our observations of "feeding behaviour" at that time are limited. We did observe distinctively marked individuals undertaking deep dives and resurfacing frequently in the same lead or hole in the fast ice. However, narwhals seem to move westward as soon as ice conditions permit. Inuit hunters in western Eclipse Sound reported that narwhals appeared there (a distance of about 100 km) only 1–2 days after they began moving through the ice cracks in Pond Inlet.

Feeding during the open water season

During late summer, after ice has dispersed, narwhals occupy traditional summering areas in western Eclipse Sound, particularly Milne Inlet. The observations of Mansfield et al. (1975) and results of this study indicate that narwhals feed very little during this period. Despite the large runs of anadromous char in this area, none were found in the stomachs of narwhals. H. B. Silverman (1979, personal communication) observed that narwhals spent more time in social interactions while in Eclipse Sound than at the ice edge, and there was little behaviour indicative of feeding. We also noted that narwhals in Eclipse Sound spent much of their time "loafing" at the surface and engaged in local movements. Thus the traditional preference of narwhals for summer areas in Eclipse Sound and Admiralty Inlet does not seem to be related to feeding but may be related to calving, which occurs during July and August (Best and Fisher 1974; Mansfield et al. 1975).

We have few narwhal stomachs from September, but observations strongly suggest that narwhals resume feeding, perhaps intensively, after they leave the summering areas. Finley and Gibb (1982) document several cases of mixed "feeding frenzies" involving narwhals, white whales, and harp seals with attendant flocks of seabirds in late August and September. They suggest that these feeding aggregations involve an inshore movement of arctic cod in late summer. Similarly at Grise Fiord on 14 September 1980, one of us (K.J.F.) observed large numbers of cod driven into shallow water by a feeding aggregation of harp seals and narwhals; the stomach of a male narwhal from this group contained large numbers of fresh arctic cod.

Significance of arctic cod

Arctic cod occupy a key trophic position in the arctic marine ecosystem (Ponomarenko 1968; Hognestad 1968; Frost and Lowry 1981). When they are accessible in local concentrations, they are often heavily utilized by several species of marine mammals including narwhals, while whales, ringed seals, harp seals, and bearded seals (*Erignathus barbatus*) (Davis et al. 1980; Finley and Gibb 1982). In 1978 arctic cod were abundant in the Pond Inlet area apparently accounting for the unusual abundance of harp seals (Finley and Gibb 1982). Arctic cod found in harp seals taken at Pond Inlet in 1978 were the same size (mean otolith length, 4.6 mm) as those ingested by narwhals. The decline of arctic cod in the diet of narwhals between 1978 and 1979 was also observed in the diet of the ringed seals in the same area (K. J. Finley, unpublished data) and was also evident by the absence of harp seals in the area in 1979 (Finley and Gibb 1982). The evidence strongly suggests that arctic cod were not as abundant or available in 1979 as in 1978.

Finley and Gibb (1982) suggest that changes in the numbers and distribution of arctic cod could have profound effects on dependent predators such as the harp seal since there do not appear to be alternate food sources of equivalent abundance or energetic value in arctic waters. The extent to which narwhals are dependent on arctic cod is unknown. At least part of the population is capable of obtaining halibut in the Pond Inlet area; however we did not observe a switch to this prey item when arctic cod appeared unavailable in 1979 nor did we note any movement of narwhals away from the summering areas as was noted with harp seals (Finley and Gibb 1982) and ringed seals (K. J. Finley, unpublished data) when arctic cod appeared to be scarce.

This study provides only a brief seasonal view of the narwhals' feeding habits. Nothing is known about their diet or feeding behaviour during October to June. The numerous squid beaks found in narwhal stomachs in spring may be indicative of a very different feeding habit during the winter. Indeed, it is possible that during much of the year the narwhal is primarily a squid eater or "teuthophage" as proposed by Tomilin (1957).

Acknowledgements

This research was funded by Petro-Canada Exploration Inc. as part of a multidisciplinary research program, the Eastern Arctic Marine Environmental

Studies (EAMES) program. We especially thank G. Glazier, H. Hume, G. Koenig, W. Speller, and B. Veldhoen of Petro-Canada for their support. The hunters of Pond Inlet, particularly P. Aglak and S. Attagotak, were very helpful in collecting samples. H. Silverman of McGill University provided many of the narwhal stomachs from 1978. G. W. Miller of LGL Ltd. provided much assistance in the field. D. Thomson of LGL Ltd. provided expertise in invertebrate identification. J. Fitch, California Department of Fish and Game, and L. F. Lowry, Alaska Department of Fish and Game, assisted in otolith identification. R. A. Davis and W. J. Richardson of LGL Ltd. provided helpful guidance and assistance throughout the study. Thanks also to K. Hay, L. F. Lowry, and E. H. Miller for their constructive reviews. We are grateful to all these people.

Marine Mammals Inhabiting the Baffin Bay North Water in Winter

KERWIN J. FINLEY[1] and WAYNE E. RENAUD[1]

ABSTRACT. Aerial surveys in March-April 1978 and March 1979 showed that some species of marine mammals overwinter in isolated areas of open water in the North Water in northern Baffin Bay. About 700 walruses and 37 bearded seals were seen, most over deep water (200-500 m) near SE Ellesmere Island in March 1979. Both species were much less common in 1978. Approximately 500 belugas were found in recurrent leads along the edge of the fast-ice in eastern Jones and Lancaster sounds and, to a lesser extent, in Smith Sound. Only 12 narwhals were seen. It has been concluded that the North Water is not a major overwintering area for marine mammals.

RÉSUMÉ. Les reconnaissances aériennes effectuées en mars et avril 1978 et en mars 1979 ont montré que quelques espèces de mammifères marins peuvent passer l'hiver dans les aires isolées des eaux libres dans les "Eaux du Nord", au nord de la baie de Baffin. En mars 1979, environ 700 morses et 37 phoques barbus ont été observés, la plupart à la surface des eaux profondes (200-500 m.), près de la partie sud-est de l'île Ellesmere. Ces deux espèces étaient moins fréquentes en 1978. Environ 500 bélougas furent découverts dans les fissures qui se forment périodiquement sur les bords de la banquise dans les parties orientales des détroits Jones et Lancaster, et á un moindre degré, dans le bras de mer Smith. Seulement 12 narvals furent apercus. Ainsi, les "Eaux du Nord" ne sont pas une aire majeure d'hivernage pour les mammifères marins.

INTRODUCTION

In northernmost Baffin Bay, between NW Greenland and the islands of the Canadian High Arctic, isolated areas of open water persist throughout the winter. During spring and early summer the open water expands greatly as the pack-ice drifts southward. This "great open sea" or "North Water" was a haven for the 19th-century whalers who pursued the bowhead or Greenland right whale (*Balaena mysticetus*) northward in the spring through the treacherous pack-ice of southern Baffin Bay (Markham, 1874). Explorers who overwintered in the area (Kane, 1854; Hayes, 1867) noted the profound influence of the open water on the climate and the lives of the Thule Inuit of NW Greenland, who depended primarily on the sea for subsistence. The North Water continues to be the subject of oceanographic and climatological studies (Dunbar *et al.*, 1967; Dunbar and Dunbar, 1972), and satellite imagery has documented its extent and seasonality (Aber and Vowinckel, 1972).

Except for a few early anecdotes, little is known about the biological significance of the North Water during winter. Some workers have speculated that it is a winter refugium for beluga (white) whales, *Delphinapterus leucas*, and narwhals, *Monodon monoceros*, far to the north of the nearest areas of extensive open water (Sergeant and Hoek, 1974; Sergeant and Brodie, 1975; Mansfield *et al.*, 1975). The possibility of oil and gas exploration in northern Baffin Bay provided the

[1]LGL Ltd., environmental research associates, 44 Eglinton Avenue West, Toronto, Ontario, Canada M4R 1A1

incentive and funding to assess the significance of the North Water for marine mammals. In this paper we present the results of aerial surveys for marine mammals in the winters of 1978 and 1979. Observations of birds during these surveys are presented elsewhere (Renaud and Bradstreet, 1980.)

METHODS

Two aerial surveys were conducted over the North Water in 1978: 1448 linear km on 15-17 March and 1506 km on 18-20 April. Inclement weather in 1979 prevented a complete survey of the North Water, but 1158 linear km of surveys were flown. Place names referred to in the text are shown in Figure 1 and survey routes are shown in Figures 2 and 3.

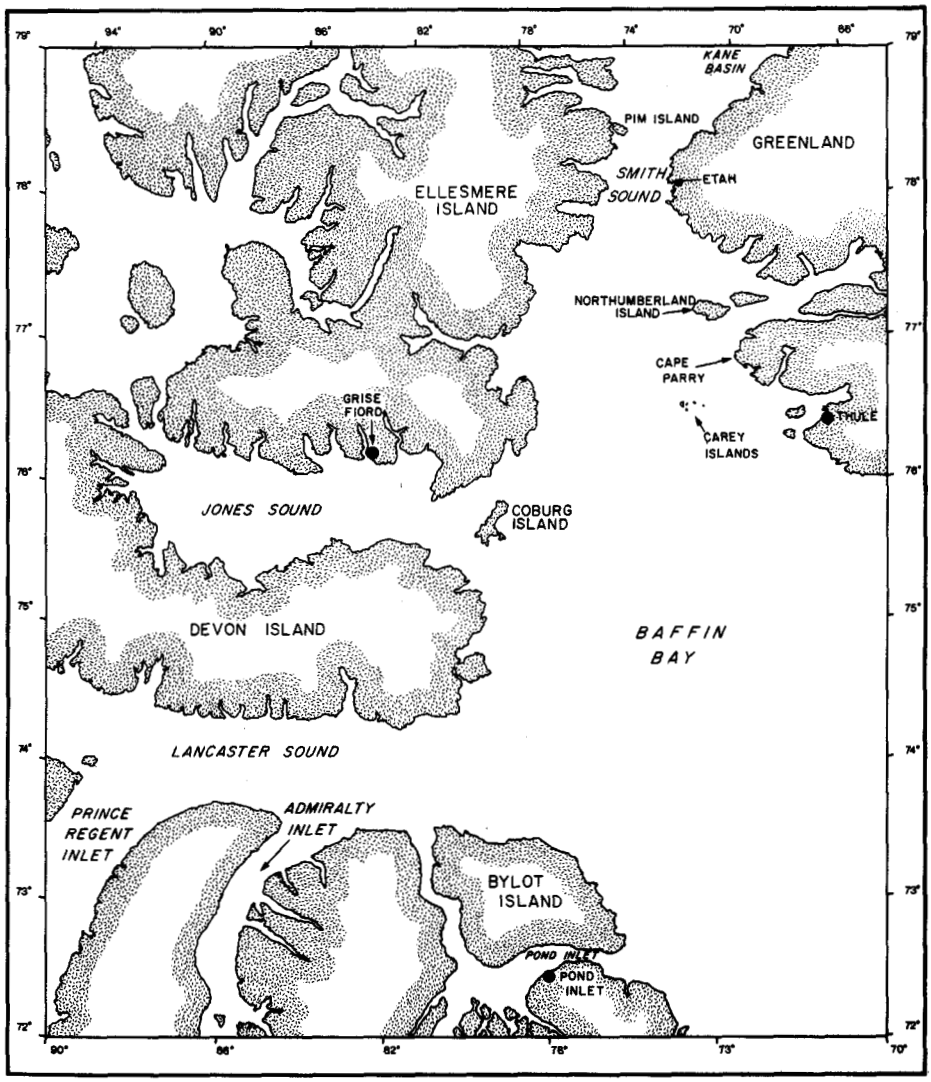

FIG. 1. Study area showing the place names mentioned in the text.

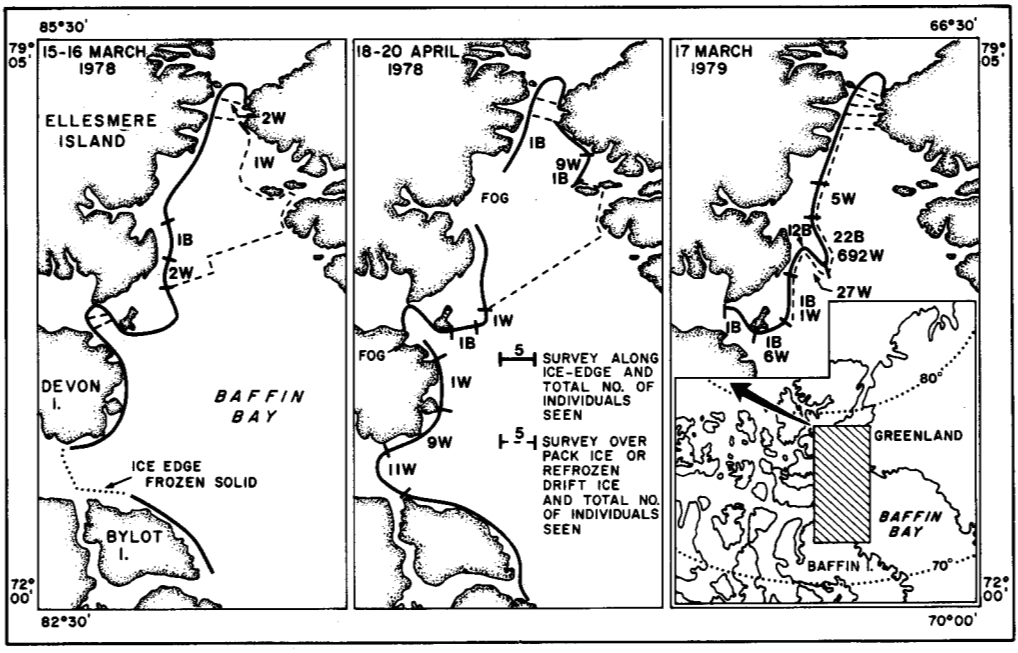

FIG. 2. Distribution of walruses (W) and bearded seals (B) in the North Water, late winter 1978 and 1979.

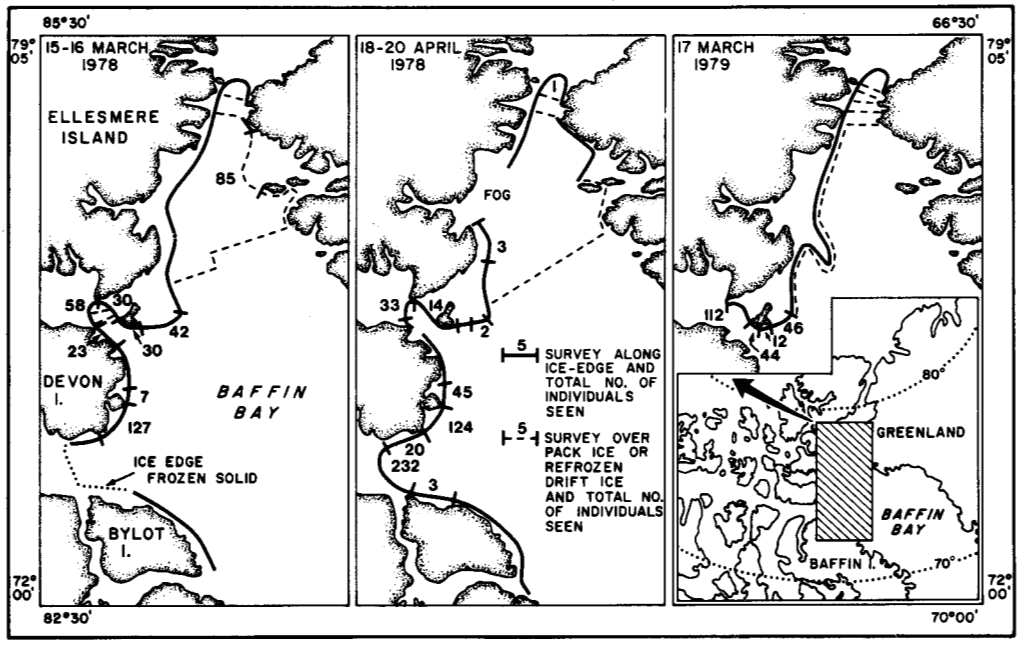

FIG. 3. Distribution of belugas in the North Water, late winter 1978 and 1979.

Surveys were conducted in a de Havilland Twin Otter, usually at altitude 100-200 m ASL and airspeed 200-220 km/h. Occasionally we flew at lower altitudes (about 50 m ASL) or airspeeds (185 km/h) when low cloud or fog was encountered, or when it was necessary to examine animals more closely. Two observers were present, one in the right front (co-pilot's) seat and another in the passenger area on either the right or left side depending on whether open water was present on one or both sides of the aircraft. Because open water was usually restricted to narrow leads (< 500 m wide) along the edge of the fast-ice, most surveys were flown about 50 m to the left of the lead with both observers seated on the right side of the aircraft. When wide leads were encountered, the aircraft was flown 500 m off the ice edge and the observers surveyed on both sides of the aircraft. Offshore transects over open water and pack ice were also flown with the observers surveying on both sides of the aircraft.

Observations of mammals, birds and ice conditions were dictated into tape recorders. Times of all observations were recorded and positions were fixed from landmarks and a Global Navigation System (GNS-500). For each individual or group of animals, the observer recorded the number of individuals, behaviour, and habitat. Whenever possible and appropriate, age, sex, direction of movement and reaction to aircraft were also recorded.

ICE CONDITIONS

In late winter, the west, east and north margins of the North Water are sharply defined by landfast ice-edges along the periphery of the eastern Canadian arctic archipelago and NW Greenland, and across Smith Sound (Figs. 4, 5). The southern limits of the North Water are defined more diffusely by the heavy pack-ice of Baffin Bay. Typically the North Water is most restricted in area during March and begins to enlarge in early spring as the pack-ice in Baffin Bay drifts to the south.

In March of 1978 and 1979, the extent of the North Water appeared typical (*cf.* Anon., 1970; Aber and Vowinckel, 1972; Lindsay, 1975), with the exception that Lancaster Sound was frozen solid to its eastern entrance. Usually Lancaster Sound is covered by pack-ice that remains in intermittent restricted motion throughout the winter (Anon., 1970). In both 1978 and 1979 Lancaster Sound remained frozen, with an ice-edge across its entrance, until July.

Calm cold conditions prevailed during the surveys in March 1978, and areas of open water were very restricted along the fast ice-edges and almost non-existent elsewhere (Fig. 6). At this time the most extensive open water (up to 500 m wide) occurred along the ice-edge across the mouth of Jones Sound. In Lancaser Sound open water was restricteed to intermittent narrow leads between the pack-ice and fast-ice along NE Bylot Island. Open water was less extensive than expected in Smith Sound; the area between the landfast ice-edge across the sound and the pack-ice to the south was covered by a continuous sheet of new ice. This was, no doubt, a temporary phenomenon attributable to the calm, cold conditions. The ice-edge along the coast of NW Greenland was less distinct than elsewhere, and much of the survey in this area was flown over pack-ice interspersed with narrow leads.

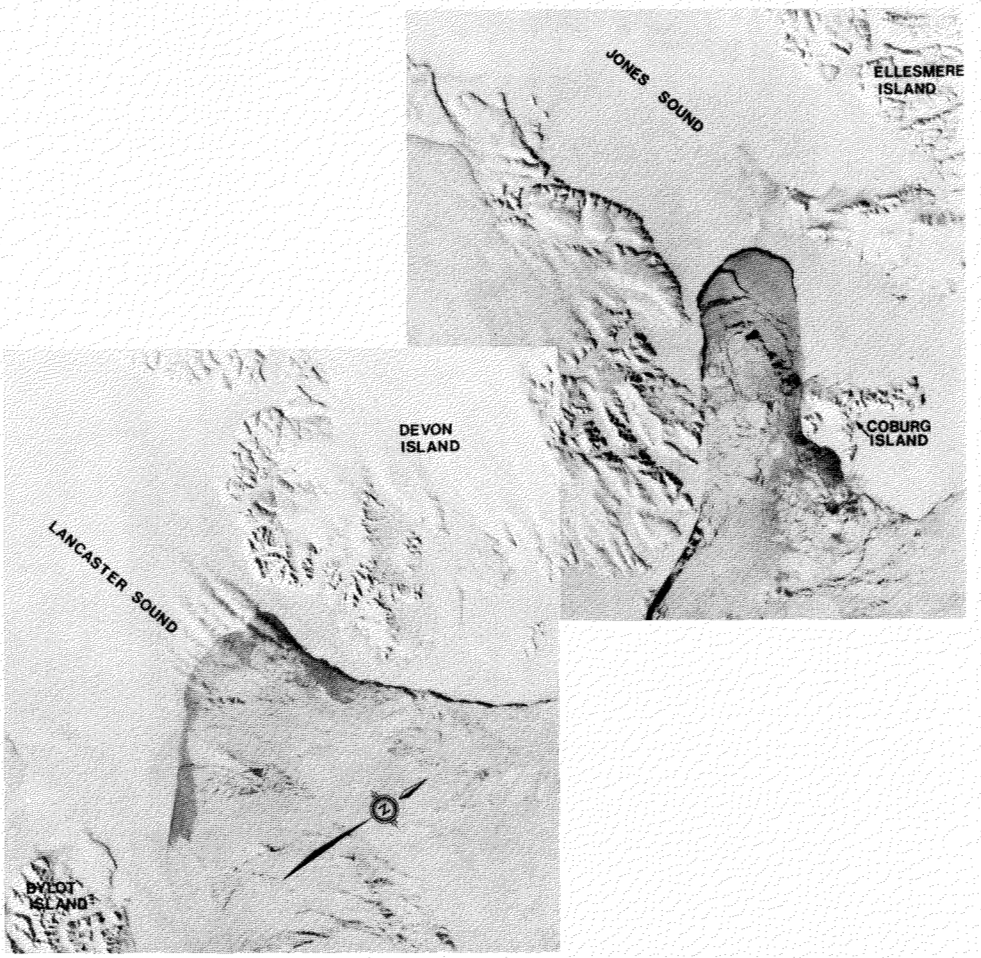

FIG. 4. Ice conditions in the vicinity of Jones and Lancaster sounds, 7 April 1978 (LANDSAT Imagery).

In March 1978, offshore Baffin Bay was almost entirely covered by pack-ice; open water was restricted to occasional cracks and narrow leads, particularly around the Carey Islands. Newly forming ice in most areas of open water in March 1978 appeared to be quickly consolidated into extensive thin ice that was more or less continuous with the pack-ice fields. The gradation of ice thickness is evident in LANDSAT imagery (Figs. 4, 5); however, it is often impossible to distinguish thin ice from open water on LANDSAT imagery, and consequently the open water appears more extensive than it really is.

By mid-April 1978, the leads along ice-edges had widened and the adjacent pack-ice was somewhat more dispersed than in March. A frozen lead that had extended across the entrance to Lancaster Sound in March had opened by April. Its western margin was the Lancaster Sound ice-edge, which persisted until mid-July.

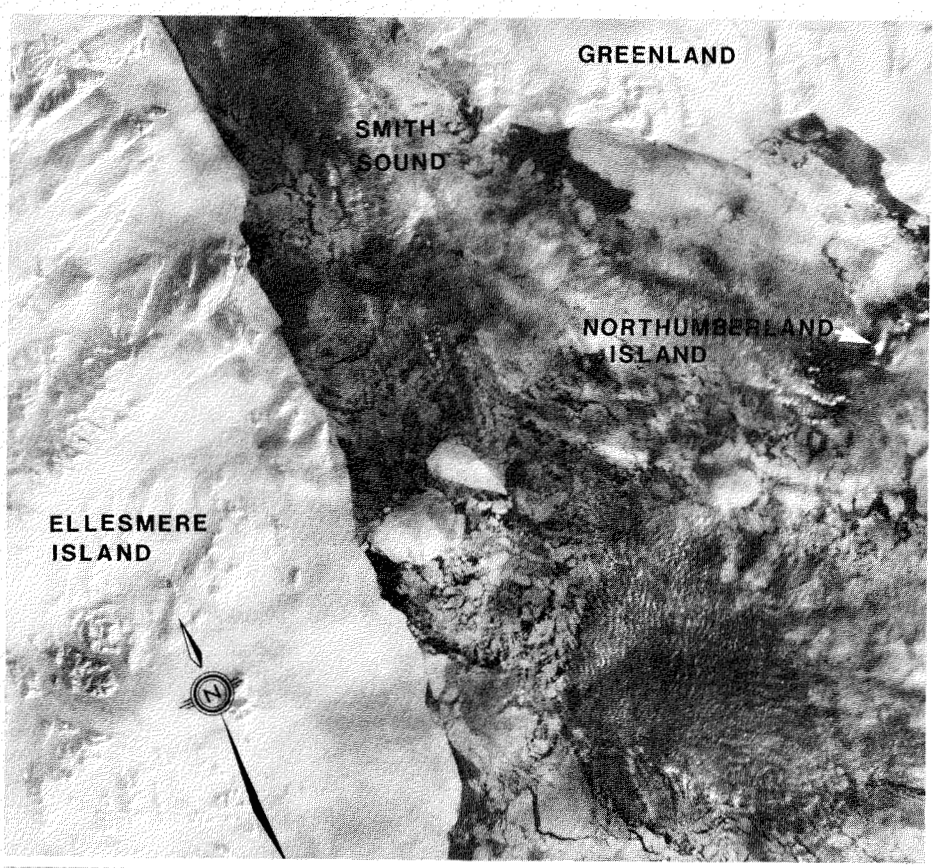

FIG. 5. Ice conditions in Smith Sound and northern Baffin Bay, 16 March 1978 (LANDSAT Imagery).

The positions of the ice-edges in March 1979 were similar to those in March 1978. However, the pack-ice was more dispersed in 1979, probably because of the extensive weather disturbances that also prevented completion of our surveys.

RESULTS AND DISCUSSION

Polar Bear

Stirling and Archibald (1977) suggested that polar bears (*Ursus maritimus*) tend to concentrate in areas of unstable ice where they can prey upon immature ringed seals. However, our limited evidence indicates that polar bears were not particularly concentrated along ice-edges bordering the North Water; few bears or bear tracks were seen during our surveys. Only four single adults were seen during the March 1978 survey and none were seen in April. Only one adult was seen during the March 1979 survey. All polar bears were seen along the edge of the fast-ice, and most (4 of 5) of these were along SE Ellesmere Island.

Ringed Seal

The ringed seal (*Phoca hispida*) is the most abundant marine mammal in the Arctic. During March and April, adults occupy areas of stable fast ice, which is

FIG. 6. A narrow intermittent lead along the east coast of Ellesmere Island, 17 March 1978. The consolidated pack-ice field of northern Baffin Bay is on the right side of the lead and the fast-ice is on the left.

critical for pupping, whereas subadults are thought to be excluded from prime breeding habitat and occupy areas of thin, unstable ice (McLaren, 1958a). Throughout the winter ringed seals are able to maintain breathing holes in solid ice and they are seldom seen before May and June when they begin to haul out on the ice near their holes (Finley, 1979).

Few ringed seals were observed during aerial surveys of the North Water. Four were observed in March and seven in April of 1978; only two were observed in March 1979. Most of these seals were swimming in narrow leads along the fast-ice, although in April 1978 four were observed hauled out on thin ice in Smith Sound. Some seal breathing holes were seen in thin ice.

Bearded Seal

During the winter, bearded seals (*Erignathus barbatus*) are mostly restricted to areas where ice cover is thin or broken. In addition, since bearded seals are normally bottom feeders, they must have access to relatively shallow areas where benthic prey is available (Vibe, 1950; Burns, 1967). Burns and Frost (1979) concluded that bearded seals in the Bering Sea were restricted primarily to waters of less than 100 m where they had access to drifting ice upon which they could haul out. Stirling *et al.* (1977) found that bearded seals preferred shallow areas (< 75 m) in the Beaufort Sea.

Few bearded seals were seen during the two surveys in 1978; only three were observed in March and eight (hauled out on the ice) in April. Seven of these seals were seen along the east coast of Ellesmere Island (Fig. 2).

During the 1979 survey along the east coast of Ellesmere Island a total of 37 bearded seals was seen (about 0.1/linear km, compared with 0.02/linear km in April 1978). At least 21 of these 37 bearded seals were in areas where water depths exceeded 500 m. The others were in areas where the average water depth exceeded 200 m. These depths are much greater than those where bearded seals have been found previously (*cf.* Stirling *et al.*, 1977; Burns and Frost, 1979), although little is known of the winter distribution of this species.

Bearded seals tend to be solitary throughout most of the year (Burns, 1967). Their clumped distribution off SE Ellesmere Island in March 1979, including at least four closely associated pairs, suggests the occurrence of breeding activities. However, conception does not occur until April or May (McLaren, 1958b; Burns, 1967).

Walrus

Walruses (*Odobenus rosmarus*) overwinter in areas with sufficient open water and productive bivalve communities in relatively shallow water. Kane (1892:348), who spent two winters (1853-1855) near the North Water, was "inclined to the opinion that walruses frequent the half broken ice margin throughout the year". Hayes (1867:245), who spent the winter of 1860-61 near Etah, NW Greenland, remarked that in February "The walrus had been very numerous in the open waters outside the harbour all through the winter, and their shrill cry could be heard at almost any time from the margin of the ice". Although some walruses overwinter in polynyas around NW Devon Island (Davis *et al.*, 1978; Kiliaan and Stirling, 1978) and off NW Greenland, the majority are thought to migrate to more southerly wintering grounds along the west Greenland coast (Freuchen, 1921; Vibe, 1950; Loughrey, 1959).

During aerial surveys, walruses on ice pans can be detected from a distance of several kilometres (Estes and Gilbert, 1978). In addition, their presence is often evident from faecal staining of ice pans or from distinctive patterns created when walruses surface through thin ice.

Few walruses or signs of walruses were seen during the surveys in 1978; five walruses were seen in March and 31 in April (Fig. 2). The majority of those seen in April were in the Lancaster Sound - SE Devon Island area, where none had been seen in March.

About 700 walruses were seen in March 1979; all were near SE Ellesmere Island where few walruses had been seen during March-April of 1978 (Fig. 2). The estimate of 700 walruses is approximate because most of these walruses were huddled closely together in groups as large as 45-50 individuals. Attempts at closer examination from 100 m ASL were abandoned because many walruses entered the water before they could be counted. It was rarely possible to determine sex or age, but at least two yearlings were seen, each in close

association with an adult. Most of the 700 walruses were hauled out along the edges of cracks and narrow leads in the pack-ice field close to the fast-ice edges.

Most of the 700 walruses seen in March 1979 were clumped in an area where water depths ranged from 200 to over 500 m. Extensive faecal staining on the ice suggested that they were able to forage in this area, although it is generally believed that walruses cannot feed at depths greater than 80 m and are, therefore, restricted in distribution to shallow waters (Vibe, 1950; Mansfield, 1973; Fay *et al.*, 1977). However, previous discussions of walrus distribution and diving capability have been circular in logic, because statements about diving capability have been based largely on distribution relative to water depth.

The occurrence of large numbers of walruses in the North Water in March 1979 and their virtual absence in early 1978 is not readily explained in the context of the considerable literature about walrus distribution and migrations in this area (*cf.* Freuchen, 1921; Vibe, 1950; 1967; Loughrey, 1959; Mansfield, 1958; 1966). Major wintering grounds formerly were considered to be on the west coast of Greenland between 66° and 69° (Freuchen, 1921) and along the south margin of the Davis Strait pack-ice (Loughrey, 1959; Vibe, 1967). Because of the great distance (about 1000 km) between summering and wintering areas, Freuchen (1921) and Vibe (1967) believed that the migration was not annual but continuous, and that walruses sought favourable ice conditions and foraging areas along the way. However, the Pacific walrus undertakes annual migrations that, in some cases, cover round-trip distances of at least 3200 km (Burns, 1965).

Beluga or White Whale

Belugas vacate their summering areas in the central Canadian High Arctic during September and October (Davis and Finley, 1979). Occasionally some are trapped during freeze-up and attempt (usually unsuccessfully) to maintain breathing holes in the ice (Hill, 1968; Freeman, 1968; Davis and Finley, 1979). However, most of the population of about 10 000 have moved eastward through Lancaster Sound by early October. It has been suggested that these belugas probably make only local migrations and overwinter in the North Water, thus isolating them from populations in west Greenland and southern Baffin Bay (Sergeant and Hoek, 1974; Sergeant and Brodie, 1975). However, this suggestion is unproven. Vibe (1950) suggested that small numbers of belugas may overwinter in the North Water, but he knew of only one winter record: on 6 February 1923, a herd of belugas was observed off Cape Parry (Nielsen, in Vibe, 1950).

We observed 402 belugas during the North Water survey in March 1978; most were in narrow leads along SE Devon Island (134 or 2.1/linear km) and along the Jones Sound ice-edge (183 or 1.8/linear km) (Fig. 3). North of 76°N, the only belugas observed were groups of 35 and 50 in heavy pack-ice near Northumberland Island close to where Nielsen (in Vibe, 1950) had seen a herd in the winter of 1923. The groups of belugas in Lancaster Sound, Jones Sound and Smith Sound appeared to be at least temporarily isolated from one another by extensive areas of impenetrable ice.

A herd of about 100 belugas was seen near Pim Island in Smith Sound on 5 April 1978 (Corp. T. Grant, R.C.M.P., pers. comm.). By mid-April the ice had begun to disperse somewhat and many belugas had moved southward to the entrance of Lancaster Sound (Fig. 3). On 18 April, 189 belugas (2.1/linear km) were seen along SE Devon Island and 232 (2.9/linear km) were seen along a newly formed lead across the mouth of Lancaster Sound. Most of the whales seen along SE Devon Island were moving southwest. When the Lancaster Sound ice-edge was resurveyed two days later, 303 belugas (3.8/linear km) were seen. We saw fewer belugas in and near Jones Sound in April (49) than in March (183), and we saw only four belugas in Baffin Bay north of 76°N during April.

An incomplete survey of the North Water on 17 March 1979 revealed a distribution of belugas similar to that during March 1978. All 214 belugas seen during March 1979 were in the vicinity of Jones Sound and Coburg Island (Fig. 3). The density there (1.6/linear km) was similar to that recorded there in March 1978 (1.8/km).

Most of the belugas observed during the March-April surveys were in narrow leads along the edge of the fast-ice. Their presence was usually evident from the distinctive patterns of breathing holes that they left in thin ice. In several instances belugas were observed beneath ice cupolas (Fig. 7).

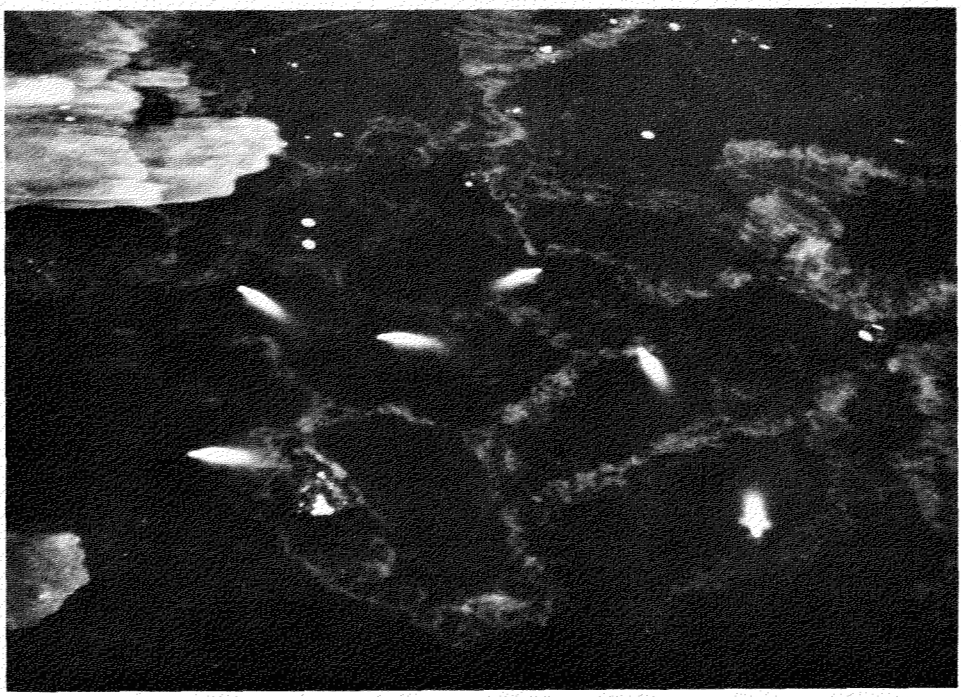

FIG. 7. Six adult belugas lie beneath a thin sheet of ice. The white spots are areas where exhaled air has been trapped beneath the ice. The light diffused patterns are thin sheets of ice that have rafted together.

Many of the groups of belugas along the Jones and Lancaster Sound ice-edges consisted of adults (presumably females) accompanied by immatures. Of 82 belugas classified as adults during the March 1978 survey of these areas, at least 38 were closely accompanied by immatures. Many of the other adults were near immatures but the degree of association was not clear. Of 232 belugas classified as adults during the April 1978 survey, at least 86 were in close association with immatures and many additional immatures were interspersed among the other adults (Table 1). Groups composed entirely of large adults were uncommon

Table 1. Age composition of belugas observed in Lancaster and Jones sounds during Northwater surveys in 1978 and 1979.

Survey Date	Adult		Immatures		Not Classified
	#	%	#	%	
March 1978	82	55	67	45	168
April 1978	232	66	120	34	126
March 1979	81	62	50	38	83

along the Jones and Lancaster Sound ice-edges, but the two groups (total of 85 belugas) observed on 16 March 1978 off NW Greenland consisted entirely of adults. In March 1979, only three all-adult groups (consisting of 4, 5 and 8 individuals) were positively identified. At least 45 of 81 other adult belugas were closely associated with immatures. Subjectively, the proportion of immature belugas and of adult-immature groups seemed high and the proportion of all-adult groups seemed low in relation to our unsystematic observations in the summering areas.

During the period of maximum ice cover, belugas overwintering in northern Baffin Bay appear to be restricted to isolated areas of open water along SE Devon Island, in eastern Jones Sound, and in Smith Sound. Overwintering belugas are apparently most numerous in Jones Sound and along SE Devon Island, which suggests that conditions for overwintering are more favourable or dependable here than in Smith Sound. The extensive formation of new ice that we observed in March of 1978 and 1979 along the Smith Sound ice-edge may preclude continuous occupation of this area by belugas during the winter. Because belugas were very conspicuous and restricted to narrow leads in March 1978, we believe that we detected most of the belugas in northern Baffin Bay. No belugas were observed during offshore transects over the pack-ice and there was no evidence of their conspicuous breathing holes in areas of thin ice. We estimate that about 500 belugas wintered in the North Water in 1978 and it appeared that similar numbers were present in 1979 although we were unable to complete the survey. Clearly, most of the eastern Arctic belugas do not overwin-

ter in the North Water. Vibe (1950) stated that belugas left the Thule area of NW Greenland when ice began to form in October and followed the coast south. These animals are thought to winter along the west coast of Greenland between Disko Bay (70°N) and 63°N (Vibe, 1967; Kapel, 1977).

Narwhal

Narwhals vacate their summering areas in the eastern and central Canadian High Arctic during September and October (Johnson *et al.*, 1976; Finley and Johnston, 1977). Kane (1892) considered their presence in the North Water during winter to be accidental; Inuit of Etah, NW Greenland, secured a young narwhal in the winter of 1854-55. Mansfield *et al.* (1975:1042) suggested, however, that narwhals "probably spend the winter in open water in Baffin Bay, especially in the 'North Water' . . .".

Only one small group of 12 narwhals was observed during the three March-April North Water surveys. They were along the east coast of Ellesmere Island near 78°N on 17 March 1979. The group consisted of seven adult females (one of which was accompanied by a small calf), two adult males, and two individuals of undetermined status.

THE NORTH WATER AS OVERWINTERING HABITAT

In mid-March of 1978, heavy pack-ice covered offshore areas of northern Baffin Bay and most leads had recently frozen over because of prevailing calm conditions. The action of winds and currents on the pack-ice of northern Baffin Bay produces narrow leads along landfast ice-edges at the northern perimeter of the pack-ice. Areas of open water appear to be found most consistently along SE Devon Island, in eastern Jones Sound and, less reliably, in Smith Sound (Figs. 4, 5). These areas of open water provide limited overwintering habitat for some species of marine mammals far to the north of their normal wintering ranges.

The ringed seal and its predator, the polar bear, are the only marine mammals that regularly occupy extensive areas of solid fast-ice. Other pinnipeds, notably the bearded seal and walrus, have only a limited capability to maintain breathing holes in solid ice, and therefore are restricted during the winter to areas where ice cover is (at most) thin or broken. Another factor believed to limit the winter distribution of walruses and bearded seals is their dependence on adequate and accessible benthic food resources. The combination of these factors may severely limit the potential winter range of these two species within the North Water. Most nearshore shallow water areas where benthic food would otherwise be accessible to walruses and bearded seals are covered by fast-ice in winter. Indeed, Burns and Frost (1979) attributed low numbers of bearded seals in the Beaufort Sea to the lack of shallow feeding areas, particularly in the winter when landfast ice extended beyond the continental shelf. Vibe (1950) noted that although the bearded seal was better able to maintain breathing holes than walruses, it was forced to leave coastal waters to winter near the ice-edge. Vibe observed that the bearded seal fed on arctic cod, *Boreogadus saida*, in areas where the water depths exceeded 100 m. Walruses only rarely feed on arctic cod (Mansfield, 1958) and occasionally they are known to feed on ringed seals (Vibe,

1950; Fay, 1960), but it is unlikely that these non-benthic types of food could support many walruses through the winter in the North Water.

Northern Baffin Bay can be an extremely harsh environment for overwintering whales; entrapment by ice is usually fatal. Whales are likely to avoid areas where potentially fatal ice conditions occur, even if these conditions occur only once every few years. Of the three cetaceans that often occur near ice, the narwhal, bowhead and beluga, the last appears to be best adapted for survival in the most restrictive of winter ice conditions.

The prime behavioural adaptations of belugas to ice are their ability to relocate annually those areas with ice conditions suitable for survival, and their ability to maintain holes in thin ice. The presence of belugas in certain areas of the North Water in winter is indicative of the dependence of certain ice conditions necessary for their survival. Such conditions must also exist in local areas of Hudson and James bays, where belugas also overwinter in restricted areas of open water isolated by extensive areas of heavy ice from the closest large areas of open water (Jonkel, 1969; Sergeant, 1973). Kleinenberg *et al.* (1964) reported that in the Soviet Arctic, belugas overwinter in severe ice conditions north to 82°N, particularly in areas of recurrent polynyas that are often hundreds of kilometres from extensive ice-free water.

Although some belugas do overwinter in isolated and restricted areas of open water, it appears that in the Canadian Arctic most belugas and narwhals undertake longer migrations to areas where ice conditions are not as severe. There is no evidence that the limited open water of the North Water supports more than a small percentage of the High Arctic population of belugas during late winter.

ACKNOWLEDGEMENTS

This study was funded by Petro-Canada as part of the Baffin Bay EAMES program administered by the Department of Indian Affairs and Northern Development, Ottawa. We thank G. Glazier, H. Hume, B. Veldhoen and G. Koenig of Petro-Canada and N. Snow and B. Kemper of DIAND for their support.

A Distinctive Large Breeding Population of Ringed Seals (*Phoca hispida*) Inhabiting the Baffin Bay Pack Ice

K.J. FINLEY[1], G.W. MILLER[1], R.A. DAVIS[1] and W.R. KOSKI[1]

ABSTRACT. Aerial surveys in June and July, 1978 and 1979, documented an unexpectedly large population (at least 417 000) of ringed seals, some with pups, inhabiting the pack ice of Baffin Bay. Pack-ice seals are smaller than their fast-ice counterparts and have a different diet and gut parasite load. Age and reproductive data, although limited, indicate that the offshore seals are a normal breeding population. Pack-ice seals probably mix with fast-ice seals in coastal areas during the brief open-water season but morphological and ecological differences suggest that the populations are reproductively isolated. This study prompts reconsideration of the importance of offshore pack ice to ringed seals and, therefore, to the coastal hunting economy of Inuit in Greenland and Baffin Island.

Key words: ringed seals, Baffin Bay, pack ice, distribution, population discreteness, management

RÉSUMÉ. Des inventaires aériens effectués en juin et juillet, 1978 et 1979, ont documenté une population importante d'au moins 417 000 phoques annelés, certains accompagnés de jeunes, habitant le pack de la baie Baffin. Les phoques du pack sont plus petits que ceux de la banquise côtière et ont un régime alimentaire et des parasites intestinaux différents. Des données sur l'âge et le reproduction, quoique limitées, indiquent que les phoques au large des côtes suivent un cycle de reproduction normal. Les phoques du pack se mêlent probablement à ceux de la banquise dans les régions côtières durant la brève saison d'eau libre mais les différences morphologiques et écologiques suggèrent que les populations se reproduisent peut-être indépendamment l'une de l'autre. La présente étude encourage une reconsidération de l'importance du pack chez les phoques annelés et ainsi, de son importance dans l'économie côtière des Inuit chasseurs du Groenland et de l'île de Baffin.

Mots clés: phoque annelés, baie Baffin, banquise, distribution, isolation reproductrice de la population, contrôle de la population

Traduit pour le journal par Maurice Guibord.

INTRODUCTION

The life of the ringed seal (*Phoca hispida*) is intimately related to the dynamics of sea ice. The circumpolar distribution of the ringed seal is attributed to its ability to maintain breathing holes in solid ice — a unique adaptation that allows it to occupy large areas of the arctic seas that are inaccessible to most marine mammals during much of the year.

Like most phocid seals, the ringed seal uses sea ice as a platform on which to give birth and suckle its young. McLaren (1958a) hypothesized that stable ice in March-April was critical to pupping success, and that the species therefore preferred complex coastal areas where the ice was most stable. He believed that population size was limited by the amount of suitable fast ice. Immature seals were thought to be excluded from the preferred breeding habitat and to occupy areas of unstable ice. Subsequent accounts have also emphasized the significance of stable fast ice in the life history and population dynamics of this species (McLaren, 1961, 1962, 1966a; Smith, 1973, 1975; Smith and Stirling, 1975; Stirling and Smith, 1977; Finley, 1979; Burns *et al.*, 1981).

Nonetheless, ringed seals do not necessarily depend only on fast ice as preferred breeding habitat. Fedoseev and Yablokov (1964) recognized, on morphometric evidence, a distinctive ringed seal that inhabited and reproduced on the pack-ice fields of the Sea of Okhotsk. Fedoseev (1975) later recognized two basic 'ecotypes' of *P. hispida* in eastern Siberian waters — seals of the fast ice and of the pack ice. He concluded that seals of the pack ice were smaller, grew relatively faster and matured earlier than did seals of the fast ice.

As part of the Eastern Arctic Marine Environmental Studies program (Sutterlin and Snow, 1982) extensive aerial surveys were undertaken during 1978 and 1979 to document the distribution and abundance of marine mammals and birds in NW Baffin Bay. In May and June 1978 we saw unexpectedly large numbers of ringed seals, some with pups, in the offshore pack ice of Baffin Bay. In 1979 the study was expanded in order to better define the status of the offshore seals. We attempted to determine whether seals on pack ice were predominantly non-breeding subadults as implied by McLaren (1958a) and Smith (1973), or a breeding population such as occurs in the Sea of Okhotsk. This question was addressed with: 1) aerial surveys to assess relative numbers and distribution, 2) specimen collections on the pack ice to determine age and reproductive status, and 3) morphological and biochemical comparisons of animals collected on offshore pack ice and coastal fast ice. We also examined the diets, stomach parasites and development of moult of pack-ice and fast-ice seals.

METHODS

Study Area and Ice Conditions

The study area encompassed the coastal waters of NE Baffin Island from Lancaster Sound south to Clyde and adjacent offshore waters of Baffin Bay (Fig. 1). Baffin Bay forms a deep (500-2400 m), enclosed depression between Baffin Island and Greenland. The basin is dominated by cold arctic waters of the southward-flowing Baffin Current along the western side of Baffin Bay, and an intrusion of cold Atlantic water, the West

[1]LGL Limited, environmental research associates, 44 Eglinton Avenue West, Toronto, Ontario, Canada M4R 1A1

Greenland Current, on the eastern side of Baffin Bay (Collin and Dunbar, 1964; Fissel *et al.*, 1982). The physiography, oceanography and climate of Baffin Bay interact to produce a seasonal ice sheet that has a predictable degree of organization.

Freeze-up occurs rapidly in fiords during October leaving characteristically smooth ice. During early winter the fast ice extends in a shelf 30-50 km wide along eastern Baffin Island, anchored in part by numerous stranded icebergs, and fluctuating in extent depending on prevailing winds. In June 1979,

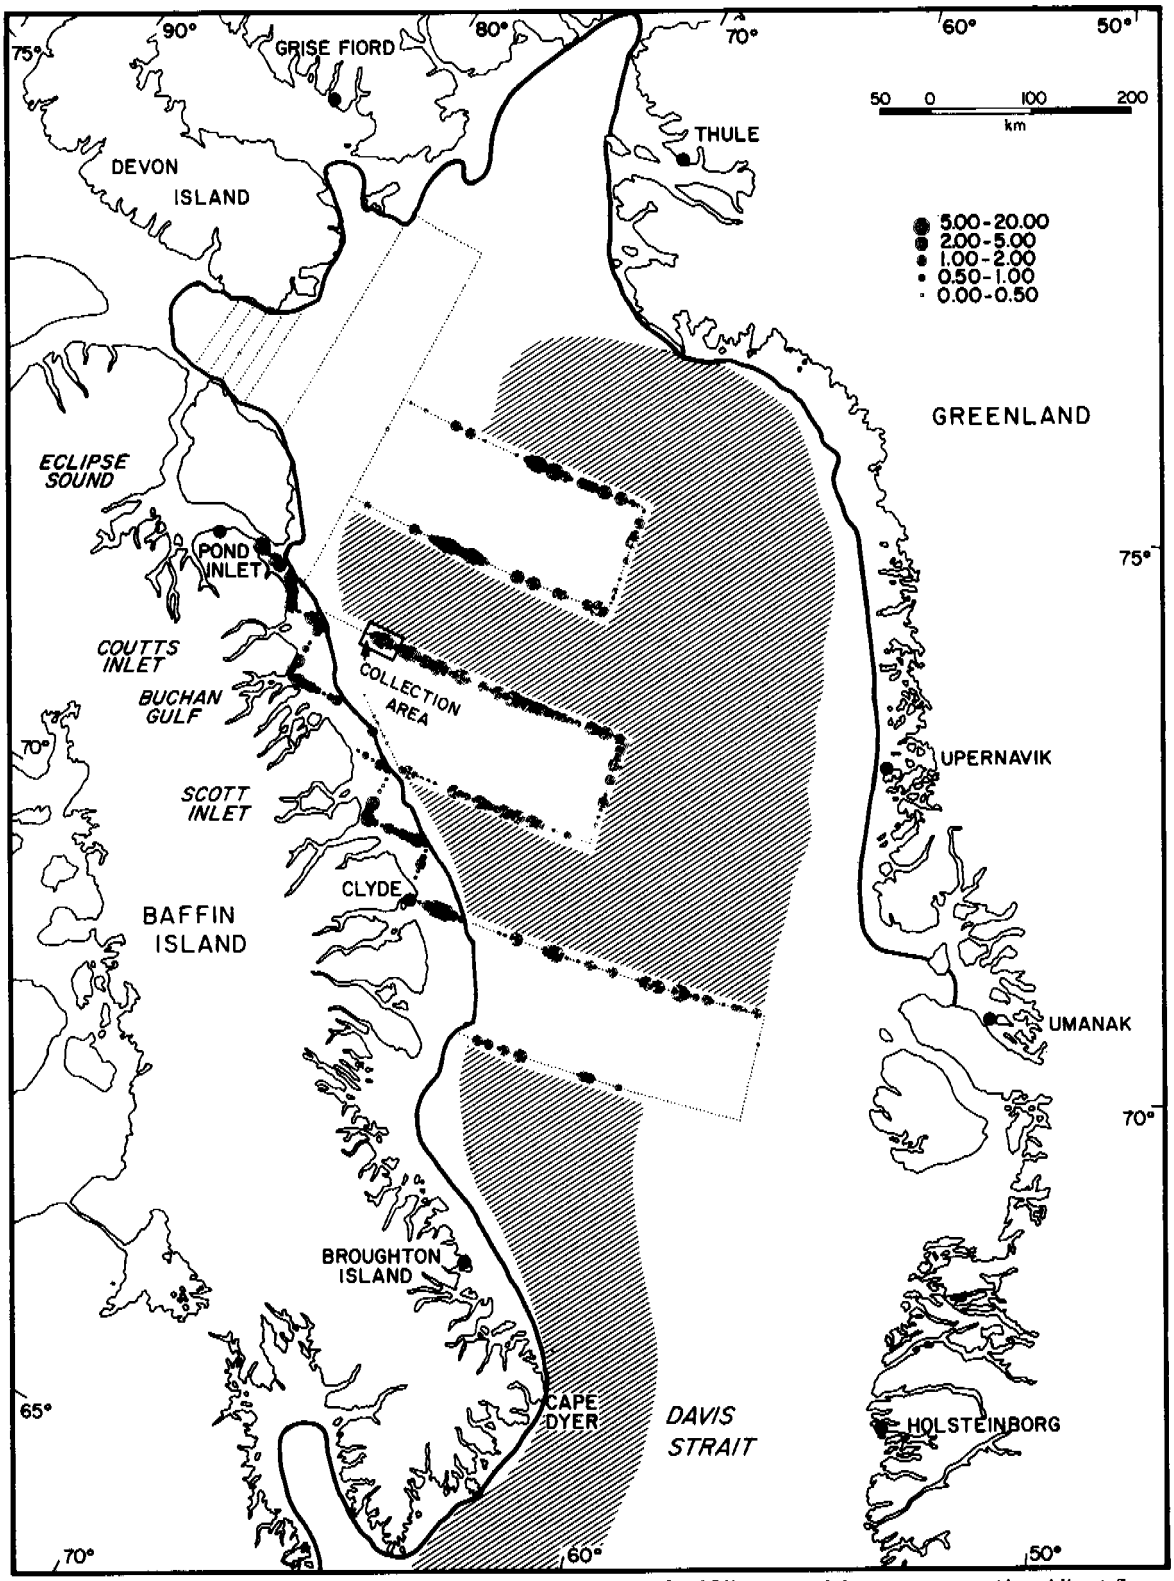

FIG. 1. The Baffin Bay area showing the extent of pack ice (hatched area) of >75% cover and the survey routes (dotted lines) flown repeatedly in 1979. The solid line indicates the edge of the landfast ice (from NOAA imagery, June 1979). Symbols are densities (seals·km^{-2}) in 2-min segments of transects. The collection area for pack-ice seals is shown.

this shelf between Cape Dyer and Pond Inlet covered an area of about 20 000 km² (Fig. 1). Within the same area the fiord ice is constant at about 16 000 km² and remains solid (land-fast) from October until July. The fiord complex of Pond Inlet, Eclipse Sound and Navy Board Inlet has an additional 8000 km² of fast ice.

At its maximum extent in March, the pack ice covers most of Baffin Bay. The ice in western Baffin Bay continually drifts southward, and in spring the first area of open water, the 'North Water', appears along the northern periphery of the ice fields (Fig. 2). In late June 1979, close pack ice (>75% cover) covered about 300 000 km² of Baffin Bay (Fig. 1). Extensive pack ice, known as the 'Middle Ice' to nineteenth-century whalers (cf. Markham, 1874), persists into August on the west side of Baffin Bay. In 1979, Baffin Bay was ice-free by late August but by mid-October new ice was beginning to develop.

Aerial Surveys

In 1978 and 1979 extensive aerial surveys were conducted in NW Baffin Bay and Lancaster Sound from early May to mid-July. These surveys were designed to document the distribution and abundance of marine mammals and seabirds as part of the Eastern Arctic Marine Environmental Studies (EAMES) program (Sutterlin and Snow, 1982). Because of the large

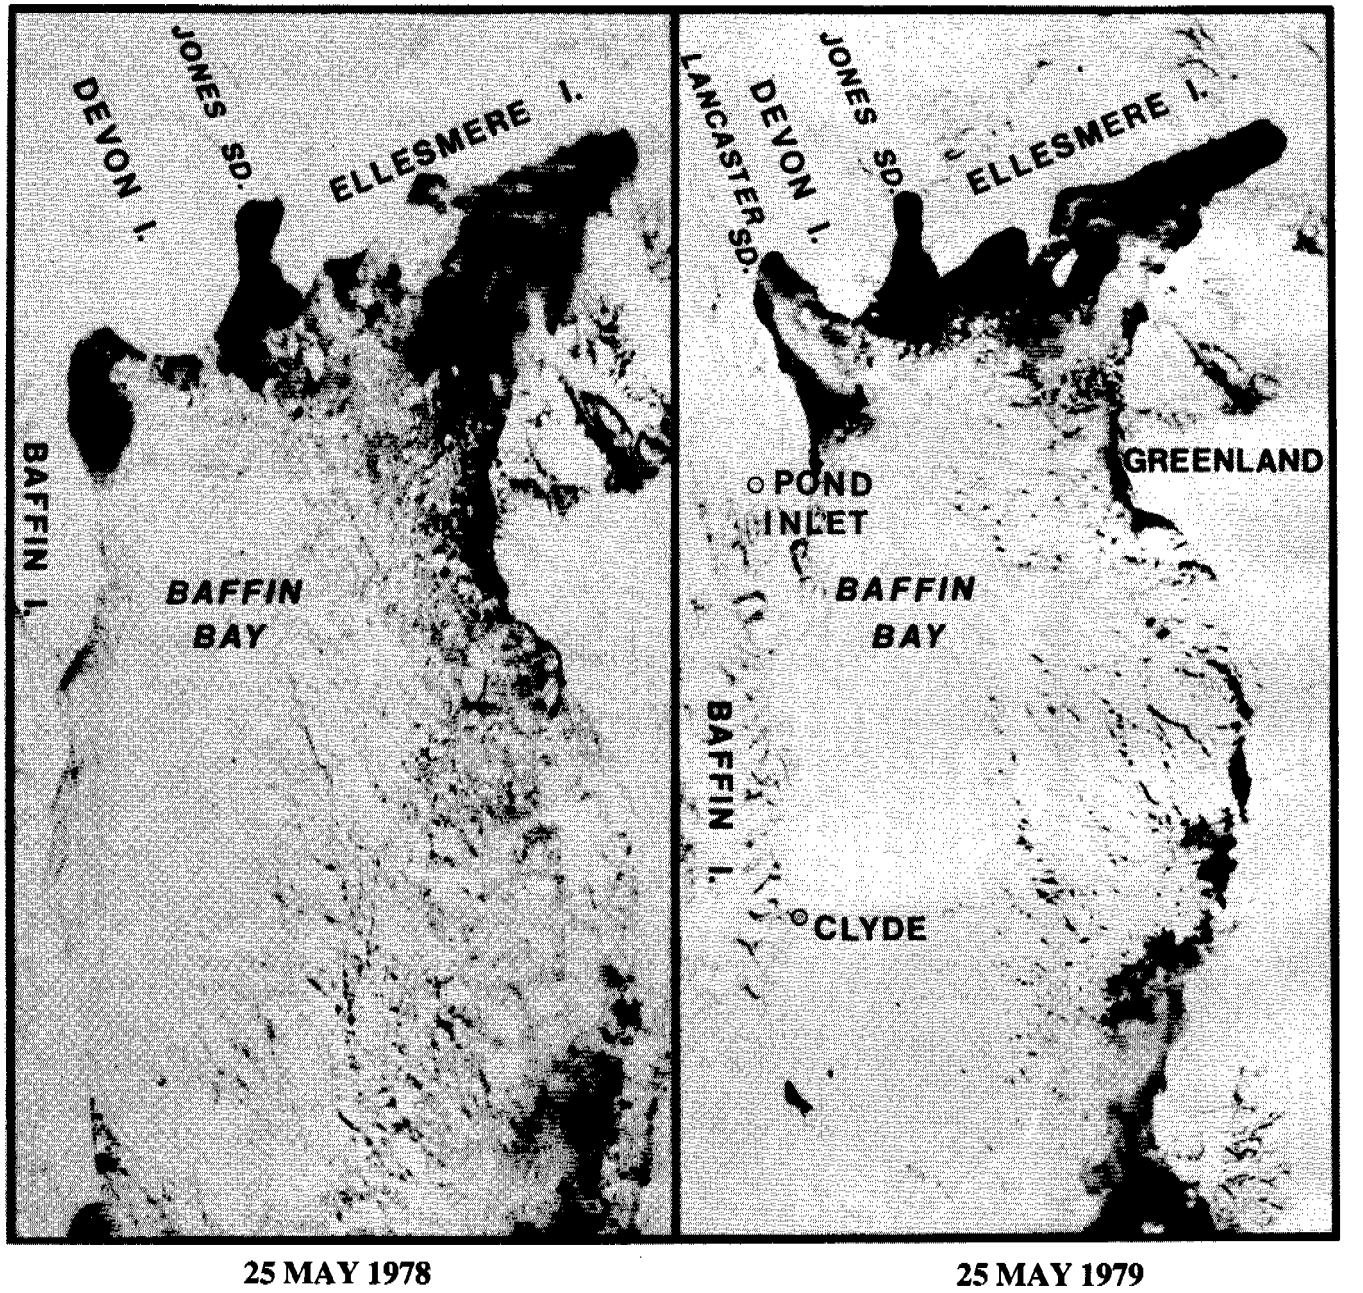

FIG. 2. Synoptic view of ice cover in Baffin Bay on 25 May, 1978 and 1979. Note the clearing of pack ice from the northern periphery of the fast ice leaving a large area of open water, the North Water.

survey area and associated logistic costs, both birds and mammals were counted during low-level (45 m) surveys with a transect width of 400 m. While this technique is adequate for describing the distribution of marine mammals, the low altitude and narrow transect strip are generally of limited value in quantitative evaluations of density, especially of seals that are hauled out on the ice. Thus, in addition to the low-level surveys, we conducted special surveys at 90 m with an 800-m transect width in order to provide density estimates of ringed seals during late June and early July. These surveys were conducted over the fast ice of fiords in NE Baffin Island in 1978, and over the adjacent shelf of fast ice and the pack ice in 1979.

All surveys were conducted in a DeHavilland DHC-6 Twin Otter with one observer in the right front seat and another on the left in the second seat behind the pilot. During surveys at 45 and 90 m, airspeeds were approximately 185 and 240 $km \cdot h^{-1}$, respectively. Survey altitude was maintained by radar altimeter, and accurate navigation in offshore areas was provided by a Global Navigation System (GNS-500).

Survey routes were divided into transects of lengths 18-140 km; most offshore transects were 56-111 km long. Each transect was subdivided into 2-min segments (6.2 km at 185 $km \cdot h^{-1}$ and 8.0 km at 240 $km \cdot h^{-1}$). The observers dictated information concerning transects, seals, visibility and ice conditions into audio recorders. These data were later transcribed, keypunched, and keyverified for computer tabulation, analysis, and mapping. Computer-produced maps were based on the density of seals recorded in each 2-min transect segment. Additional details on survey design and analyses are given in Koski and Davis (1979) and Koski (1980).

Population Estimation and Correction Factors

Only high-level (90 m) surveys during the peak of the haul-out season were used in estimating population sizes. Densities were obtained from three ice types — fiord, coastal shelf and pack ice — and then extrapolated to the total area of each ice type. Coverage with 45-m surveys indicated that extrapolation of densities in a particular ice type was reasonable given the wide and rather uniform distribution of seals. The population estimates are conservative since they do not account for seals that were not hauled out during the surveys. To the extent possible, this source of underestimation was minimized by conducting the surveys during the peak of the haul-out period, during midday and during good weather conditions, but even then only about 70% or fewer of the seals may be on top of the ice (Finley, 1979).

Ringed seals are conspicuous on the ice and it is unlikely that many are missed by competent observers in an aircraft. However, the right front observer in the Twin Otter aircraft has considerable forward-scanning advantage over observers in rear seats. Thus, seals that dive in front of the aircraft or those in the narrow blind strip beneath the aircraft are probably missed by the rear observers. In 1978 and 1979 at 90 m elevation, the front and rear observers recorded 1260 and 639 seals, respectively — a ratio of 1.97:1.

Specimen Collections

We accompanied Inuit who shot ringed seals on fast ice within 10 km of the community of Pond Inlet (n = 12) and on pack ice 65-130 km off NE Baffin Island (n = 45) (Fig. 1). Transport to the pack ice was by helicopter. Most (10 of 12) of the fast-ice seals were taken between 8 and 13 June, and all pack-ice seals were taken between 23 June and 7 July. The hunters used white screens to approach basking seals and attempted to take every seal that was encountered (i.e. no apparent selectivity was exercised). Since pups shed their neonatal coat by May they were not well represented among the moulting seals in late June and early July.

Morphometrics

Body measurements included straight-line body length, axillary and maximum girth, and blubber thickness over the sternum. With the exception of body length these measurements conform with the recommendations of the American Society of Mammalogists (1967). Body length was determined by the criteria used by McLaren (1958a) and Usher and Church (1969). Eleven features were measured from skulls of all adult seals; ten additional features were measured from skulls of adult males. Cranial measurements were made according to the procedure illustrated by Timoshenko (1975). Only adult seals, eight years of age and older, were used in morphometric analyses; at this age they have achieved most of their final body length (McLaren, 1958a). Measurements were made with dial calipers read to 0.1 mm. Student's t tests were used to compare body length, girth and skull measurements of fast-ice and pack-ice seals.

Age Determination

Lower jaws were kept frozen until they were boiled in the laboratory for approximately 1 h to facilitate the extraction of the canine teeth. Thin cross-sections (0.2-0.3 mm) of the extracted canines were cut about one third of the distance from the root end to the crown. Extracted teeth and the thin sections were stored in ethanol and glycerine. Dentinal annuli were counted using a 20X binocular microscope, usually under transmitted light, following McLaren (1958a) and. Smith (1973). Each section was read by one of us (GWM) in blind replicates, i.e. with no knowledge of previous estimates, until two identical readings were obtained or until three estimates had been made. When no two of the three readings were identical, mean age was calculated and rounded to the nearest integer. All seals were aged to their most recent birthday, i.e. April. In 29 of 57 examples (51%), age readings 1 and 2 were identical, and in 18 of the other 28 cases, reading 3 was identical to one of the two previous readings.

Enzyme Electrophoresis

Tissue samples from the heart, liver, kidney and muscle were cooled in ice and frozen within 24 h of collection. To assess genetic variability in seals from pack ice (n = 45) and fast ice (n = 12), tissue samples were examined by J. Bogart

and D. Lavigne, University of Guelph, using horizontal starch-gel electrophoresis (methods as in Lavigne *et al.*, in press). They examined 27 genetic loci from 16 enzyme systems: two acid phosphatase loci; adenylate kinase; α-glycerophosphate dehydrogenase; two general protein loci; two glutamate oxaloacetic transaminase loci; two isocitrate dehydrogenase loci; two lactate dehydrogenase loci; malic enzyme; two malate dehydrogenase loci; 6-phosphogluconate dehydrogenase; three superoxide dismutase loci; four phosphoglucose mutase loci; one sorbitol dehydrogenase locus; aconitase; esterase; and a glucose-6-phosphate dehydrogenase locus.

Reproductive Condition

Female reproductive tracts were preserved in 10% formalin. In the laboratory, uterine cornua were opened and examined for the remains of placental material from a recent pregnancy. Ovaries were cut in 1-mm slices and examined macroscopically for corpora lutea and albicantia.

Pelage and Moult

In the field, seals were examined for evidence of skin (epidermal) and hair moult and the skins were photographed. Strips of skin (4 x 8 cm) were taken from the mid-dorsal area of seals collected in July and these samples were later examined under a 10X microsope. Old hair was easily distinguishable from developing hair by its dull, yellowish appearance. Hair growth was measured from small clumps of hair plucked from the skin. Developing, non-erupted hairs were measured in cross-sections of the epidermis. The epidermis was examined for evidence of sloughing.

Diet and Stomach Parasites

Food items from stomachs and faecal material from colons were collected and frozen. Later, thawed stomach contents and faecal material were weighed and then diluted with water in a shallow tray. The various constituents were separated through differential specific gravity (i.e. panning). Fish otoliths were identified and counted. Crustacean parts were examined under a low-power microscope and an estimate was made of the species composition on a percentage basis.

Seal stomachs were examined for nematodes. Clumps of nematodes on the stomach wall were classified as major (> 10 individuals) or minor (< 10 individuals); major and minor clumps and all individually attached nematodes were counted.

RESULTS

Distribution and Abundance

Small numbers of ringed seals were seen during surveys in May but the peak of haul-out in both offshore and coastal areas occurred during the latter half of June and into early July. Group sizes of seals were similar in offshore and coastal areas, although they tended to increase in size from May to the peak of haul-out (Fig. 3). There were no discernible shifts in the population from offshore to coastal areas or vice versa during the surveys.

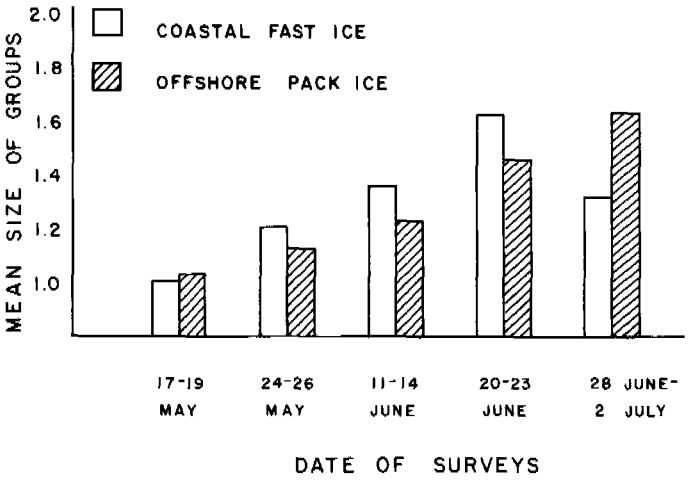

FIG. 3. Group sizes of ringed seals observed on coastal fast ice and offshore pack ice, 17 May-2 July 1979.

Ringed seals were distributed throughout the offshore pack ice and the coastal fast ice of NW Baffin Bay (Fig. 1). Few seals were seen in peripheral areas of the pack-ice fields where the ice was more active and broken. Within the pack-ice fields densities tended to be rather uniform; a series of transects at 90 m elevation conducted during the peak of haul-out in 1979 provided an overall density of 1.39 seals·km^{-2}. This was similar to the density (1.31 seals·km^{-2}) found on the coastal shelf during the same period (Table 1). Densities of seals in fiords in 1978 were variable (0.86-3.20 seals·km^{-2}) but the overall mean density (1.72·km^{-2}) was somewhat higher than that for shelf ice and offshore pack ice in 1979 (Table 1).

TABLE 1. Densities of ringed seals on various ice types in NW Baffin Bay during the period of peak haul-out, 1978-79

Ice Type	Area[a]	Date	Area Surveyed (km²)	Seal Density (km^{-2})
Pack ice	Baffin Bay	2 July 1979	606	1.39
Fast ice (Shelf)	NW Baffin I.	20, 21 June 1979	341	1.31
Fast ice (Fiord)	Coutts Inlet	25 June 1978	121	2.46
	Buchan Gulf	25 June 1978	97	3.20
	Scott Inlet	25 June 1978	133	1.47
	Eclipse Sound	22 June 1978	128	0.96
	Pond Inlet	26, 30 June 1978	118	0.86
	All fiords	22-30 June 1978	597	1.72

[a]For areas covered see Fig. 1.

Application of these raw density estimates to the total area of pack ice in Baffin Bay and the bordering fast ice between Cape Dyer and Navy Board Inlet indicates that the pack ice of Baffin Bay supports a substantially larger population of seals than

does the bordering fast ice along the east coast of Baffin Island. We estimate that the pack ice was inhabited by at least 417 000 seals in late June-early July 1979, whereas the fast ice was inhabited by at least 67 000 seals. These are underestimates since they do not account for seals missed by the left rear observer and seals that were not hauled out during the surveys. Application of correction factors would increase the population estimate for the Baffin Bay pack ice to 550 000 seals, if we allow for reduced efficiency of left rear observers, and to 787 000 seals if we also consider that roughly 30% (Finley, 1979) of the total number of seals may not have been hauled out during the surveys.

Ringed seals apparently abandon offshore Baffin Bay after the ice disappears in late summer. Few ringed seals were seen during low-level surveys during August and September of 1978 and 1979 (details in Koski, 1980; Koski and Davis, 1979, 1980). Seals are not easy to detect in rough water, but some offshore surveys were flown during calm conditions when seals could have easily been detected at the surface. For example, on 11 September 1979, mirror calm conditions prevailed over Baffin Bay, and during 292 km of offshore survey no seals were seen. Most ringed seals observed during aerial surveys in late summer were found in coastal waters. During many hunting trips by boat in Eclipse Sound in August and September we encountered ringed seals, sometimes in considerable concentrations (e.g., KJF counted at least 80 ringed seals within a 1-km radius of a stationary boat in Eclipse Sound on 27 August 1978).

Age Distribution and Reproductive Status

Both the samples (45 pack-ice seals and 12 fast-ice seals) exhibited a similar age range of adult and immature seals, indicating that both samples were drawn from a breeding population (Fig. 4). Young-of-the-year and one-year-old seals were not represented in either sample; this was expected for the young-of-the-year seals but not necessarily for the one-year-olds, which would be expected to moult with older seals. We did observe small seals swimming in leads among the ice pans, and the aerial observers saw adults with pups on the pack ice in May.

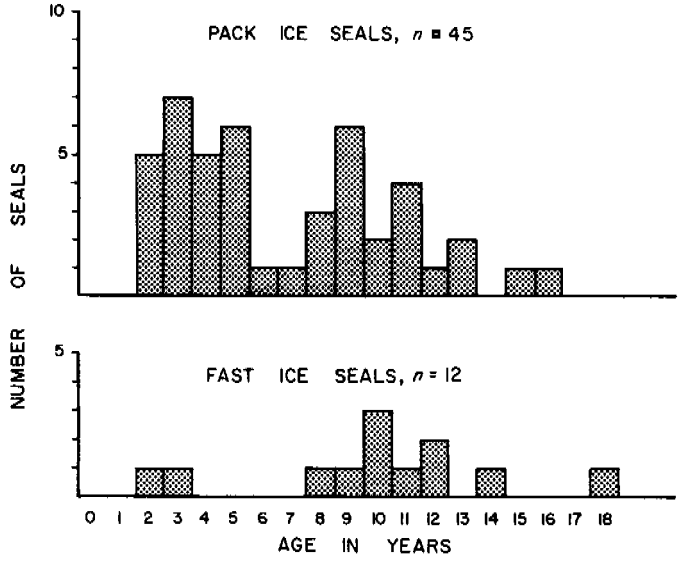

FIG. 4. Age distribution of ringed seals collected on pack ice and fast ice, June-July 1979.

Of the 45 pack-ice seals, 27 were females, of which 14 were sexually mature (Table 2). All females >5 yr old from both the pack ice and the fast ice had ovulated (corpus luteum present) during the most recent breeding season (April-May), but were taken during the period of delayed implantation, when embryos are not detectable. All these females also retained at least one corpus albicans from a previous ovulation. The uterine cornua of these individuals were thick and heavily vascularized with longitudinal foldings (quite distinct from the small, smooth cornua of immature specimens), indicating that these females had been pregnant in previous years.

TABLE 2. Reproductive condition of female ringed seals collected on pack ice and fast ice.

Age	*n*	No ovulation	First ovulation	Previously pregnant

	27	13	3	11
Fast Ice				
2	1	1	—	—
8-12	5	—	—	5
	6	1	0	5

An indication of recent pregnancy was the presence in some uteri of orange stains on the inner wall of a cornus whose ovary contained a corpus albicans. We believe that these stains form at the site of placental attachment on the endometrial lining. This feature was observed in five of eleven of the parous pack-ice females and in four of five of the parous fast-ice females. The earlier collection dates of the fast-ice females may account in part for the greater frequency of this feature in those seals.

Our data are too limited to indicate anything conclusive about the age of sexual maturity; however, it is noteworthy that of the 4-yr-old pack-ice females, three out of four had ovulated (Table 2).

Morphometry

Male ringed seals (≥8 yr old) from the pack ice were significantly smaller in length and girth than males from the fast ice (Table 3). Average estimated weights (calculated by the method of Usher and Church, 1969) of pack-ice and fast-ice males were 51.4 and 72.8 kg, respectively. Female ringed seals from the pack ice were also significantly shorter (t = 2.82, $p<0.05$) in body length than fast-ice females (116.4 cm + SD 6.67, n = 11 *vs.* 126.2 cm + SD 5.40, n = 5).

Pack-ice males were significantly smaller than fast-ice males

in 12 of 21 cranial features (Table 3). In general, the skulls of fast-ice males appeared more robust than those of the pack-ice males (Fig. 5). Females from the pack ice also averaged smaller in all cranial measurements but our sample sizes were too small for statistical treatment.

We plotted skull measurements *vs.* age for seals ≥ 8 yr old to assess whether age-related biases occur in these older seals. Examples of these plots are presented in Figure 6. The size differences between the two groups are consistent across the age span of the animals examined and there is little or no overlap in most measurements.

Genetic Variability

Of 27 genetic loci from 16 metabolic enzymes, 24 (88.9%) were monomorphic and demonstrated no variation. Variability was encountered for aconitase, one esterase locus, and a glucose-6-phosphate dehydrogenase locus, but the apparent variability was low and was not statistically different between the pack-ice and fast-ice seals. Low variability has also been found in the same enzyme systems examined for the harp seal (*Phoca groenlandica*) (Lavigne *et al.*, in press).

Pelage and Moult

Although the colouration and markings of the ringed seals varied considerably, we could not discern any consistent differences in the pelage of the pack-ice and fast-ice seals. Fedoseev (1975) identified two pelage types and noted that one type was more predominant in Okhotsk ringed seals than in seals in Bering Strait and the Chukchi Sea.

Only two of ten fast-ice seals taken between 6-12 June showed any epidermal moult. Between 23-30 June epidermal moult was evident in eight of nine pack-ice seals. All seals re-

FIG. 5. Skulls and lower jaws of 10-yr-old male ringed seals from the pack ice (left) and the fast ice (right). Note the generally more robust appearance of the skull of the fast-ice seal.

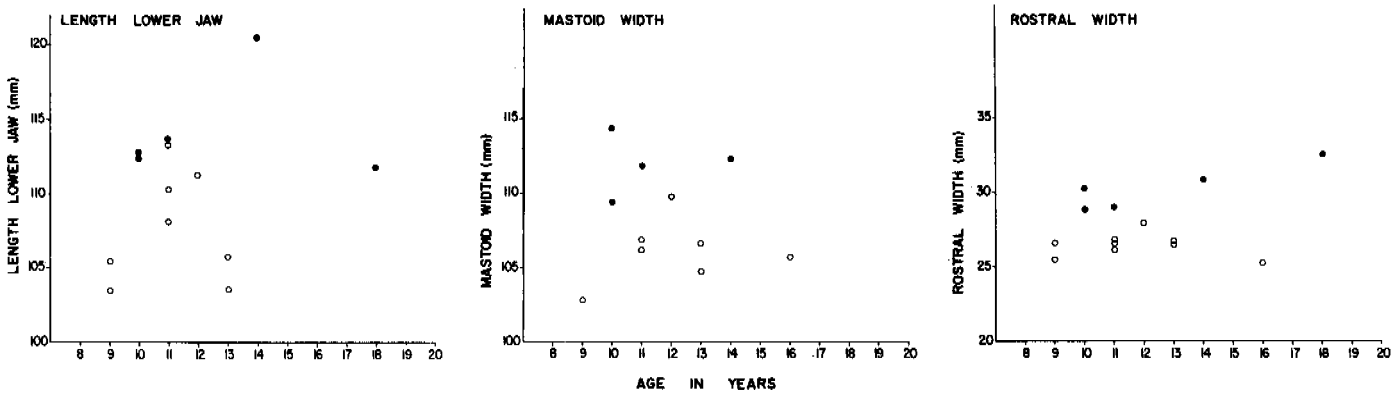

FIG. 6. Age-related comparisons of three cranial measurements of pack-ice (○) and fast-ice (●) seals.

tained their old pelage in June, though by late June it was noticeably looser.

Hair and epidermis in 25 skin samples from pack-ice seals collected during 1-7 July were in various stages of moult, ranging from one animal which had not begun to moult to two in which moult was complete (all old hairs had been shed) (Fig. 7). On most seals new hairs showed early stages of development and epidermal moult was well advanced. Apparently epidermal moult begins before new hairs erupt and is complete when new hairs are about 8 mm long. Old hair does not moult until after mid-July when the new hairs are nearly full length. The pattern and timing of moult appeared similar for both fast-ice and pack-ice seals.

Diet

More pack-ice seal stomachs (18 of 44) than fast-ice seal stomachs (1 of 12) contained food items ($\chi^2 = 4.46$, $df = 1$,

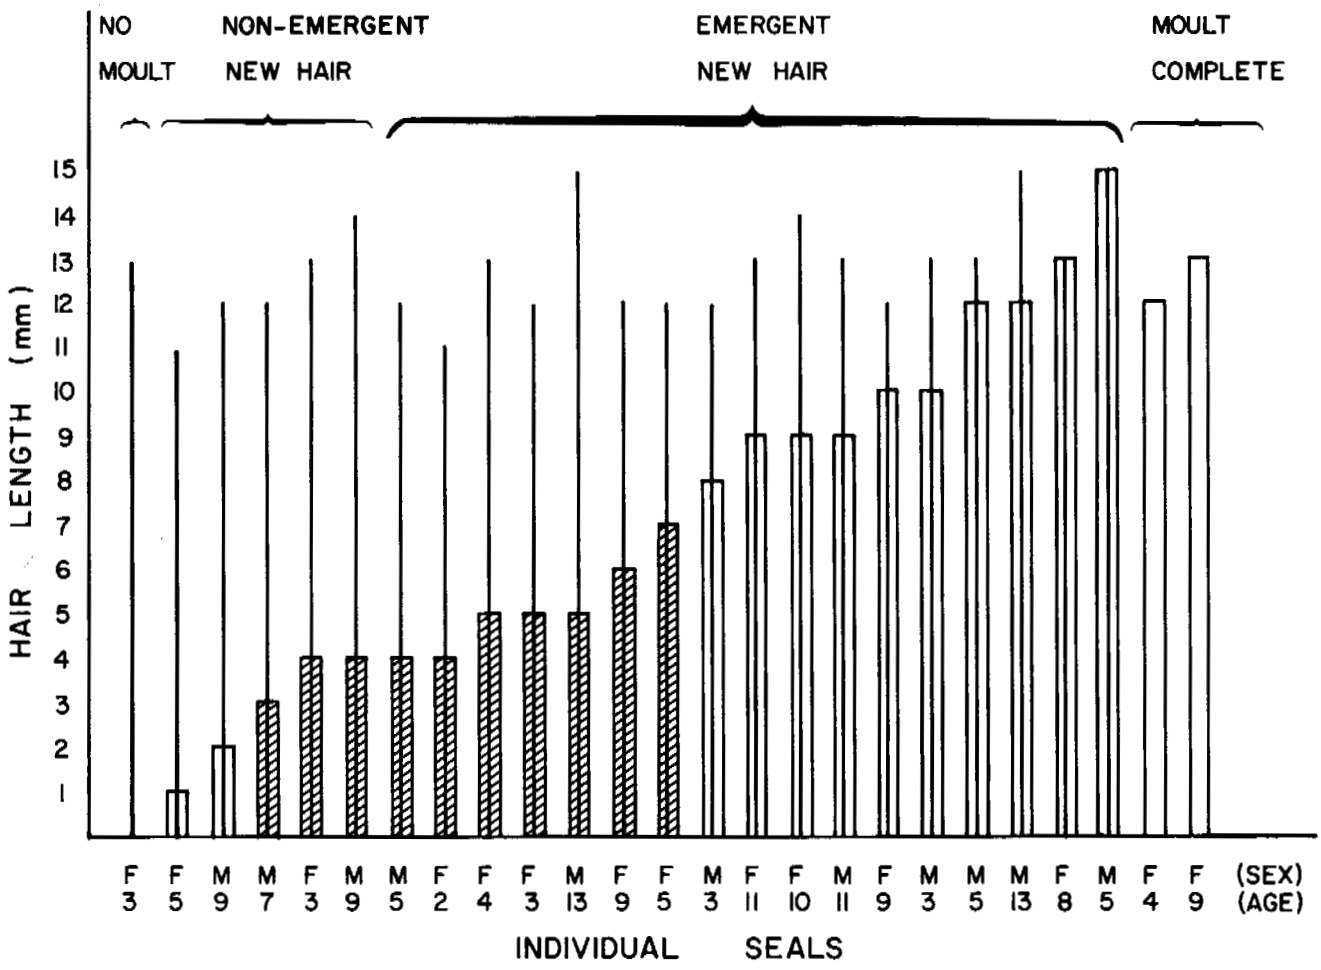

FIG. 7. Stages of hair and epidermal moult of ringed seals collected on offshore pack ice, 1-7 July 1979. Old hair is represented by solid lines and new hair by bars. Hatched bars represent individuals that were undergoing epidermal moult.

$p<0.05$). The amphipod *Parathemisto libellula* was found in all 18 pack-ice seal stomachs that contained food. *P. libellula* comprised 95-100% of the contents of these stomachs and was the only organism present in 14 of the stomachs. Some fish otoliths, primarily seasnails (Cyclopteridae), and a single mysid were the only other food items found. Analysis of faecal matter collected from 39 pack-ice seals also demonstrated the prevalence of *P. libellula* in the diet. Fish otoliths, primarily seasnails, were found more frequently (77%) in faecal samples than in stomach contents (22%), but usually occurred in small numbers.

Stomach Parasitism

The stomachs of pack-ice seals were notably less parasitized than were those of fast-ice seals. Nematodes were present in 10 (91%) of 11 fast-ice seal stomachs but in only 6 (14%) of 44 pack-ice seal stomachs ($\chi^2 = 25.5$; $df = 1$, $p<0.001$). Also, the stomachs of pack-ice seals that did contain nematodes were less parasitized than were the stomachs of the fast-ice seals: most of the fast-ice seals but none of the pack-ice seals contained major clumps of nematodes imbedded in lesions of the stomach wall. An index of the number of nematodes in stomachs of infested seals was significantly lower for pack-ice seals (mean 4.0 $\pm$ SD 2.8, $n=6$) than for fast-ice seals (25.4 $\pm$ 18.8, $n = 10$, Mann-Whitney U = 7, $p<0.02$).

DISCUSSION

Pack ice covers Baffin Bay for more than nine months of the year; both extent and timing are predictable. This platform provides both stable breeding habitat and access to pelagic areas that would otherwise be unavailable to the seals. By its dynamic and transitory nature the pack ice imposes a unique set of living conditions quite different from the fast ice.

Offshore Distribution and Abundance

Our surveys demonstrate that ringed seals are widely and fairly evenly distributed throughout the Baffin Bay pack ice from May through early July. Maintaining this even distribution would require that the seals undertake northward movements, since the pack ice generally flows south in western Baffin Bay throughout winter. The seals presumably

occupy the pack ice when it forms in October and November, and pupping occurs when ice conditions are most stable in March-April. In June and July we noted that the seals and their holes were almost always along refrozen cracks or leads where ice thickness seldom exceeded 50 cm. Unlike seals of the fast ice, which must maintain breathing holes in solid ice up to 2 m thick, pack-ice seals can occupy thin ice that continually forms during winter and thus probably need not maintain and defend one breathing hole (or small groups of holes) throughout the winter.

For purposes of rough estimates of the ringed seal population around Baffin Island, McLaren (1961, 1966a) and Smith (1973) depicted offshore areas as nearly devoid of seals. In fact, densities of seals in offshore Baffin Bay do not appear to be markedly different from densities in coastal areas. Our coverage of the offshore pack ice with 90-m surveys amounted to only 0.2% during the peak of haul-out, which is inadequate to attempt a realistic estimate of the pack-ice ringed seal population. However, we are confident, based on extensive coverage at 45 m, that several hundred thousand ringed seals occupy the pack ice, and certainly the pack ice supports a much larger population of seals than does the bordering area of fast ice.

Breeding Status

Previous studies in coastal Baffin Island have found that floe edges and areas of unstable ice are occupied primarily by immature and non-breeding ringed seals (McLaren, 1958a; Smith, 1973). Miller and Finley (1982) also found that the floe edge is occupied by a high percentage of failed breeders and immatures. Our samples from much farther offshore indicate that many of the offshore seals are breeding animals. Although the sample size is small, the age structure of the offshore seals approximates that of a normal breeding population (cf. composite life table in Smith, 1973:44). All females ≥ 8 yr showed evidence of recent and past reproductive activity. Fedoseev (1975) suggested that the age of first breeding in ringed seals on the pack ice of the Sea of Okhotsk was lower than in areas of fast ice in the Bering Sea, but his data on this are equivocal. Our sample from Baffin Bay is too small to determine the average age of first breeding, although it may be of interest that three of four 4-yr-old females had ovulated. Generally most females do not ovulate until their fifth or sixth year (see review by Davis *et al.*, 1980). Fedoseev (1975) also stated that the lactation period for seals on the pack ice was only three weeks compared to the more normal six weeks on fast ice, but we have no data from Baffin Bay. There is no reason to suspect that ice stability would greatly affect the duration of lactation since the pack ice was stable well into June; the aerial observers saw pups in close association with adults on the pack ice in May and June.

Population Discreteness

Inuit hunters from northern Baffin Island recognize two distinct types of ringed seals; one of these, the *pulajuraaq*, is described as a small seal that enters the fiords after ice disperses in summer and leaves during freeze-up to occupy offshore areas. [*Pulajuraaq* is a syllabic transliteration of the north Baffin Inuktitut dialect. Phonetically it would appear as poo lá ú raá. The fiord seal is distinguished as *tuvamiutaaq*. A resident of Cumberland Sound (Pangnirtung) referred to the offshore seals as *pulaniit*.] Inuit of NW Greenland also distinguish between ringed seals of fiords and those from offshore areas (Vibe, 1950:77). McLaren (1958a:64) noted that Inuit of south Baffin Island were "convinced, through observation, that the 'bay-ice seals' average larger regardless of age"; however, he believed that size differences were related to ice stability (i.e. larger pups were produced on stable coastal ice and smaller non-breeding seals were excluded from this habitat). Our measurements indicate that ringed seals from the Baffin Bay pack ice are smaller than those from nearby coastal fast ice, which agrees with the observations of Inuit hunters. Fedoseev (1975) also found that ringed seals from the "drift ice" were smaller than those from coastal fast ice.

The relationship of the pack-ice seals to the fast-ice seals in Baffin Bay is unclear. Fedoseev (1975) suggests that the pack ice "ecotype" is a genotypic expression of the specific environmental influences of a pack-ice existence. Evidence of such a genotypic response to pack-ice breeding has been shown in the spotted seal *Phoca largha*. The *largha* seal of the Bering Sea was long thought to be an ice-adapted variant of the coastal harbour seal (*Phoca vitulina*), but it was recently accorded species status on the basis of morphological, behavioural and ecological evidence (McLaren, 1966b; Shaughnessy and Fay, 1977). Biochemical analyses were inconclusive in demonstrating genetic distinctiveness between the two species (Shaughnessy, 1975). Given the overall low genetic polymorphism among phocid seals (Lavigne *et al.*, in press; J.P. Bogart, D.M. Lavigne, and R.G. Danzmann, pers. comm. 1982), and the fact that (limited) enzyme electrophoresis was unable to demonstrate genetic differences even between ice-breeding *Phoca largha* and land-breeding *P. vitulina* (Shaughnessy, 1975), it is not surprising that we found no difference between the pack-ice and fast-ice ringed seals of Baffin Bay.

The marked differences in the gut parasite load of pack-ice and fast-ice seals suggests quite different feeding regimes for the two populations. Delyamure (1955) stated that the helminth fauna of the Okhotsk ringed seal differed quantitatively and qualitatively from that of the coastal population, which had a much richer helminth fauna. In fact, the nematode *Terranova skrjabini* was said to be unique to the Okhotsk ringed seals. Unfortunately, few nematodes were properly preserved for identification in our study; several specimens from three stomachs of fast-ice seals were *Contracaecum* sp., while specimens from the stomachs of pack-ice seals were *Terranova* sp.

Our data suggest that the pelagic amphipod *Parathemisto libellula* is important to pack-ice seals, whereas ringed seals from coastal NE Baffin Island feed primarily on arctic cod throughout the year (Finley, pers. obs.). Fedoseev (1975) also observed that Okhotsk seals fed primarily on a pelagic

euphausiid in contrast to the fish diet of coastal ringed seals. K. Frost (pers. comm. 1982) notes that "a difference in diet, which is almost assuredly a reflection of different prey availability, will account for a different parasite load" and that "in general, fish eaters have more parasites than crustacean eaters because fish are usually the final intermediate host."

The question of genetic distinctiveness of the pack-ice ringed seals in Baffin Bay may be resolved through further studies, but for now, it is prudent to recognize the existence of a large and distinctive pack-ice population. This has important management implications.

Management Implications

Ringed seals are the primary renewable resource for Inuit on both sides of Baffin Bay (McLaren, 1958b, 1961, 1962; Vibe, 1950; Bissett, 1967; Haller *et al.*, 1967; Smith, 1973; Kapel, 1975; Treude, 1977; Wenzel, 1978; Davis *et al.*, 1980; Finley and Miller, 1980). In Greenland, catches of ringed seals have averaged 50 000-70 000 per year with an increasing trend, and although there is no knowledge of the population size, it is believed "that the stocks of ringed seals in Greenland are not threatened by hunting" (Kapel and Petersen, 1982). The annual harvest of ringed seals by hunters from Broughton Island, Clyde and Pond Inlet is between 12 000 and 15 000 (Davis *et al.*, 1980; Finley and Miller, 1980). Allowing for hunting losses, Miller *et al.* (1982) estimated that about 17 300 seals are killed annually in this area. Our uncorrected estimate of the number of ringed seals occupying coastal fast ice from Cape Dyer to Navy Board Inlet was about 67 000. When we correct for differential visibility and conservatively assume that half the seals were under the ice during the surveys, then the estimate is about 177 000 seals. If the sustainable yield of the population is 7% (Smith, 1973), then 250 000 seals would be necessary to support an annual kill of 17 300. Obviously this kill cannot be supported by the fast-ice population alone. Yet there is no evidence that coastal populations of ringed seals are declining; present harvest levels appear to have been maintained for many years (Finley and Miller, 1980). Therefore it is highly probable that a considerable portion of the annual harvest comes from the pack-ice population. The limited fast ice in West Greenland suggests that much of the harvest there must also consist of pack-ice seals (Miller *et al.*, 1982).

In 1979, 37-39% of the ringed seal catches at Pond Inlet and Clyde were taken during the open-water season (Finley and Miller, 1980) when the *pulajuraaq* are said to enter the fiords. It may eventually be possible to estimate the proportion of pack-ice seals in coastal harvests by using morphometric analyses of jaws that have been collected from hunter kills. More systematic collections of pack-ice and fast-ice seals will be needed to verify this.

The present documentation of a previously unrecognized large population of ringed seals in Baffin Bay serves to demonstrate how little is known about the population dynamics of this species in the Canadian Arctic. Present knowledge, particularly of population sizes, is inadequate to assess the impact of increasing hunting pressure (Davis *et al.*, 1980) or industrial activities (Davis, 1981) on seal populations in the Canadian Arctic. By contrast, much more attention has been given to the management of the politically sensitive harp seal (*Phoca groenlandica*) hunt (Wenzel, 1978). In view of the cultural and economic importance of the ringed seal to Inuit (Bissett, 1967; Wenzel, 1978; Myers, 1982), at a time when populations of indigenous people are increasing at a rapid rate (Hamelin, 1979), this lack of knowledge is a significant impediment to proper management decisions. The situation is complicated by its international scope. It also has implications to the large population of polar bears (*Ursus maritimus*) that is dependent on the seals of the Baffin Bay pack ice. Management of ringed seals in the Baffin Bay region should, therefore, be international in scope and should consider the conflicting demands for seals by polar bears and by Inuit.

ACKNOWLEDGEMENTS

This research was funded by Petro-Canada Explorations as part of a multi-disciplinary research program, the Eastern Arctic Marine Environmental Studies (EAMES) program. We especially thank G. Glazier, G. Koenig, W. Speller and B. Veldhoen of Petro-Canada for their assistance and support.

This study could not have been accomplished without the assistance of the Pond Inlet hunters, particularly P. Aglak who taught us much. G. Sleno of the Arctic Biological Station, Ste. Anne de Bellevue, assisted in the preparation of tooth sections. D. Campbell of the National Museums of Canada, Ottawa, prepared the skulls and assisted in measurements. A. Sekerak of LGL Ltd. identified the stomach parasites and W.J. Richardson, as usual, kept us in line. K. Frost and I. McLaren provided constructive comments on the manuscript. We are grateful to all of these people.

Summer foods of Atlantic walrus, *Odobenus rosmarus rosmarus*, in northern Foxe Basin, Northwest Territories

K.I. Fisher and R.E.A. Stewart

Abstract: Stomach contents of Atlantic walrus, *Odobenus rosmarus rosmarus*, taken by Inuit hunters in northern Foxe Basin in July 1987 and 1988 (n = 105) and September 1988 (n = 2) were examined. In July, 20 of 94 stomachs from immature and adult walrus contained >5 g of food representing 17 prey taxa, including bivalves, gastropods, holothurians, polychaetes, and brachiopods. The bivalve *Mya truncata* contributed 81.4% of the total gross energy in the diet, with the bivalve *Hiatella arctica*, holothurians, and the polychaete *Nereis* sp. contributing 7.5, 3.5, and 2.8%, respectively. The diets of male and female walrus were similar except that females received a significantly ($P < 0.05$) greater percentage of gross energy in their diet from *H. arctica* than did males. Walrus less than 3 years old (n = 11) consumed mostly milk, although some benthic invertebrates were eaten. Analysis of the contents of two stomachs collected in September suggested that walrus may feed more intensively in the fall. *Mya truncata* was again the predominant prey, contributing 59.9% of total gross energy, with the bivalve *Serripes groenlandicus* (37.9%) replacing *H. arctica* (0.3%) as the second most important prey.

Résumé : Les contenus stomacaux de Morses de l'Atlantique, *Odobenus rosmarus rosmarus*, capturés par des chasseurs inuits dans la partie nord de Foxe Basin en juillet 1987 et 1988 (n = 105) et en septembre 1988 (n = 2), ont été examinés. En juillet, 20 sur 94 estomacs de morses immatures et adultes contenaient plus de 5 g de nourriture, représentant 17 taxons, bivalves gastropodes, holothuries, polychètes et brachiopodes. Le vivalve *Mya truncata* représentait à lui-seul 81,4% de l'énergie brute totale contenue dans le régime, le reste étant fourni par *Hiatella arctica* (7,5%), des holothuries (3,5%) et des polychètes du genre *Nereis* (2,8%). Le régime était semblable chez les mâles et les femelles, mais les femelles recevaient une part significativement plus grande ($P < 0,05$) de leur énergie brute d'*H. arctica*. Les morses de moins de 3 ans (n = 11) consommaient surtout du lait, mais quelques invertébrés benthiques ont également été trouvés dans leurs estomacs. L'analyse des contenus stomacaux de 2 morses capturés en septembre indique que les animaux se nourrissent probablement plus intensément à l'automne. À ce moment, *M. truncata* était encore la proie dominante, constituant 59,9% de l'énergie brute totale, mais c'est le bivalve *Serripes groenlandicus* (37,9%) qui était la proie secondaire le plus commune, non plus *H. arctica* (0,3%).
[Traduit par la Rédaction]

Introduction

Atlantic walrus (*Odobenus rosmarus rosmarus*) inhabit arctic waters from the Arctic Archipelago to the Kara Sea (Richard and Campbell 1988; Born et al. 1995). Major concentrations occur in the Canadian eastern Arctic in northern Hudson Bay and Foxe Basin and to a lesser extent in Davis Strait, Baffin Bay, and the High Arctic Islands east of 100°W (Davis et al. 1980; Born et al. 1995).

The food habits of Pacific walrus (*O. r. divergens*) have been studied extensively (Nikulin 1941; Brooks 1954; Fay et al. 1977, 1984; Fay and Lowry 1981; Fay 1982; Fay and Stoker 1982), but there is little information on the foods of Atlantic walrus. Vibe (1950) described the stomach contents of five walrus from the Thule District, Greenland, and Mansfield (1958) examined 19 stomachs containing food in a sample of 111 stomachs of walrus from five locations in the Canadian eastern Arctic. Both authors concluded that bivalves were the major prey group. Loughrey (1959) found food in 5 of 20 walrus stomachs collected in northern Hudson Bay but did not identify the prey.

The Inuit of Igloolik and Hall Beach, on the coast of Foxe Basin, Northwest Territories (N.W.T.), rely heavily on walrus (Anderson and Garlich-Miller 1994; Department of Fisheries and Oceans 1991, 1992*a*, 1992*b*, 1993, 1994) for food for themselves and their dog teams (Beaubier 1970), but little is known about walrus ecology in this region (Mansfield 1966). In the only study of walrus diets in Foxe Basin, three stomachs were examined (Mansfield 1958). The objectives of the present study were to identify major prey species for walrus in northern Foxe Basin and to quantify the relative importance of prey types.

Materials and methods

Walrus stomachs were collected during Inuit subsistence hunts in Foxe Basin near Igloolik and Hall Beach in July 1987 and 1988 and September 1988 (Fig. 1). For each walrus, morphometric data were taken (Garlich-Miller 1994), the stomach and jaw were collected, and the sex was recorded. Samples were frozen (−20°C), usually within 24 h of collection, until they were analysed in the laboratory.

Two samples of benthic invertebrates were collected as reference

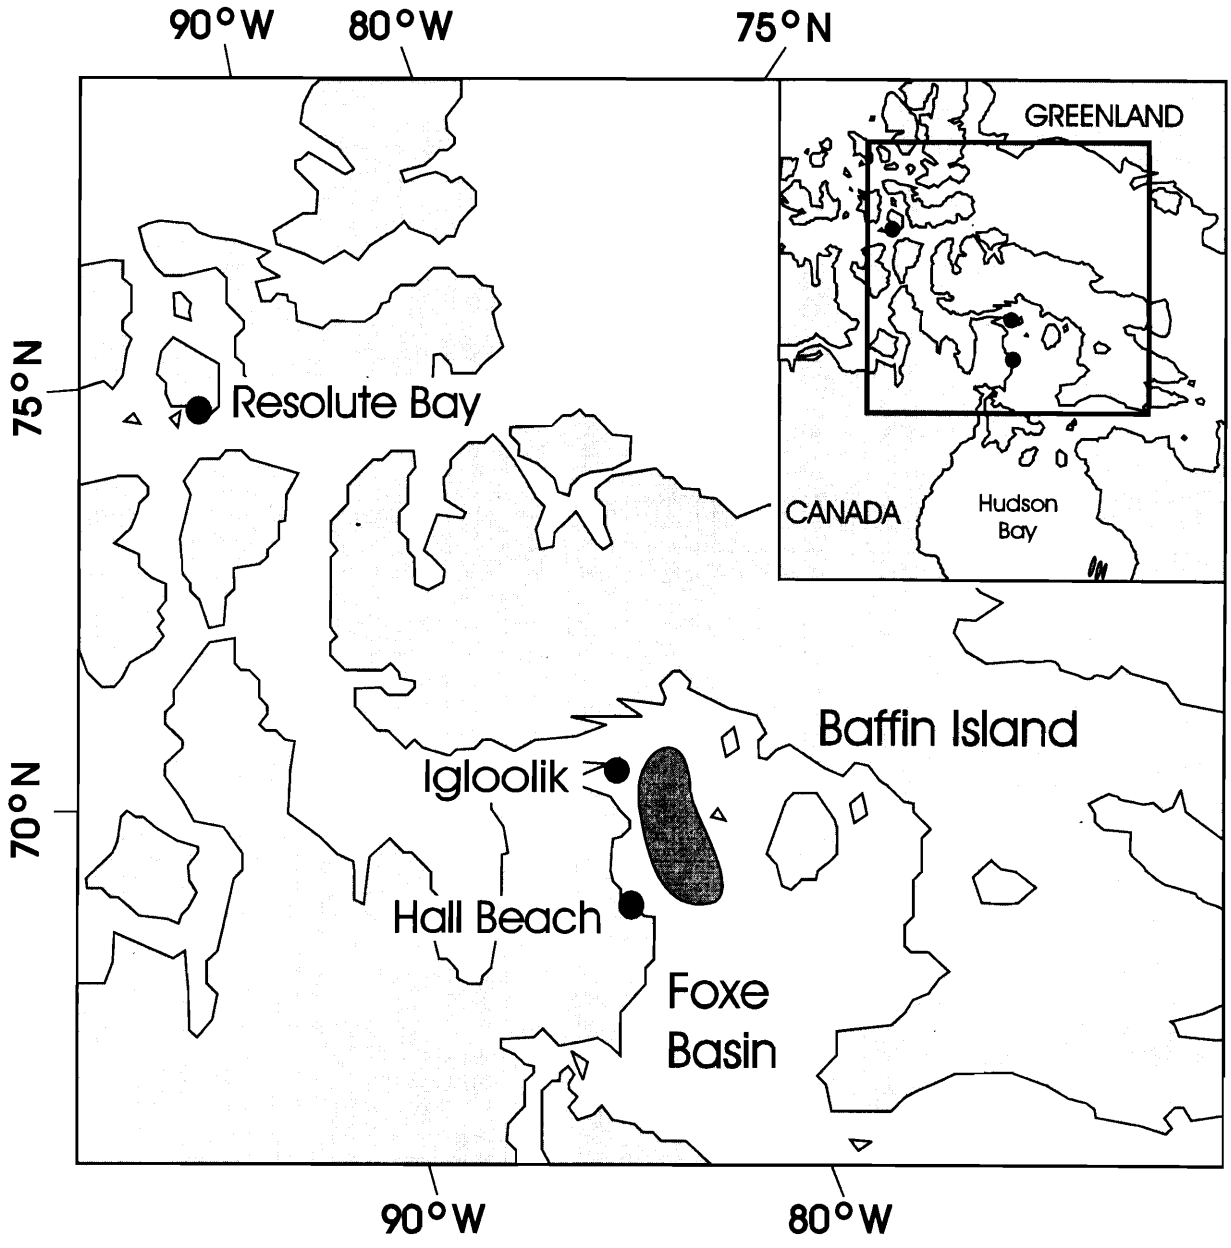
Fig. 1. Walrus (*Odobenus rosmarus rosmarus*) sampling area (darkly shaded) and benthic sampling sites (●).



material and for energy-content determinations. One sample was collected in July 1988 near Igloolik, near the walrus sampling area, by SCUBA divers, an underwater air-lift (Chess 1978), and a bottom grab, all at depths ≤20 m, as well as by hand in the intertidal zone. A second benthic sample was obtained by SCUBA divers near Resolute Bay, N.W.T. (74°42′N, 94°50′W; Fig. 1) in 1986 in water 5–20 m deep. Samples for caloric density analysis were frozen. Reference samples were preserved in 10% neutral buffered formalin or 70% ethanol.

In the laboratory, stomach contents were washed through 4 and 1 mm mesh sieves. Items were identified to the lowest taxonomic level possible using the reference collection and published keys (Shorygin 1948; Grainger 1955; Bousfield 1960; MacPherson 1971; Clarke 1974; Lubinsky 1980). Some representative species were sent to invertebrate taxonomists for identification. Bivalves could only be identified to genus because species identification is based on shells (Keen and Coan 1974), which were usually absent from stomachs. When bivalve genera were represented by only one species in Foxe Basin, genus identification was equated with species identification. The cockles *Serripes groenlandicus* and *Clinocardium ciliatum* (previously known as *Cardium groenlandicus* and *Cardium ciliatum*, respectively; Lubinsky 1980) could not be distinguished using fleshy parts. All cockles were considered to be *S. groenlandicus* because their shell fragments were found in stomachs but *C. ciliatum* shell fragments were not.

Identified prey were counted, blotted dry, and weighed to the nearest 0.1 g. Bivalve numbers were based on maximum counts of identifiable siphons, feet, bodies, or shells. Gastropod, polychaete, and brachiopod numbers were based on diagnostic hard parts such as opercula, jaws, and shell teeth. Numbers of most other prey were counts of whole individuals.

The quantity (percentage) of each prey found in walrus stomachs was quantified as (*i*) occurrence of each prey (number of stomachs in which the prey occurred/total number of stomachs × 100) (Hyslop 1980); (*ii*) numbers of each prey (number of individuals of a prey type in all stomachs/total number of all prey in all stomachs

[b]Estimated from length.

× 100) (Lowry and Frost 1981; Murie 1984); (*iii*) mass of each prey (total mass of a prey in all stomachs/total mass of prey in all stomachs × 100) (Hyslop 1980; Lowry and Frost 1981); (*iv*) energy contribution (estimated gross energy content of individuals of a prey in all stomachs/total gross energy content of all prey in all stomachs × 100) (Murie 1984). Average reconstructed mass of prey individuals was determined from undigested stomach contents when possible. Mass of ingested individuals of other species was estimated from specimens in benthic collections. Polychaete masses were provided by J.A. Fournier (personal communication in a letter, 1988).

The caloric density and percent dry matter of major prey were determined from the benthic collections. Samples were freeze-dried to a constant mass. Caloric density was measured using an adiabatic bomb calorimeter and is presented as the mean of two replicates that differed by <3%. Means of caloric density estimated for *Mya truncata* from the two collection sites were the same (*t* test, $P \geq 0.05$) and the data were pooled. Data on dry matter and caloric density of taxa not present in the benthic collections were obtained from undigested stomach contents or taken from the literature (Tyler 1973; Wacasey and Atkinson 1987; G. Atkinson, personal communication in a letter, 1988).

To estimate the gross ingested energy represented by each prey type, the number of individuals of a prey in a stomach was multiplied by the average reconstructed mass of those prey or prey components and the average caloric density (wet mass) of the prey. Holothurians were found only in pieces in stomachs and could not be counted, so their energy contribution was calculated by multiplying the mass of holothurian tissue present by the caloric density.

Siphon sheaths were found in walrus faeces, so we assumed that the sheath contributed a negligible amount of energy to the walrus. Siphon sheaths were not included in the calculations of gross energy intake for clams.

Inorganic and unidentifiable organic remains on the small-mesh sieve were sorted by specific gravity in a water column, drained, and weighed to the nearest 0.1 g. The volume of milk in stomachs was measured to the nearest 25 mL.

Two faecal samples were collected in July 1988 from ice floes where walrus had recently hauled out. Samples were washed through a 1 mm mesh sieve and prey remains identified from diagnostic hard parts.

Walrus were aged by counting cemental annuli (Fay 1982; Garlich-Miller et al. 1993). Readings were made in three to five blind replicates, outliers were removed using the 95% maximum normed residual (Snedecor and Cochran 1980), and the median value was accepted as the final age estimate (Stewart and Lavigne 1979[1]; Garlich-Miller et al. 1993). Based on 87% of asymptotic body size (Laws 1956), we considered females to be adults at age 5 and males at age 8 (Garlich-Miller 1994).

Differences in diet between the sexes were tested by the non-parametric Wilcoxon test for ranked data (Sokal and Rohlf 1969) at $P \leq 0.05$ for all analyses.

Results

Twenty-six stomachs were collected in July 1987 and 79 in July 1988 (Table 1). Of the total of 105 walrus stomachs collected in July, 94 were from immature (n = 10) or adult (n = 84) animals and 11 were from calves (<3 years). Among these immature and adult walrus, 20 (21%) of the stomachs contained >5 g of food, 13 (14%) had trace quantities (<5 g) of food, and 61 (65%) were empty. The 20 walrus stomachs with >5 g of food contained 590.6 ± 424.2 g (mean ± SD). The two stomachs collected in September contained 5095.4 ± 1080.1 g of food. Examination of dietary composition was based on the stomachs of the 11

calves and the 20 immature and adult walrus collected in July, unless noted otherwise.

Diet composition

Eleven calf stomachs were examined. Five of eight age 0 calves had milk (100–1650 mL) in their stomachs (Table 2). One of these also contained one gastropod, *Natica clausa*, and another contained one brachiopod, *Hemithyris psittacea*. One yearling stomach contained milk (25 mL) only, while the other contained both milk (200 mL) and invertebrates (nine individuals of four genera). One 2-year-old had milk (75 mL) only in its stomach.

Seventeen taxa were identified in the stomachs of immature and adult walrus, with the bivalves *M. truncata* and *Hiatella arctica* accounting for 90.9% of all organisms ingested (Table 3). *Mya truncata* occurred most frequently and was the most numerous (0–917 individuals/stomach) of all items consumed. Only the siphons, sheaths, and shell fragments of *M. truncata* were found in stomachs; bodies were absent. *Hiatella arctica* was found in 75% of stomachs and comprised 23.7% (0–588 individuals/stomach) of ingested items. Siphon, sheath, and shell remains were present but no intact bodies. Unidentified bivalve remains, including sheaths, viscera, and muscle fragments were found in 90% of the stomachs and comprised 31.4% of the total wet mass in all stomachs. *Astarte* sp. was also found in 75% of stomachs but only a few individuals, found only as shell fragments, were present.

Gastropods were recognized primarily by opercula. *Buccinum* sp. and *N. clausa* occurred in about half the stomachs (Table 3) and comprised 2.6% of all organisms. Four genera of polychaetes were found in walrus stomachs. The most frequent was *Nereis* sp., found in 55% of stomachs, followed by *Thelpus cincinnatus* (15%), and *Eunoe* sp. and *Flabelligera affinis* (10%; Table 3). *Nereis* sp. was the most numerous polychaete (0–123 individuals/stomach). Polychaetes constituted 4.4% of all organisms but contributed less than 1% of total mass.

Holothurians were found in 12 stomachs but could not be counted accurately or identified further because of the absence of diagnostic hard parts in the stomachs we examined. They contributed 8.9% to the total mass, but 85% of this was in three stomachs. *Priapulus caudatus*, which were swallowed

[a]Two pieces of holothurian were found, representing an unknown number of individuals.
[b]Based on 287 cal/g wet mass (Cummins and Wuycheck 1971), not reconstructed.

whole, occurred in 20% of all stomachs and represented 0.2% of total numbers. Brachiopods occurred in 45% of stomachs but contributed less than 1% to total numbers or mass. Amphipods, isopods, echinoderms, and decapods each occurred infrequently and contributed little in terms of numbers or mass (Table 3).

Stones (85.7 ± 124.8 g) were found in stomachs containing food. The largest single amount was 501.5 g in the stomach of an adult male that had fed on bivalves. Shell fragments occurred in small quantities (0–10 g) in 80% of the 20 stomachs.

Both faecal samples contained shell parts of *M. truncata* and *Astarte* sp., opercula of *Buccinum* sp., and jaws of *Nereis* sp. One also contained *N. clausa* and *H. psittacea*. Siphon sheaths were found in both samples. Only 35 individual prey were identified and no taxa were identified that had not been found in the stomachs.

Both stomachs collected in September contained more food than the fullest stomach in July. *Mya truncata* predominated (Table 4), but stomachs collected in September also contained large numbers (269) of *S. groenlandicus*. Not only were the feet of *S. groenlandicus* found, but many bodies and fragments of adductor muscle and mantle were also present, indicating that all fleshy parts were eaten. *Hiatella arctica* was found in small numbers (7 and 23 siphons) and contributed <1% of the total mass.

Prey size and energy contribution

Of the major prey species, only *M. truncata*, *H. arctica*, and *S. groenlandica* were well enough represented in undigested stomach contents to allow reconstruction of the average mass of individuals consumed (Table 5). Individual mass of food components was estimated by weighing all the intact specimens found in two stomachs and dividing by the number of individuals.

The caloric content of food components generally ranged from 0.3 to 6.0 kcal/component (Table 5). For *M. truncata* and *H. arctica*, the estimated gross energy intake was based on siphons only. For *S. groenlandicus* and *Astarte* sp., the caloric content of bodies and siphons was added when gross energy intake values were calculated.

In July, *M. truncata* contributed 81.4% of the gross energy intake (Table 3), followed by *H. arctica*, holothurians, *Nereis* sp., *Buccinum* sp., and *P. caudatus*. *Priapulus caudatus* represented over 15 kcal/individual but contributed little to the total energy content represented by the stomach contents. All other organisms contributed less than 1.0%. *Mya truncata* was the predominant source of energy in 15 of 20 stomachs, while holothurians predominated in three stomachs. *Nereis* sp. and *Buccinum* sp. each predominated in one stomach.

In September, *M. truncata* contributed 59.9% of the gross energy intake in stomach contents (Table 4), followed by *S. groenlandicus* (37.9%) and *Buccinum* sp. (1.2%). All other prey contributed <1.0%.

Sex and age: differences in diet

The occurrence of food in stomachs of male and female walrus was similar (females: 9 of 35, 25.7%; males: 11 of 54, 20.3%). Females tended to consume more food items (females: 679.8 ± 516.7; males: 223.8 ± 173.3), to have larger amounts of food in their stomachs (793.7 ± 463.3 vs. 424.1 ± 320.4 g), and to have greater estimated gross energy ingested (1433.7 ± 1024.7 vs. 519.9 ± 400.6 kcal). These differences, however, were not significant (nonparametric Wilcoxon test for ranked data, $P > 0.05$). *Mya truncata* contributed the same proportion of energy in stomachs of males (74.2%) and females (84.6%), but females received a significantly greater proportion (9.9%) of their energy from *H. arctica* than did males (2.2%, Wilcoxon test, $P < 0.05$).

[j]Weighted average of four decapod species (Tyler 1973).

There was no significant difference between the sexes in the percentage contributed by holothurians to the total energy content (females 0.3%; males 10.8%). Males were much more variable, with over 50% of the energy from holothurians in three stomachs and <1.0% in four.

Although the sample size was too small for statistical comparison, there were no obvious differences in stomach contents between immature walrus (n = 4) and adults (n = 16). The range of stomach content masses from immature animals (6.0–1447.2 g) was similar to that from adults (112.9–1370.4 g). The estimated gross energy ingested was also similar (immature walrus: 13.5–2112.4 kcal; adults: 168.7–2887.7 kcal). *Mya truncata* contributed 71.5% of the energy in the stomachs of immature walrus and 83.2% in adults.

Discussion

Biases in sampling and stomach content analyses

The stomachs we analysed came from the Inuit subsistence hunt. Virtually all walrus examined were hauled out on floating ice, and may have been somewhat removed, in time and space, from the actual feeding site. Also, it may be easier for hunters to approach and kill a walrus that has been hauled out for some time than a recent arrival, biasing the sample towards animals with empty stomachs. However, passage rates in walrus and other pinnipeds range from 5 to 9 h (Parsons 1977; Fisher 1989). Simulated digestion indicated that siphons and feet may persist in stomachs for more than 6 h but bodies disappear within 1 h (Sheffield and Fay 1995). Assuming a random feeding pattern and a 6-h clearance, about 25% of stomachs could be expected to contain feet and siphons. We found that 21% of non-calf stomachs contained >5 g of food, and digestion may be faster than in simulations or feeding intervals may be shorter than assumed, but there did not appear to be a strong sampling bias favouring empty stomachs.

Group feeding could have biased the data if several samples came from one group of walrus. The feeding and haulout rhythms of these walrus are unknown (Loughrey 1959; Richard and Campbell 1988), but a systematic sampling bias is unlikely because stomachs were collected from many groups throughout the 24-h day and over several weeks.

Analysis of stomach contents has been used for many

years to describe the diet of marine mammals (Lowry and Frost 1981; Beddington et al. 1985). However, it is difficult to assess the relative importance of prey in the diet accurately because of potential errors resulting from the differential digestion and retention of prey types (Bigg and Fawcett 1985). In the present study, percent occurrence, numbers, mass, and estimated gross energy contribution of prey species were used to describe the diet of walrus, although each has limitations.

Percent occurrence provides a qualitative picture of the variety of prey eaten but can overestimate the contribution of relatively unimportant prey types (Berg 1979). For example, *Astarte* sp., *Buccinum* sp., and *N. clausa* were found in 50% or more of our walrus stomachs in July but together provided <1% of the total mass or energy of prey in the stomachs.

Counts of individual prey items are generally accurate, but differential digestion of prey species and the retention of hard parts can obscure the true relative contribution of different species (Bigg and Perez 1985). Some prey that are digested rapidly or have small, easily overlooked diagnostic parts, such as holothurians and some polychaetes, are underrepresented in counts, while the importance of other taxa may be overestimated because of the retention of hard parts (Bigg and Fawcett 1985). The extent to which polychaete jaws and gastropod opercula were retained in walrus is unknown and their representation in the stomachs in this study may not reflect the true significance of these prey types in the walrus diet. However, polychaetes and gastropods represented <2% of the total estimated energy in the diet in July and would have to be greatly underestimated to substantially alter the conclusions.

Mass measurements of stomach contents are also affected by differential digestion rates that cause easily digested prey to be underrepresented (Berg 1979). This error increases with time after feeding and was significant in this study because many of the stomachs contained well-digested contents. The contribution of each prey type based on the mass present is unlikely to be a good indicator of the relative importance of different prey species in the walrus diet.

Back-calculation of the actual gross energy contribution of various prey types provides a good estimate of the relative importance because it is based on numbers, original size, and caloric density of prey. Although it is subject to the same errors as abundance measurements, as well as to errors inherent in estimating mean size, energy, and dry matter content, this calculation allows the diet to be evaluated relative to an energy budget for the consumer.

In this study, the reconstructed masses for the *M. truncata* siphons, *H. arctica* siphons, and *S. groenlandicus* were based on undigested stomach contents. The accuracy with which the mass of other individual bivalves, collected by divers, represents walrus diets remains to be examined. Bivalve siphons and feet were counted easily and the sample size for back-calculating sizes and energy density was large. In July and September, however, 31.4 and 17.0%, respectively, of the mass of stomach contents was unidentified bivalve remains. The gross energy intake represented by these remains could not be calculated because neither the number of individuals consumed nor their mass could be determined, so the energy contribution of bivalves is an underestimate.

For minor prey such as holothurians, which were probably underestimated by all methods, even a tripling of their energy contribution would not have significantly affected their rank as the third most important prey in the diet in July. Similarly, the potential retention of gastropod opercula and polychaete jaws does not alter their minor energy role.

For the calculation of gross energy intake, we assumed that the bodies of *M. truncata* and *H. arctica* were not consumed. Bodies of *S. groenlandicus*, but not *M. truncata*, were present in the two fresh stomachs in September, although those of *M. truncata* were 5 times as numerous. The fresh siphons of *M. truncata* in these stomachs appeared jagged and stringy, consistent with being ripped off and inconsistent with removal of the body by digestion. When our divers tried to pull *M. truncata* out of the ocean floor, even after partially excavating the clam, they produced torn siphons that looked similar to these.

In some areas, Pacific walrus may consume all the soft tissue of clams (Fay and Lowry 1981; Fay and Stoker 1982), and *Mya arenia* buried in sand were consumed whole by Pacific walruses in captivity (Kastelein et al. 1989; Kastelein and Mosterd 1989). However, the ability of walrus to obtain whole clams depends on the behaviour of the clams, which is species-specific, and the substrate in which they reside. The nature of the substrate in Alaska was not reported, but in the study using captive walrus, the sand was loosely deposited in a trough.

Based on the stomachs we examined and the experience of our divers, we concluded that *M. truncata* bodies are seldom eaten by walrus in Foxe Basin. However, if bodies of *M. truncata* were consumed at the same rate as siphons, the caloric content would increase to 9.7 kcal/individual. The total contribution of *M. truncata* would increase to 94% in July and 84% in September, with concomitant decreases in the proportions contributed by other species. However, the ranking of prey species in the diet would not change.

Diet composition

The quantities of milk and benthic invertebrates found in the stomachs of calves in our study were similar to those previously reported (Freiman 1941; Nikulin 1941; Mansfield 1958; Loughrey 1959; Fay 1982). Newborns rely heavily on milk during the first year, although some invertebrates are eaten (Fay 1982). The dependency on milk decreases as foraging skills are acquired, and most calves are fully weaned by 2 years of age (Fay 1982). Some, however, continue to suckle, and calves 25–27 months old have been found with only milk in their stomachs (Freiman 1941; Nikulin 1941; this study). Continuation of nursing into the third summer most likely occurs when females do not produce a new calf (Fay 1982).

Our results for older animals are also similar to those of previous descriptive studies of the food habits of Atlantic walrus. Vibe (1950; n = 5 walrus) and Mansfield (1958; n = 19 walrus) identified the bivalve genera *Mya*, *Hiatella* (= *Saxicava*), and *Serripes/Clinocardium* (= *Cardium*) as major prey items. Holothurians, gastropods, crustaceans, polychaetes, and other organisms were consumed to a lesser extent. The holothurian *Thyonidium* sp., the isopod *Mesidotea sabini*, and ascidaceans (tunicates) were identified by Mansfield (1958) in Foxe Basin samples but were not found in this study. Polychaetes, brachiopods, amphipods, sea urchins, and the isopod *Arcturus baffini* found in this study were not reported by Mansfield.

Pacific walrus in the Bering and Chukchi seas also feed

For personal use only.

mainly on bivalves. In the Bering Sea, the genera *Mya*, *Spisula*, *Hiatella*, *Serripes*, and *Clinocardium* composed 60–80% of identifiable food items in the diet, although over 60 genera of benthic organisms were reported (Nikulin 1941; Brooks 1954; Fay et al. 1977, 1984).

Ringed seal (*Phoca hispida*) and bearded seal (*Erignathus barbatus*) remains have been found in several walrus stomachs in the Canadian Arctic (Mansfield 1958; Loughrey 1959) and other areas (Chapskii 1936; Tsalkin 1937; Vibe 1950; Lowry and Fay 1984). Consumption of ringed seals has been inferred from high organochlorine levels in walrus from northern Quebec (Muir et al. 1995; Wagemann et al. 1993). Fish otoliths (Chapskii 1936; Mansfield 1958) and squid beaks (Mansfield 1958) have been identified in a small number of stomachs. None of these was present in our sample.

Selective feeding, in which the proportions of various species found in stomachs differ significantly from the proportions collected from the sea floor, has been reported for Atlantic (Vibe 1950) and Pacific (Fay et al. 1977) walrus. Fay (1982) suggested that walrus select bivalves but that other foods may be consumed opportunistically. Whether the walrus in our collection were selecting prey or consuming a representative sample of benthic invertebrates on the sea floor is unknown. Asteroids, crinoids, and ophiuroids inhabit Foxe Basin (Grainger 1955; this study) but were not found in our walrus stomachs.

Walrus of both sexes aged ≥3 years consumed the same prey types. As previously reported for Pacific walrus (Fay et al. 1977, 1984), females obtained a larger percentage of their gross energy intake from *H. arctica*, but other differences were not statistically significant. The similarity in diets among walrus age and sex classes suggests that their primary prey, which are relatively small and sedentary, are effectively located and consumed by all segments of the population.

Seasonal feeding patterns of Atlantic walrus are not well documented, largely because of the inaccessibility of walrus populations during the winter. Walrus off Greenland feed throughout the summer and fall (Vibe 1950), but information on walrus feeding in the Canadian Arctic in fall and winter is scant. Mansfield (1958) found an increase in the number of stomachs containing food from July (18%, $n = 39$) to September–November (31%, $n = 42$) in the eastern Canadian Arctic. Although our September sample was quite small ($n = 2$), both stomachs contained food and the mean mass of the stomach contents was 5095 g, 3.5 times that of the contents of the largest stomach sampled in July (1447 g).

A female walrus from Foxe Basin has an asymptotic body mass of approximately 630 kg (Garlich-Miller 1994) and, when not pregnant or lactating, requires 155 kcal · $kg^{-0.75}$ · d^{-1} (Fisher 1989; Fisher et al. 1992), or roughly 19 500 kcal/d. In July, the average reconstructed gross energy intake was 931.8 kcal. With a nominal clearance rate of 6 h and feeding 4 times a day, this represents about 3727 kcal/d, or about 19% of the female's daily energy requirement. If whole *M. truncata* are eaten, the average reconstructed gross energy intake increases to 2900.9 kcal, or about 11 603 kcal/d, representing 59.5% of the daily requirement. This crude calculation and the high percentage of empty stomachs in July (68%; Table 1) suggest that walrus over 3 years old may be in a negative energy balance in Foxe Basin in July, requiring greater energy intake at other times.

In the fall, walrus in Foxe Basin may feed more often or eat larger meals, or both, than they do in July. In the fall, walrus are closer to the west side of Foxe Basin (Orr et al. 1986), where the water is shallower and *S. groenlandicus* is expected to be found (Vibe 1950). The average reconstructed gross energy content in the two stomachs colledted in September was 3179.3 kcal, or 12 717 kcal/d, about 65% of the asymptotic female's daily needs. If whole *M. truncata* are eaten, the value is 8132.3 kcal, representing about 32 529 kcal/d, or 167% of daily requirements. There are several untested assumptions in these calculations, and testing hypotheses about feeding rates and seasonal shifts in prey requires more walrus stomachs to be collected in September, and better distributional data for bivalves to be obtained.

Acknowledgements

We thank the hunters of Igloolik and Hall Beach, R. Walker, and J. Garlich-Miller for their capable assistance in obtaining samples. R. Walker also assisted with the collection of benthic samples during SCUBA dives. Benthic samples from Resolute Bay were provided by H.E. Welch, Department of Fisheries and Oceans, Winnipeg. Representative samples of polychaetes were identified by J.A. Fournier, Canadian Museum of Nature, Ottawa; gastropod opercula by J. Topping, Canadian Museum of Nature, Ottawa; and amphipods and isopods by M. Curtis, Department of Fisheries and Oceans, Winnipeg. We thank them all for their assistance. We also appreciate the assistance of B.E. Stewart, who made the caloric density determinations. This study was part of the requirements for an M.Sc. degree in the Department of Animal Science, University of Manitoba, for K.I.F. We thank the members of her supervisory committee, J. Babaluk, R. Fudge, and anonymous reviewers for their constructive comments on earlier drafts of this paper. Funding was provided by the Department of Fisheries and Oceans, the Science Institute of the Northwest Territories, and the Northern Studies Training Program.

1 Introduction

ConocoPhillips Global NVE Greenland Ltd., DONG E&P Grønland A/S and Nunaoil A/S (referred to collectively as "ConocoPhillips") are pleased to submit an Environmental Impact Assessment (EIA) to the Bureau of Minerals and Petroleum (BMP) for a proposed 2D-seismic survey in Block 2 (Qamut Block). This region is located in northeast Baffin Bay, licence number 2011/11. The 2D-siesmic survey would occur from early August to mid-September 2012, with the option of extending to 1 October 2012 if ice conditions, weather conditions, sea state or other factors delay the program.

This report describes the "Final EIA". It was prepared by revising or amending the EIA that was submitted to BMP in mid-March 2012. A non-technical summary in English, Greenlandic and Danish was submitted at the same time. That version of the EIA will be referred to as the "Preliminary EIA". BMP released the Preliminary EIA Report to the public for a consultation period that was eight weeks in length. ConocoPhillips's responses to Information Requests from this consultation with stakeholders and communities formed the basis for producing the Final EIA.

The Final EIA Report has been prepared by Golder Associates A/S and INUPLAN A/S, in consultation with ConocoPhillips. It was produced in accordance with the January 2011 BMP "Guidelines for preparing an Environmental Impact Assessment [EIA] report for activities related to hydrocarbon exploration and exploitation offshore Greenland" and December 2011 BMP "Guidelines for application, execution and reporting of offshore hydrocarbon exploration activities (excluding drilling) in Greenland", including Appendix G ("Guidelines to environmental impact assessment of seismic activities in Greenland waters", 3rd revised edition) prepared by Danish Center for Environment and Energy (DCE).

ConocoPhillips is aware that Block 2 (Qamut) is closer to the Melville Bay Reserve than other licence areas. It also recognizes that there is an overlap of the proposed seismic survey region with Narwhal Protection Zone I (NPZ-I) in northeast Baffin Bay, where "seismic activities shall be avoided or of limited extent (a few widely spaced (>10 km) lines)", and consequently, if operations occur in NPZ-I between 1 June and 15 October, that "a detailed shooting program is subject to BMP approval, and if approved, impact studies on narwhal shall be considered" (NERI 2010). ConocoPhillips is concerned about the possible effects of underwater sound on marine mammals during the survey period mentioned above. It will support programs carried out on these effects by DCE and the Greenland Institute of Natural Resources (GINR). ConocoPhillips understood before submission of the Preliminary EIA that more discussion with BMP or DCE about seismic operations in NPZ-I would be necessary during the application process, and that it was important to address all aspects of this subject in a proper and appropriate way. This situation was taken into account during preparation of the Final EIA.

ConocoPhillips looks forward to applying its experience from many years of operations in Alaska and other northern locations to exploration activities in northeast Baffin Bay. It welcomes the opportunity to interact and engage with members of communities, the authorities, and other stakeholders about the seismic survey proposed for 2012.

1.1 Project Overview

The proposed exploration program in northeast Baffin Bay during 2012 involves a 2D-seismic survey in the central part of Block 2 (Qamut). This program, referred to as "the Project" below, is described in Section 3 of this report. ConocoPhillips Global NVE Greenland Ltd is "Operator" during exploration activity in Qamut Block. DONG E&P Grønland A/S is a "Partner"; Nunaoil A/S is a "Partner" as well.

1.2 Purpose and Structure of the Preliminary and Final EIA

An EIA has been performed on the Project because BMP decided that it has the potential to have significant impacts on the environment, either by itself, or in combination with other planned exploration activity, in northeast Baffin Bay this year. This decision was made after ConocoPhillips submitted a detailed Scope of Project Report to BMP on 1 February 2012.

The offshore setting of the Project, and the nature of the exploration activity that would occur during the Project, have a strong influence on the purpose and structure of the EIA. It has three objectives: determine if the Project will have an effect on the marine environment in a specific and broader sense of potential impact; identify the

extent of possible effects; and develop or specify means to mitigate, or reduce where possible, the identified possible effects. Possible effects of the environment on the Project are also addressed.

To meet the objectives mentioned above, the physical and biological environments, and land & sea use in Qamut Block, were described from a local and regional point of view. A project description was also developed. A summary of the national and international legal frameworks that provide guidance and set limits on the Project, and on methodology used for impact assessment, was prepared. An assessment was performed on the Project, including potential impacts of the exploration program on the marine environment at local and regional scale, as well as cumulative effects and trans-boundary effects. Other work was conducted during preparation of the Preliminary EIA, including acoustic modeling to investigate cumulative effects from multiple operations occurring at the same time in northeast Baffin Bay, and assembly of an Environmental Protection Plan (EPP) for the Project. This plan was based on the assessment, on regulatory requirements in Greenland, and on "best practice" in other jurisdictions.

After the Preliminary EIA Report was submitted to BMP in mid-March 2012, it was released to communities, agencies, and other stakeholders by posting on <www.nanoq.gl> for a review and consultation process that was eight weeks long. Responses to Supplemental Information Requests that resulted from this process were used to prepare the Final EIA. BMP will make a recommendation about the Final EIA to the Greenland Government. A decision will be made by the Greenland Government to approve the Project, in whole or in part, with or without conditions, and grant a licence for it to proceed.

The Final EIA Report is structured as follows:

- Section 2 provides a brief overview of the Greenland and International legal and regulatory frameworks.
- Section 3 introduces the Project activities, location, survey plan and other details; provides BMP's required tables (four in total), and describes alternatives considered during design of the Project.
- Section 4 presents the exisiting physical and biological environment as well as land & sea use in the Project area.
- Section 5 describes the impact assessment methodology, and how the assessment was performed.
- Section 6 presents the impact assessment on the residual effects from project activities on valued ecosystem components (VECs).
- Section 7 describes acoustic modeling and assessment of cumulative effects of underwater sound on marine mammals and fish in a regional setting.
- Section 8 contains the Environmental Protection Plan (EPP), including the mitigation measures that ConocoPhillips will be applying to Project activities.
- Section 9 describes data gaps and subjects for research that were identified during the assessment process.

Figures are located at end of the main text before a series of appendices. Please refer to these appendices for references, a list of acronyms and abbreviations, a glossary,a summary of the legal and regulatory frameworks, a technical report on acoustic modelling, supporting information on EIA methodology, a summary of project mitigation measures, a Marine Mammal and Seabird Observation (MMSO) Plan, and a table with attachments containing ConocoPhillips's responses to Supplemental Information Requests.

2 Legal and Regulatory Setting

Greenlandic legislation, regulations and guidelines applicable to the Project are listed in Appendix B. Table B-1.

Greenland and Denmark are signatories to a number of international agreements and thus have obligations under several international conventions with regards to the use, administration, and protection of the environment and wildlife. Those potentially applicable to seismic surveys in Greenlandic waters are described in Appendix B, Table B-2.

3 Project Description

The section provides, in accordance with BMP Guidelines (December 2011 version, including Appendix G), a description of the proposed exploration activity, the area where this work will occur, schedule, and equipment and materials for the 2D-seismic survey that ConocoPhillips is proposing to undertake in Qamut Block. Table 3.1-1

contains the details that BMP has requested on the seismic survey. This table, and the other three tables that are specified in the Guidelines, are found at the end of Section 3.1. The location of the survey is shown in Figure 3-1, including a lay-out of the planned seismic lines. This survey grid is a modification of the survey grid that was included in the Preliminary EIA Report. This change was agreed to at a meeting between ConocoPhillips and DCE in Copenhagen on 22 May 2012. The reasons for this change are described in more detail below.

3.1 Scope of Work

The offshore exploration program that ConocoPhillips is proposing for West Greenland in 2012 is a 2D-seismic survey in northeast Baffin Bay, including collection of marine gravity and magnetic data. Roughly 3,000 line-kilometres (line-km) of high quality 2D-seismic reflection data, as well as marine gravity and magnetic data, will be collected in the survey region during the Project. ConocoPhillips will use this data to conduct a detailed geological and geophysical evaluation of the license area.

The Project location will be in the central, eastern and northern parts of the Qamut Block. The survey region extends into the west-central part of Narwhal Protection Zone I (NPZ-I) and northern part of NPZ-II.

Four sail lines extend slightly north of the licence area boundary for line-tie purposes. During preparation of the Preliminary EIA, ConocoPhillips discussed the possibility of obtaining a supplementary or additional exploration licence for the tie-in lines with BMP. It was decided that an extra licence would not be required for this part of the survey.

The portion of the survey that is located in NPZ-I was discussed at a meeting between ConocoPhillips and DCE in Copenhagen on 22 May 2012. This part of the survey has been changed, which ConocoPhillips brought to BMP's attention after the meeting with DCE. It was agreed that modifying the survey grid in NPZ-I would address concerns about proximity to the Melville Bay Reserve, line spacing in NPZ-I, and possible impacts of underwater sound on narwhals during the seismic survey period.

The background and basis for the modification is as follows: ConocoPhillips believes that two of the primary sub-surface targets (possible hydrocarbon reservoirs) in the Qamut licence area extend into the region that is part of NPZ-I. To mature these leads, and determine whether or not an exploration well is justified, additional seismic data in the form of either a 3D survey or an approximately one km by one km 2D-seismic survey is required. ConocoPhillips decided to pursue the 2D solution. In order to limit exposure to underwater sound in the NPZ-I area, the 2D survey plan has been altered to cover only the area occupied by the identified leads, leaving a small number of widely-spaced 2D lines for regional mapping. Two measures are being implemented in this regard:

- The total amount of seismic data within NPZ-I will be reduced by removing every other north-south line in the area between the mapped leads. This effectively removes roughly 100 line-km of acquisition from the survey. To meet the licence obligation of acquiring 3,000 line-km of 2D-seismic data, ConocoPhillips will add roughly 100 line-km of acquisition to the area southwest of the NPZ-I boundary.
- Great effort will be expended to execute a shooting pattern that alternates operations inside NPZ-I with operations outside NPZ-I. The goal is to not operate continuously in NPZ-I for long periods of time.

The proposed schedule for the Project is early August to mid-September, with an option of extending it to 1 October if the seismic survey is delayed by weather conditions, ice conditions, sea state, or other factors. It would proceed for four to six weeks, and take place 24 hours per day, seven days per week based on safe operations when sea ice is not present.

Three vessels have been chartered to carry out the Project, including: one ice-class seismic survey ship; one ice-class chase vessel; and one support and re-supply vessel. The CGGVeritas M/V *Princess* will be used to conduct the 2D-seismic survey (including collection of marine gravity and magnetic data). The chase ship and support/re-supply ship will be the M/V *Thor Supplier* and the M/V *Thor Beamer*, respectively. This information was mentioned in the Preliminary EIA. In early June 2012, it was necessary for ConocoPhillips to change these ships. They have been replaced by equivalent vessels, including the *Artemis Angler* as the seismic ship, F/F *Meredian* as the chase ship, and MV *Arctic Star* as the support/re-supply ship (which may act as a second chase ship). The airgun array and single streamer that will be used by the *Artemis Angler* will be identical to the airgun array and single streamer that would have been used by the *Princess*. CGGVeritas will also continue to be the seismic contractor for the survey.

ConocoPhillips decided that the Final EIA would not be altered to reflect this change in the fleet, since it was an operations planning adjustment that is not uncommon during seismic surveys when release of a ship, or ships, from a previous charter has been delayed, or when any or all of the proposed ships are not available for other reasons. The change is not regarded as material or significant for environmental assessment purposes. It will be addressed by ConocoPhillips as part of the "Application Package" process for the 2012 program in Qamut Block (which is distinct or separate from the EIA process described in Section 1.2), or in a Supplementary Filing or Submission to BMP. Consequently, mention of the *Princess*, *Thor Supplier* or *Thor Beamer* in the rest of Section 3, or in other sections of the Final EIA, was left as is.

Health, Safety & Environment (HSE) performance was taken into account during selection of CGGVeritas as the contractor for the seismic survey, including policies, procedures, vessels, and equipment that were "fit for purpose" in Arctic environments, including conditions in northeast Baffin Bay. This factor was included in the evaluation to lower the likelihood, as much as possible, of the seismic survey having impacts on the environment in the survey region.

The *Princess* is a dual-source, multi-streamer seismic ship well-suited for performing the 2D seismic survey described below. This vessel has integrated geophysical and navigation data acquisition systems, full quality assurance capabilities and onboard positioning and seismic data processing facilities. The seismic source on the ship consist of tuned arrays of G-gun II airguns. The *Princess* is equipped with a full acoustic system to position the in-water seismic equipment. Standard quality control products available in real-time include brute stacks, signal-to-acoustic ratio analyses on shot gathers, and near-trace displays.

The *Princess* will be using or deploying a single airgun array for seismic signal generation. A seismic receiver cable (or streamer) will be towed behind the vessel for recording the reflected signal. Details of the air gun array are provided in Tables 3.1-2 and 3.1-3 at the end of this section. The M/V *Princess* will sail along a total of 50 pre-planned sail lines and release high pressure air to provide a down-going pressure wave at regular intervals. The sail lines are planned to infill the existing license database in order to obtain a regular grid of seismic data to allow an adequate definition of subsurface structures. A line change plan for the seismic survey will be developed. This plan needs to be flexible, and take sea ice and glacial ice conditions, weather conditions, sea state and other factors at the time of survey into account. The survey vessels, equipment and material brought into Qamut Block will leave the licence area at the end of the survey. CGGVeritas has a strict "no spill" policy during operations in Arctic waters. There are no planned discharges into the sea, with the exception of normal discharges permitted by the authorities under Greenlandic regulations or international conventions. No waste disposal is planned, on land, during port calls. No ballast water discharge is contemplated, unless re-ballasting to set or establish an ice draft for any of the ships, or related to re-fuelling, is needed. Re-fuelling may or may not occur during the survey period. It is possible that ship-to-ship transfer from the support/re-supply vessel will be done if re-fuelling is required.

The marine gravity and magnetic measurements will be recorded along the sail lines. The system for collecting gravity data is hull-mounted; the magnetic data is obtained with a submerged system that is towed behind the *Princess*. No energy or sound is emitted by either system when the data are obtained. Equipment for these measurements will be provided by Austin Exploration Inc. The survey ship will not deviate from the sail lines to collect this information. It is normal industry practice to collect gravity and magnetic data during seismic surveys. The ship will use two systems for depth measurements during the survey. The *Princess* is equipped with an Atlas Echograph 461 echosounder for navigation and safety purposes. A single-beam bathymetry system will be used for survey purposes only, to accurately measure water depths along the sail lines. This system is a Kongsberg EA600 echosounder that operates at a frequency of 12 kHz, 32 kHz or 200 kHz. The two echosounders are the only active (hull-mounted) sound sources on the *Princess* that ConocoPhillips is aware of.

It is noted that a simultaneous operations plan, with mitigation added that is related to reducing effects of underwater sound on marine mammals in a regional setting, will be developed and implemented by the three operators in northeast Baffin Bay before their programs, if approved, begin in 2012. The usual purpose of this plan, in addition to safety related to transit and manoeuvring when several ships are operating in one area, is to minimize problems with data quality or integrity when two or more seismic surveys are occurring at the same time. Addition of mitigation to a simultaneous operations plan is not a standard practice. It is one of the actions that the operators will be taking to reduce possible impacts of underwater sound on marine mammals from a cumulative effects point of view. This situation is also discussed in Section 7 and 8 of the Final EIA.

All of the steps outlined in the BMP Guidelines (December 2011 version, including Appendix G), involving operation of an airgun array during a seismic survey, will be followed. These steps, including any survey-specific procedures and measures developed by ConocoPhillips for the Project, are being implemented to reduce or mitigate the effects of underwater sound on the marine environment that are related to operation of the airgun array."Best Practice" during seismic surveys at sea will be employed throughout.

A Safe Operations Plan, or equivalent, including an Emergency Response Plan (for example, procedures for responding to accidental discharges and environmental incidents), is being developed by ConocoPhillips and CGGVeritas. This plan is mentioned in the EPP for the Project (Section 8), but it is not attached to the Final EIA at this time. An Ice Management Plan for the Project is also being developed by ConocoPhillips, assisted by CGGVeritas and other companies. A multi-tier or multiple-level approach, involving actions or procedures before, during and after the survey, will be followed. An important part of this plan, which is summarized in the EPP (Section 8), but not attached to the Final EIA at this time either, will be "ice avoidance" at tactical (near-ship) level. Towing of bergy bits and small icebergs is not anticipated during the survey.

A Marine Mammal and Seabird Observation (MMSO) Plan has been be developed by ConocoPhillips, and will be carried out during the seismic survey. This plan is summarized in the EPP (Section 8), and attached in Appendix J (Marine Mammal Management Plan). The *Princess* will be using a Passive Acoustic Monitoring (PAM) system during the survey period. Table 3.1-4 contains the details requested by BMP on this system. A plan or approach for PAM during seismic operations is discussed in the EPP (Section 8). A mitigation airgun will also be used. It is part of the approach that will be implemented by ConocoPhillips to mitigate impacts of underwater sound on marine mammals.

Table 3.1-1 Survey Data

Specify	Description	Provided
Type of survey (2D, high resolution (3D), well testing, other)	2D seismic survey	ConocoPhillips
Map of the area with all transect lines shown	please refer to Figure 3.1-1	ConocoPhillips
Start and end dates for the survey	Planned operation is from the beginning of August 2012 to middle of September; however, ConocoPhillips requests an option to operate until 1 October 2012 in case of delay caused by weather, sea ice, sea state, or other issues.	ConocoPhillips
Expected duration of seismic program	four (4) to six (6) weeks	ConocoPhillips
Duty cycle of operation (in hours/24 hours); number of hours in the dark per 24 hours	24 hours per day, 7 days per week, based on safe operations when sea ice is not present (i.e., when conditions are "open water" or ice-free" only, and ships can operate safely)	ConocoPhillips
Number and types of accompanying vessels	two (2) chase vessels	ConocoPhillips
Intended use of icebreakers. Will survey be carried out in ice?	Icebreaker will not be used. Seismic survey will not occur when sea ice is present – "open water" or "ice-free" conditions only. Ice management plan being developed (mostly involves glacial ice, but sea ice will not be overlooked in this plan, or at sea).	ConocoPhillips

Table 3.1-2 Array Specification

Specify	Description	Provided
Number and names of vessels towing airgun arrays	one (1) vessel; CGGVeritas *M/V Princess*	ConocoPhillips
For each vessel provide geometric layout of complete airgun array with individual volume specified (in PSI per airgun and in^3 per airgun)	please refer to Figure 3.1-2 and 3.1-3	CGGVeritas
Size of total array (in^3 and PSI for the entire array)	3,940 in^3 (one array consisting of three sub-arrays, as shown in attached diagram),	CGGVeritas
Firing rate in shots/sec. Will sub arrays fire simultaneously or alternate?	firing rate: 10 sec/shot; the sub-arrays will fire simultaneously	CGGVeritas
Operation speed of the vessel in km/hours or knots.	approximately 5 kt over bottom	CGGVeritas

Table 3.1-3 Acoustic Properties of the Airgun Array

Specify	Description	Provided
Far field pressure signature of total airgun output (provide figure)	please refer to Figure 3.1-4	JASCO
Frequency spectrum of the far field airgun signature (broadband) (provide figure)	please refer to Figure 3.1-5	JASCO
Source level (source factor) of airgun array on acoustic axis below array given in all of the following units		
dB re 1 µPa peak-peak (broadband)	262.4 dB re 1 Pa	JASCO
dB re 1 µPa rms (Over 90%* pulse duration) (provide duration for rms calculation) *as defined in Malme et al., 1986; Blackwell et al., 2004	247.1 dB re 1 µPa, duration is 33.5 milliseconds (ms)	JASCO
dB re: 1 μPa^2s. per pulse	232.8 dB re: 1 Pa^2s	JASCO
Energy, joule/m^2 per airgun pulse	9,643 J/m²	JASCO
Signal duration. (Define how it is measured)	33.5 ms (90% rms pulse duration as defined in Malme et al., 1986)	JASCO
Map showing modeled sound pressure levels (rms*), peak-peak and sound exposure level (μPa^2s) for the survey area and surroundings (to levels likely to affect marine mammals or nearest land) * rms calculated by the 90% energy approach for derivation of the duration (Malme et al., 1986; Blackwell et al., 2004).	please refer to Appendix D	JASCO
Provide description of the acoustic propagation model, including assumptions of sound speed profiles.	please refer to Appendix D	JASCO

Table 3.1-4 Specifications of PAM System

Specify	Description	Provided
Number of hydrophones	4	Seiche Measurements Ltd.
Threshold of the recording system	band width20Hz to 200kHz +/–3dB	Seiche Measurements Ltd.
Sample rate of the recording system	low frequency cetaceans samples up to 98kHz higher frequency cetaceans (such as porpoises) sampling rate of 500kHz	Seiche Measurements Ltd.
Where will hydrophones be placed?	behind the vessel mounted on the trailing equipment (rigging / lead-ins), the exact distance aft has not been determined by CGGVeritas	Seiche Measurements Ltd.
Will there be duty cycling of recordings? In that case when will the PAM system be used?	equipment will be recording and manned continuously	CGGVeritas / ConocoPhillips
Name of software	WindowsXP,"Ishmael", Pamguard Sigview	Seiche Measurements Ltd.
Species covered	all vocalizing species	Seiche Measurements Ltd.
Estimated range accuracy, m.	as per manufacturer's specifications	Seiche Measurements Ltd.

3.2 Alternatives Considered

ConocoPhillips is committed to acquiring additional seismic data as part of its license requirements. It has an obligation to obtain a minimum of 3,000 line-km of 2D-seismic data during Exploration Phase 1.

A number of methods have been evaluated for accessing the Qamut sub-surface configuration and hydrocarbon potential. Different geophysical methods can be applied to an area to evaluate its sub-surface geology, including marine gravity surveys, marine magnetic surveys, and marine controlled source electromagnetic surveys, in addition to marine seismic data acquisition. However, seismic surveys are the only viable means of providing enough detail of the sub-surface to better understand the hydrocarbon potential of the licence region, and identify locations for possible drilling sites. Investigating the Qamut Block without acquiring additional seismic data is not possible, and a "no activity" option in 2012 cannot be considered at this time.

ConocoPhillips has evaluated the need for 2D- versus 3D-seismic acquisition for the Qamut license. It was concluded that acquisition of additional 2D lines would provide sufficient data coverage to allow interpretation of the strata and structural configuration at this point in the exploration phase. The interpretation of the 2012 seismic data would help to highlight the areas with significant hydrocarbon potential.

The seismic source will generate an elevated sound level in the northeast Baffin Bay area. ConocoPhillips evaluated alternatives to determine if a solution existed to mitigate the elevated sound levels from a seismic survey in this region. All commercially available seismic airgun systems produce a broadband signal, even though only the lower parts of the frequency spectrum is being recorded in the reflected signal. Methods for reducing the high frequency content have been investigated during Joint Industry Projects (JIPs), but no successful methods have been developed. Alternative seismic signal generation has also been investigated. However, both the watergun and the marine seismic vibrator are not commercially available. The current prototypes appear to produce a frequency spectrum that cannot be used for seismic imaging of deep basins. ConocoPhillips concluded that an airgun system is the only available seismic source for the Qamut seismic survey.

ConocoPhillips evaluated different options for airgun volume to see which volume was needed to produce the required data quality for the proposed 2012 survey. Several seismic surveys have been undertaken in the Baffin Bay area; different airgun volumes have been used during these surveys. For example, employing up to 5,016 in^3, as in the Kanumas 1992 seismic survey, does not appear to provide uplift compared to the 4,100 in^3 volume used in 2009 and 2010. Reducing the volume to 2,050 in^3 in volume, as in the 2000 survey, has an effect on data quality, especially in the deeper parts of the area, and would reduce the value of the seismic data for understanding the structural development of the basins and structures. The proposed airgun volume of 3,940 in^3 will produce the best seismic image.

The seismic acquisition lines proposed for the 2012 seismic survey are pre-planned to in-fill existing seismic data to provide sufficient data coverage over the most prospective sub-surface areas. The current survey layout is the most effective based on the current data base. Other layouts are possible, but these lines would lead to an irregular grid pattern. This pattern could create a requirement for more data, and consequently, a longer survey period, which is not desirable.

With respect to timing of the proposed survey, early August 2012 to mid-September 2012 was deemed the most appropriate period. The actual duration will be dependent on ice conditions, weather conditions, sea state, and other factors at time of survey, but deploying a streamer up to 10 km in length means that data acquisition must occur during a period when sea ice is absent or at a minimum in Qamut Block.

4 Environmental Baseline

4.1 Physical Environment

4.1.1 Introduction

This section of the EIA describes the physical environment of northeast Baffin Bay. It includes information that is relevant to assessment from a regional point of view, as well as information that applies at local (block or licence) level. The following subjects are covered: the setting in Baffin Bay; marine weather; oceanography (including acoustic conditions and bathymetry/seabed); and ice climatology (including sea ice and glacial ice). The Strategic EIA on northeast Baffin Bay (NERI 2011) is not as comprehensive on physical environment as it is on biological environment, and consequently, the approach taken below is detailed and thorough to support the assessment on the Project.

4.1.2 Regional Setting

Baffin Bay is situated between the Arctic Ocean and the Labrador Sea (northwest Atlantic Ocean), between the west coast of Greenland and the east coast of Baffin Island (Canada). The coastal features around Baffin Bay are mountainous, and contain many ice sheets and glaciers, particularly the massive Greenland Ice Sheet (or the “Inland Ice”).

Baffin Bay is about 1,400 km long by 550 km wide and is characterized by relatively shallow sills at its connections with the Arctic and Atlantic Oceans, and by a deep and large abyssal plain in its center. Three narrow (width of the order of 50 km or less) channels connect Baffin Bay to the Arctic Ocean: Smith Sound (through Nares Strait) to the north, Jones Sound to the northwest, and Lancaster Sound to the west (Figure 4.1-1) with sill depths of 250, 120 and 125 m, respectively. On its southern boundary, Baffin Bay is connected to the Atlantic Ocean (via the Labrador Sea) by the much wider and deeper Davis Strait, which has a sill depth of about 650 m and a width of about 170 km at the 500 m isobath, or contour of equal depth.

4.1.3 Marine Weather

4.1.3.1 Atmospheric Circulation

The pattern of atmospheric circulation over Baffin Bay exhibits large changes between winter and summer, and may vary from year to year. In January (winter), in addition to a high pressure system over and north of northern Greenland), a high pressure system, often referred to as the "polar vortex", covers the eastern Canadian Arctic, centered over Baffin Island (Cappelen et al. 2001). A low pressure region develops south and east of Greenland, focused on the Icelandic Low, extending over the Norwegian Sea toward northern Europe. As a result of this pressure pattern, northerly winds will typically prevail over most of Baffin Bay. The pattern usually lasts from November until April or May. In July (summer), the mean pressure gradients are weak, especially around Greenland, resulting in variable wind conditions determined by passing cyclones. Cyclonic activity can occur anywhere in the Greenland area, with most storms or cyclones affecting Baffin Bay arriving from the south to southwest. In winter, if storms follow this track frequently, a warmer, wetter period results, contributing to less severe sea ice conditions along the northwest Greenland coast. A good summary of the regional meteorology and energy balance is found in DMI-DTU (2011).

4.1.3.2 Air Temperature

Maps of air temperature compiled by the Danish Meteorological Institute (DMI) reveal a large west to east gradient in winter, with colder temperatures in western Baffin Bay, while in summer, an almost uniform distribution of temperatures occurs over Baffin Bay (Figure 4.1-2). Mean temperatures in winter are about -20°C, with lows of about -40°C occurring in late winter over unbroken, snow-covered ice in Melville Bay and near the coast of Baffin Island. In summer, the air temperatures are similar to ocean surface temperature in these areas, though the local air temperature, at sea, can be as low as -5°C from time to time during this period. Summer temperatures as high as +5°C, or greater, have been observed at reporting stations along the northwest Greenland coast Valeur et al., 1996).

4.1.3.3 Inter-Annual Variability: North Atlantic Oscillation

Air temperature, wind and other meteorological parameters exhibit large amounts of year-to-year or inter-annual variability in northeast Baffin Bay. Air temperature measurements at coastal weather stations along the west coast of Greenland reveal large variations over time scales ranging over periods of two or three to many years (Figure 4.1-3). The inter-annual variability in annual air temperatures are associated with the North Atlantic Oscillation (NAO) index, computed as the normalized difference in sea level pressure between southwest Iceland and Gibraltar (Figure 4.1-4). Above (below) normal air temperatures off West Greenland are associated with below (above) normal values of the NAO index. A persistent and strong negative North Atlantic Oscillation (NAO) index was responsible for southerly air flow along the west of Greenland (northerly winds, in winter, are the long-term norm), which caused anomalously warm weather in winter 2010 to 2011 and summer 2011 (Box et al. 2011).

4.1.3.4 Wind

Due to the atmospheric circulation pattern noted above, northerly to northwest winds occur frequently in western and central Baffin Bay. Inflow takes place mainly through Smith Sound, Lancaster Sound and Jones Sound, while outflow is through Davis Strait. In both the north-western and north-eastern portions of Baffin Bay regions, gale-force winds often occur. In contrast to this pattern, Melville Bay is in somewhat sheltered by northern Greenland while the coastal area further to the southeast is exposed to south-southeast winds. In summer, south-southeast winds are dominant, particularly near the Greenland coast (Valeur et al. 1996).

A comprehensive wind-wave hindcast dataset (MSC50) prepared by Environment Canada (2012) was used to characterize the wind conditions of northeast Baffin Bay. This is shown in Figure 4.1-5. The time-series data were processed with a time-step of three hours, and provide continuous data for the period 1958 to 2008 inclusive. A complete description of the dataset and the hindcast method is provided by Swail et al. (2006). North-westerly winds are dominant in the western portion of northeast Baffin Bay, while winds are primarily from the southeast in the eastern part of the area. In between, at roughly long. 64°W, a transitional regime occurs. The wind intensifies toward the coast with more frequent wind at speeds greater than 10 m/s at the two sites closest to the Greenland coast. These results are consistent with the results reported by Valeur et al. (1996). Similar results are reported by DMI-DTU (2011), based on DMI's High Resolution Area Model.

The Environment Canada MSC50 datset was also used to characterize the winds in the vicinity of the Qamut Block. The diagram in Figure 4.1-5 was derived from the entire time-series (1958 to 2008); a summary table can be found in Table 4.1-1. The yearly rose demonstrates a wind dominantly from the east to southeast with little contribution from other quadrants. The seasonal pattern, from January to December, features dominant east to southeast winds that veer to southerly winds in spring and summer (May, June and July) with a light winds from the north to northwest sector on Figure 4.1-6 occur mainly in May and June. The winds return to more easterly in the fall to winter period (September to December) with a stronger regime in October. The most energetic period is the fall and winter (October to March), when the mean wind speeds are above 4 m/s, and estimated maximum speeds, above 20 m/s, in November, December and February. Lower mean and maximum wind speeds are seen during summer (June to August) with a lower mean speeds of 2.9 m/s in June and lower maximum speeds of 16.2 m/s in July.

Table 4.1-1 Qamut Block Wind Statistics from MSC50 Hindcast Data Node M3018543

	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec	Year
Mean wind speed	3.8	3.8	3.6	3.4	3.2	2.5	2.8	3.4	4.4	5.5	4.5	3.8	3.7
Dominant direction	WNW	WNW	WNW	WNW	WNW	SE	SE	SE	ESE	SE	WNW	WNW	WNW
Maximum wind speed	14.6	17.0	13.2	11.3	12.5	13.0	14.3	13.5	15.6	16.5	17.1	16.0	17.1
Direction of max. wind	SE	SE	SSE	SSE	ESE	ESE	SE	ESE	E	SE	SE	SE	SE

4.1.3.5 Precipitation

Due to the low moisture content of the air masses involved, precipitation in the Baffin Bay area is small, about 200 mm/yr, according to Valeur et al. (1996). Precipitation falls mostly in summer and fall along the northwest Greenland coast, occasionally as rain, but mainly as snow, based on observations at Upernavik (Valeur et al. 1996). The precipitation events result from passage of storms associated with atmospheric fronts. In summer, light snow or drizzle may fall from low stratus clouds. In winter, light snowfall occurs near leads and polynyas in the established ice cover. Before this ice cover is fully developed, heavy snow showers typically occur (Valeur et al. 1996).

4.1.3.6 Visibility

The predominant cause of reduced visibility in Baffin Bay is fog, which occurs mainly during the summer months. The frequency of fog events will increase during the spring, and peaks in June/July. The frequency of fog decreases by late August (Valeur et al., 1996) and through September to October as the sea surface temperatures warm following the clearing of sea ice. Coastal weather station data at Aasiaat, Nuuk and Paamiut (Figure 10 in Hansen and Buch, 2004) indicates that the highest frequency of fog occurs in July (10-18%). Fog conditions tend to decrease in August (8-5%) and further decrease in September (3-8%) and October (<1-2%) (see Figure 4.1-7). Advection fog, conditions occur when air temperature falls below 0°C, in association with low wind and clear skies. Icing is possible during periods of advection fog, and rime ice or clear ice may form on exposed surfaces. During the winter months, the fog that occurs is described as “radiation” fog, which develops over snow-covered, unbroken sea ice under clear and calm conditions. Finally, “steam” fog (also known as “sea smoke”) can form where cold air moves over an ice-free or open water area from an ice-covered region. Precipitation events and blowing snow also contribute to reduced visibility to some extent. Additional information on this subject can be found in DMI-DTU (2011).

4.1.3.7 Icing

Icing can form by freezing precipitation, fog or sea spray. Freezing sea spray is the most dangerous form of icing; it is dependent on wind speed, air temperature, sea surface temperature, and the vessel or structure involved. In Arctic offshore areas, including northeast Baffin Bay, where air temperatures and sea surface temperatures during the open water period are both typically lower than in low latitude areas, it can be especially problematic during ship operations. Significant icing by sea spray is most likely to occur from October to December if open water is present and northerly winds develop. Other forms of icing include freezing rain and freezing fog. Freezing rain is generally rare in Baffin Bay; accumulation of ice from freezing fog will be low unless the fog is persistent.

The two icing nomograms in Overland et al. (1986), or the four used by the US Navy, showing light, moderate and heavy icing as a function of air temperature and wind speed at specified sea surface temperatures, are often referred to. The first set is shown in DMI-DTU (2011), and not reproduced here.

4.1.4 Oceanography

4.1.4.1 Bathymetry and Seabed

The bathymetry of northeast Baffin Bay is relatively well-known at regional scale. It is shown on appropriate small-scale Danish and Canadian charts, and is available in digital form as the General Bathymetric Chart of the Ocean (GEBCO) and International Bathymetric Chart of the Arctic Ocean (IBCAO) gridded data. A value-added version of the IBCAO has been used for regional mapping and acoustic modeling during the EIA. This information, including isobaths derived from the elevation surface, appears to be more accurate, and more extensive, than isobath polygons available in digital format from DCE. Water depths are shown on Danish charts 1600, 1700, 3100 and 3200 at 1:250,000 scale, and consist of track or line soundings augmented by spot soundings over the historical period of charting by Danish authorities. The region is characterized by a complex continental shelf of varying width along the coast north of Disko Island. This shelf has been deeply incised by submarine valleys or canyons that were formed by glacial action (outflow from the Inland Ice) in the past.

The most prominent seabed feature in Qamut Block is Isfjeldbanke (Iceberg Bank), centered roughly 90 to 100 km south-southeast of Savissivik, in the central and eastern part of the licence area, bounded on the east by a deep submarine canyon and on the north (between the coast and the licence boundary) by a similarly deep depression. This bank has minimum depths of less than 100 m on Danish chart 3100, and occupies a large area that is less than 200 m deep. The outline of the bank is not entirely accurate compared to ConocoPhillips bathymetry derived from proprietary seismic surveys carried out by TGS Nopec and other companies, but minimum water depths are similar, and it is satisfactory for planning and assessment purposes during the EIA.

Sediment properties and benthic ecology at and below bottom on the continental shelf and slope, and on the abyssal plain at depths of 2,000 m or greater, are not well-known in northeast Baffin Bay, with the possible exception of the North Water region in northern Baffin Bay between northwest Greenland and Devon and Ellesmere Islands in northern Canada. Some reconnaissance box coring and piston or gravity coring has been done by Canadian, American and Danish scientists during international expeditions, in addition to more detailed (site-specific) work carried out by Shell Kanumas A/S during summer/fall 2011 at and near locations proposed for stratigraphic drilling in 2012.

It is very likely that frequent scouring (or gouging) of the seabed by icebergs is a key process that affects sediment properties and benthic ecology on the shelf and upper slope in northeast Baffin Bay when the keels of these icebergs come into contact with the bottom. This suggestion is based on the high numbers of icebergs in these waters, discussed further in Section 4.1.5, that could produce scours during drift or movement in response to currents and the surface wind field. This scouring will typically occur when depths are varying and become shallow, but also, it can happen when the keel depth increases as a result of rotation (roll-over) or other motion of the iceberg. Ice scours have been mapped in several offshore areas where hydrocarbon exploration or production occurs. It is almost certain that scouring takes place along the east Greenland coast, and especially, along the west Greenland coast north of Davis Strait, where high numbers of large icebergs are calved, and transported by the West Greenland Current across banks and other shallow areas on the shelf. Depending of the draft of the large icebergs involved, scouring could occur down to water depths of 250 m on the upper slope. The scours could be as deep as four to six metres in some locations (K Been, pers. comm. 2012) if soft clay sediment is present.

The scours in-fill over time with material that settles through the water column to the bottom, or from boundary layer transport along the seafloor. Depend on the amount of scouring that takes place, it can lead to an upper seabed that consists of mostly or only scoured/in-filled material over periods as short as 50 or 60 to a few hundred years in areas prone to frequent scouring (Smale et al. 2007). The pattern of past and present scours that cross each other can have an important impact on the seabed. When silt or clay soils are disturbed, they generally lose some of their strength, and may absorb water. This process is known as “remoulding”. It can take a long time for the clay soil to regain its strength after remoulding. Sands also lose strength and become looser when they are disturbed, but strength gain can be relatively rapid under wave or other hydrodynamic loading. These observations are related to scouring in the Beaufort Sea, off Sakhalin Island, and off Newfoundland and Labrador, but it is likely the same situation applies in northeast Baffin Bay. Other aspects of scouring by icebergs are discussed in Appendix C.

4.1.4.2 Circulation

The surface circulation of Baffin Bay is primarily cyclonic (counter-clockwise) with an inflow of warm and more saline water (the West Greenland Current) on the east side of Davis Strait, and a broader outflow of cold and less saline water (the Baffin Current) on the west side of the strait. This pattern is shown in Figure 4.1-8.

The West Greenland Current that enters eastern Baffin Bay consists of two components (Buch 2000, 2002 and Myers 2009):

- a modified East Greenland Current component, closest to the coast, carrying water of polar origin (from the Arctic Ocean) northward, after it rounds Cape Farewell; and
- a current component originating from the Irminger Sea and North Atlantic Current, located to the west of and below the East Greenland Current component.

The Atlantic Water component (Irminger Current and North Atlantic water from the Labrador Sea) is significantly larger than the East Greenland Current component. Clarke and Johnson (1984) estimated 11 Sverdrup (Sv, equal to 106 m^3/s) of volume transport for the Atlantic Water versus 3 Sv for East Greenland Current component, for example. As it moves north, a significant portion of the West Greenland Current turns offshore when it encounters the Davis Strait sill, which diverts this water to the interior of the Labrador Sea (Myer et al. 2009). The remaining water continues to flow north, and enters Baffin Bay through Davis Strait. The remaining East Greenland Current component (on the shelf), at this point, is greatly decreased in volume. The properties of this water have been significantly modified by local run-off and interaction with the slope water component (Buch 2000, 2002, NERI 2009). The relatively warm and saline water forming the slope current component flows along the slope and outer shelf, and can be traced as far north as Thule (Buch 1990, 2000, 2002).

A recent estimate of transport by the West Greenland Current indicates that the inflow of the warmer and more saline sub-surface component along the slope is about 1.5 Sv, and that the inflow of the colder and less saline surface component, on the shelf, is about 0.4 Sv (Curry et al. 2011). Seasonality is important; a stronger influx of water from the slope component occurs during fall and early winter (Curry et al. 2011, Tang et al. 2004). Variability from year to year and decade to decade appears to be significant as well. Myer et al (2009), for example, described quasi-decadal variability with the longest consistent period of enhanced transport over a 50-year record taking place during the 2000s. This longer-term variability is probably influenced by the North Atlantic Oscillation (Buch 2002).

As it flows northward along the east coast of Baffin Bay, the West Greenland Current is strongly affected by the topography of the shelf. The West Greenland shelf is deeply incised by large fjords and canyons. Using a numerical circulation model, Tang et al. (2004) described the topographic control and spatial variation of the currents. The results of their simulations illustrate stronger currents along the southern part of the northwest Greenland shelf, and weaker and more variable currents north of lat. 72° N. Canyons divert part the flow toward the coast and off the shelf, particularly to the south and north of Disko Island. When it enters northern Baffin Bay near the North Water Region (see “Sea Ice by Seasonal Period” below), the West Greenland Current mixes with Arctic Ocean outflow that enters Smith Sound from Nares Strait, and essentially ends as a distinct ocean current (Buch 1990, 2000, and Ingram et al. 2002). The combined outflow through Smith, Jones and Lancaster Sounds then drives the south-setting Baffin Current, with estimated volume transport ranging from 0.7 to 2.1 Sv (Tang et al. 2004). Other aspects of regional circulation in Baffin Bay are described in Appendix C.

Except for a small number of moorings deployed by the Bedford Institute of Oceanography (BIO) operational model atlas (Wu and Tang 2011) were retrieved from the BIO database (DFO ODI database 2012). A summary of the analysis is presented below.

The results from the southernmost mooring located in deep water demonstrate both velocity maxima and means that increase with depth, while the second mooring, located further north on the slope and in shallower water, demonstrate similar current strength from surface to bottom. Currents are not strong in general (mean speed <0.1 m/s) but are found to be stronger at the more southerly mooring. Deep currents (below 500 m) are noticeable. They are roughly 0.2 m/s on average during summer, and reach maximum values of more than 0.6 m/s. Seasonality is important down to the 475 m depth measurement, and overall, the currents are higher during summer and lower during winter within the surface and subsurface layer. Winter currents were barely measurable within the surface layer, at less than 1 cm/s in strength. Within the bottom layer, however, the 975 m

deep measurement does not demonstrate as much seasonality, but summer currents are still stronger than winter ones overall.

4.1.4.3 Tides

The tides of Baffin Bay are predominantly semi-diurnal and the major semi-diurnal constituent M2 is characterized by an amphidromic point located at about lat. 70° N, almost in the middle of Baffin Bay (Greisman et al. 1986). Both semi-diurnal (components of the tide that occur twice each day) and diurnal (components of the tide that occur once each day) tidal waves propagate anticlockwise (cyclonically) from this amphidromic point.

Tidal amplitudes increase away from the amphidromic point and are higher in the Davis Strait and Smith Sound regions where the M2 constituent of the tidal heights reaches amplitudes of the order of a meter and more. Strong fortnightly modulation (spring and neap) in the tidal elevations is observed in northern Baffin Bay and Kane Basin (Ingram et al. 2002).

No tidal gauge or other tidal records for the Qamut Block were found in the public domain. The closest record on the northwest Greenland coast is from Foulke-Havn about 300 km north of the area, on the east coast of Smith Sound. Recent modeling studies undertaken by the Bedford Institute of Oceanography (Collins et al. 2011) can be used to provide quantitative estimates of the tides in the Qamut Block. A map of the tidal heights over the region, including the license area, was obtained by running and extracting a 29-day prediction at regular intervals (every 0.1 degree) from lat. 74.5° N to 76.5° N and from long. 70.75° W to 61.25 °W. The results were combined to represent maximum (spring tides) tidal range and the current magnitude that can be expected in this region, as shown in Figure 4.1-10 and Figure 4.1-11. The model results indicate that the tidal range and tidal currents increase toward the northwest, as described above. The maximum tidal currents (Figure 4.1-11) also exhibit a substantial increase of current strength over the Qamut Block due to shallower depth, and particularly on the eastern side, with magnitudes above 20 cm/s.

4.1.4.4 Water Mass Distribution and Structure

The water column of northern Baffin Bay, following Tang et al (2004), consists of three layers:

- a colder and relatively fresh surface layer (temperature 0 to -1°C, salinity less than 33.5 practical salinity units(psu) equivalent to parts per thousand) in the upper 100 to 300 m of the water column;
- a warmer and more saline intermediate layer (temperature +1 to +2°C, salinity up to 34.5 psu) from about 300 to 800 m; and
- a colder and slightly less saline (compared to intermediate water) deep layer (temperature less than 0°C, salinity greater than 34 psu) from 1,200 m down to the bottom.

There is a northward deepening of isopycnals (contours of equal density) in the upper 200 m, supporting the existence of a west-setting current in northern Baffin Bay, as well as a temperature minimum at roughly 100 m depth (which is a remnant of winter cooling), and a temperature maximum at 500 to 800 m depth (Tang et al. 2004).

The upper layer consists of inflow from the Arctic Ocean through Nares Strait and other passages to the west and northwest, and to a lesser extent, inflow along the West Greenland shelf (Tang el al. 2004). The on-shelf component of the West Greenland Current, described in Section 4.1.4.2, carries the latter water north. The middle layer, known as West Greenland Intermediate Water, is related to influx of relatively warm and saline water from the northwest Atlantic Ocean. This water is also transported north, along the slope and outer shelf, by the West Greenland Current. It is warmer during winter compared to the summer period. The temperature of this water mass is not uniform, and is reduced as it circulates (Tang et al. 2004). The origin and fate of the deep layer in Baffin Bay, over the abyssal plain, known as Baffin Bay Deep Water from 1,200 to 1,800 m, then as Baffin Bay Bottom Water from 1,800 m to the bottom, involves vertical processes in the basin itself, rather than advection (inflow) from external areas, such as the Labrador Sea. Deep water exchange with other basins does not occur. Other aspects of water column structure and water mass properties in Baffin Bay are described in Appendix C.

To examine the water column structure of the Qamut Block in more detail, data from the World Ocean Atlas (NOAA 2012) were extracted and processed. The data represent a composite of profiles (a mean or average) collected over a number of years, sometimes back to the early 1900s or eariler. The temperature and salinity profiles provided represent “climatology”, rather than a given profile at a specific date and time in northeast Baffin

Bay. A one-degree latitude, west to east longitudinal profile from long. 70°W to 62°W centred on lat. 75.25° N, was extracted from the 0.25 degree resolution available dataset and averaged to create the profile. Temperature and salinity profiles during summer can be found in Figure 4.1-212.

From July to September, the Qamut Block is characterized by a thin surface layer (roughly, the upper 25 m of the water column) of warm (about 1.5°C) and fresh (less than 33 psu) water above the three water masses, mentioned above, that Tang et al. (2004) described. The lower (deep) water mass, is not present in the licence area, since only a small region in the northeast part of the block has water depths approaching the upper limit of this water mass.

Overall, the water column is slightly colder westward except for the thin surface layer in which warmer temperatures occur from west to east. It is also generally fresher, to the west, in the upper 200 m of the water column. According to Buch (1990, 2000), this surface mixed layer originates from the melting of (winter) sea ice, together with run-off from land, and the melting of glacier ice. This forms a thin, less saline layer of water during spring. Due to the intensification of solar radiation in summer and to the vertical salinity stratification, the heat is stored within this thin layer and temperatures increase significantly.

The water structure is more strongly stratified during the summer from west to east in the licence area, with higher temperatures at the surface and lower sub-surface temperatures. This could be due to higher sea ice melting volume on the western part of the area and/or stronger vertical mixing over the shallow banks present on the eastern part.

No upwelling areas were identified by NERI (2006, 2011) along the northwest Greenland coast, but strong vertical advection due to the tides along or across the steep slopes of banks can occur. This is supported by the temperature profile data reported by Valeur et al. (1996). These vertical mixing areas would be located where the tidal currents are strongest.

4.1.4.5 Large-Scale Variability due to Winds, Air-Sea Fluxes and Fronts

In the upper layer of the water column, from the time of sea ice break-up in late June through to ice freeze-up in early November, there are large temperature and salinity gradients in both the vertical and horizontal domain. An example of this situation is the vertical temperature-salinity distribution at an oceanographic station off Upernavik in July 2009 (Ribergaard 2010). The vertical gradients in this section, in the form of elevated water temperatures of up to 5°C in a thin layer at the surface, develop from the vertical exchanges of heat between the ocean and the atmosphere, in this case, during summer after melting of sea ice. Winds are also important in northeast Baffin Bay. Strong winds result in vertical mixing of water properties to greater depths; when winds are weak, the water column can be more stratified, causing larger vertical gradients. In addition, depending on direction, winds can drive the upwelling of nutrient-rich deeper water to the surface. West or north-westerly winds can lead to upwelling at the shelf edge off northwest Greenland and also along ice edges, when the ice edge is laying to the west. Precipitation and evaporation can decrease or increase the salinity of surface and near-surface waters as well. However, these vertical exchanges result in smaller changes to salinity than those due to ice melt and formation processes in northeast Baffin Bay. Variability of water column properties, which can be considerable in this region, has important effects on the presence and abundance of marine life.

Oceanic fronts, or large horizontal gradients in water properties, are also important biologically active zones in northeast Baffin Bay. Munk et al. (2003) reported that "...the establishment of hydrographical fronts are of primary importance to the plankton communities in the West Greenland shelf area, influencing the early life of fish and the recruitment to the important fisheries resources". Mossbech et al. (2002) also noted that "fronts, upwelling areas and marginal ice zones are examples of...hydrodynamic discontinuities [in Greenland waters] where high surface concentrations of phytoplankton, zooplankton, and shrimp and fish larvae can be expected".

The West Greenland Current Front (WGCF) closely follows the shelf break and the steep upper slope along the northwest Greenland shelf until it reaches long. 52° W where the slope becomes notably less steep and therefore no longer stabilizes the WGCF (Aquarone et al., 2009). This is shown in Figure 4.1-313. This front results in eddy generation that enhances cross-frontal exchange of heat, salt and nutrients, as well as zooplankton and juvenile fish. The Mid-Shelf Front (MSF) is found over the mid-shelf roughly parallel to the coast. It roughly separates the two components of the West Greenland Current, described above in Section 4.1.4.2, from each other as both continue to flow north and the on-shelf component is modified during summer and fall by fresh water from various sources, including meltwater from the Inland Ice. The front between these two components of

the West Greenland Current is weak from January to May and relatively strong the remaining part of the year, with maximum strength in September and October (Hansen et al. 2004).

Other frontal features occur in northern Baffin Bay, such as those measured off Cape York at the boundary between the relatively warm waters of the remaining West Greenland Current in this area and the cold Arctic waters exiting Smith Sound (Melling et al. 2001). The current measurements reveal large-scale or deeply penetrating horizontal gradients, or frontal features, as well as smaller frontal features occurring near the surface.

4.1.4.6 Sea Ice Melt and Upwelling

The near-surface frontal features in the upper layer of northeast Baffin Bay are primarily associated with sea ice break-up and melting, iceberg movement and melting, and direct meltwater run-off along the northwest coast of Greenland. The contribution of the first process to surface and near-surface water column properties is described in this section.

The melting of sea ice in early summer results in reduced salinity waters at the surface of northeast Baffin Bay, since the salinity of first-year sea ice is typically about 8 psu, which is considerably less than the surface water salinities of about 30 psu in this region. The average thickness of the sea ice during the melt season is in the range of 1.5 to 2.0 m (NERI 2011).

In summary, a significant amount of fresh water enters the upper part of the water column in northeast Baffin Bay when this ice melts during the break-up and clearing process on the northwest Greenland shelf. This pattern is described in more detail in Section 4.1.5.1. The volume of water involved is roughly $1.1 \times 10^{11} m^3$. Appendix C describes how this estimate was calculated, and contains other details on the significance of fresh water input from sea ice melting.

Another important attribute of sea ice break-up and melting in early summer is the location of the remaining West Ice in central Baffin Bay through June and into July. Upwelling along the pack ice edge has been shown in other Arctic regions to be an important mechanism. This was noted, for example, by Buckley et al. (1979) and Dumont et al. (2010), involving enrichment of nutrients in the upper layer of the ocean due to transport of the surface waters away from the ice edge under favourable wind conditions which are replaced by higher nutrient waters from depth, and also from beneath the ice itself. In the case of Middle Ice Pack, this means upwelling could occur during periods of westerly to northwest winds, which are not as prevalent as south-easterly winds in northeast Baffin Bay during summer, but still common (DMI-DTU 2011). The importance of ice-edge upwelling to increased ocean productivity levels has been noted in northwest Baffin Bay by Borstad and Gower (1984) and off southwest Greenland by Pederson et al. (2003).

A novel form of localized “upwelling” is possible in northeast Baffin Bay. It does not involve ice-edge processes, but rather, the effect an iceberg has on the upper part of the water column when it is moved by wind or surface currents through the ocean, including the momentum “wake” of glacial ice it creates, which trails behind the iceberg when it is drifting. The water column is locally displaced, bringing up deeper water that is nutrient-rich. Ice in the wake, and the iceberg itself, will continue to melt, contributing fresh water to the surface layer, which continues to be locally altered and mixed, but on a diminishing basis, until the ice disappears. Other aspects of this situation are described in Appendix C.

4.1.4.7 Freshwater Run-off from Land and Icebergs

Freshwater inputs to the sea from land sources are important to the oceanography of northeast Baffin Bay, especially the inshore and shelf regions. Freshwater of land origin can take three forms: direct run-off from rivers and streams along the West Greenland coast, including the extensive fjords; melting of outflow glaciers at tidewater (including drainage via meltwater channels in these glaciers that enters the ocean directly); and the export of glacial ice to the sea in the form of icebergs, which subsequently melt as they move away from the coast.

The total mass loss of Greenland glacial ice will result in considerable amounts of freshwater inputs to Baffin Bay in summer months. The total freshwater volume discharge for all of West Greenland, resulting from loss of ice sheet mass, has been estimated as approximately 2×10^{11} m^3/yr. This total is derived from ice sheet volume reductions (Box et al. 2011) and from iceberg volume fluxes (Valeur et al. 1996). The total freshwater discharge occurs as both run-off and melt into the ocean at the shoreline and at tidewater glaciers, as well as from iceberg calving. Nearly all of this freshwater would be released during the period from mid-May to mid-September during

times of above zero degree air temperature and clearing of sea ice cover. The total volume of freshwater released from land sources of $2x10^{11}$ m^3 is approximately twice that of freshwater input from sea ice melt over the shelf areas for all of eastern Baffin Bay. This input was estimated to be $1.1x10^{11}$ m^3; it was described in Section 4.1.4.6.

Direct meltwater run-off occurs from late spring to late summer (Box et al. 2011) with episodic events according to the weather conditions on the coast and over the Greenland Ice Sheet. The resulting fresh water will be most concentrated in the fjords and along the coastline in shallower waters, and will tend to be localized to higher concentrations near the coastal discharge locations. The nature of the concentrated sources of fresh water leads to formation of fronts at the edges of the brackish plumes that extend into the shelf waters, mostly from mid-July until the end of summer. The plumes and associated fronts will be mixed, and gradually erode over time due to wind forcing and other types of mixing in the ocean with increasing distance from the source areas.

The fronts associated with the freshwater run-off sources along the coast will be important in the Qamut Block on its northern side, which is located about 30 km from shore. This is within the area or zone that would be subject to these freshwater inputs, and associated processes.

The large number of icebergs that calve from tidewater glaciers in northeast Baffin Bay represents a way for freshwater from the Greenland Ice Sheet to reach much greater distance offshore, as these icebergs fracture and melt over their lifetimes. Diemand (2001) noted that the effect of the rapid side-melting of an iceberg along its length or width is "...the vertical mixing of the surrounding seawater. Driven mostly by the release of air from the bubbles in the ice and partly by the lower density of the fresh water of the melted ice, water flows upward near the berg, drawing deep water to the surface." Other aspects of this situation are described in Appendix C.

4.1.4.8 Acoustic Conditions

The propagation of underwater sound in Arctic regions, including northeast Baffin Bay, is influenced by temperature, salinity, and sound velocity variation with depth (the sound speed profile). Gradients or variation in the profile cause refraction (bending of the sound propagation direction) that focuses sound to lower velocity regions. Sound attenuates with distance due to spreading loss, interaction with the seafloor and ocean surface (including sea ice that is floating on the surface), and chemical processes in the water column (particularly at higher frequencies, that is, several kilohertz and greater). In contrast to temperate and tropical waters, the temperature and salinity structure in the upper part of the Arctic water column (typically, "cold" and "fresh", or, at least, cool and less saline, compared to deeper waters) can lead to a low velocity region at or near the surface. The difference between sound velocity profiles in the Arctic (ice-covered and ice-free) and other ocean areas is shown in Figure 4.1-14. At low latitudes, the sound profile results in downward refraction of sound, that is, sound is turned away from the sea surface toward deeper water. In contrast, the upward-refracting (ice-free and ice-covered) Arctic profiles trap sound near the surface.

When a low velocity condition develops and becomes stable in the mixed layer, this region is called a "surface sound channel" from an acoustic point of view. Sound in this part of the water column (especially at lower frequencies) can travel long distances with low transmission loss. When sea ice is present, sound speed is at a minimum at the sea surface. This creates an upward-refracting "Arctic sound speed profile". Sound is "trapped" in the water column by the surface sound channel; ice thickness, air content and bottom roughness influence sound propagation when the sound channel is at the top of the water column. When ice cover melts or ablates, salinity is reduced, but surface waters also begin to warm, or become warmer, from solar input. The depth to the sound channel axis changes – it is near to, but not at, the surface. The sound velocity minimum is typically found at 50 m depth when ice cover is not present.

The surface sound channel is stable during the summer/fall period in the West Greenland Current, which flows over the middle to outer shelf, and along the slope past the shelf break. Waters in this current, which is relatively weak and spatially variable, begin to cool and become less saline as the flow continues north of Davis Strait. This is partly or largely due to substantial fresh water input from various sources, mentioned in Section 4.2.1.8. These inputs reduce surface salinity (and, in some cases, may affect surface temperature), causing the depth of the sound channel to change (or to remain stable near the surface, once established). Other properties of this current, including volume transport, boundary conditions, seasonal differences, varying width, and location of the core flow were described earlier in Sections 4.1.4.2 and 4.1.4.4. Additional details on acoustic conditions are found in Appendix D.

4.1.4.9 Wave Climatology

The regional wind patterns of northeast Baffin Bay have been previously discussed in Section 4.1.3.4. A comprehensive 55-year wind and wave hindcast dataset (MSC50) publically available from Environment Canada (Environment Canada, 2012) was used to characterize the wind and wave conditions of the Qamut Block. The distribution of wave heights by direction (or "wave rose") at an appropriate MCS50 reference point (roughly located at the center of the licence area) is presented in Figure 4.1-15 and Table 4.1-2. Comparable data can be accessed from the ECMWF ERA Interim Re-Analysis 1979-2010 (DMI-DTU, 2011).

The wave climate of the Qamut Block is characterized by north-westerly and south-easterly modal components. As for the wind, the waves from the northwest would occur during winter (November to May) but since the area is covered by ice during that period, the winter waves are actually very small. Waves from the southeast occur during the summer (June to October). Summer wave heights are moderate on average within this area, reaching a maximum mean significant height of 1 m in October for a mean peak period of the order of six seconds. Some longer period swell waves occasionally occur, however, with maximum estimated (over the entire 55 year time-series) between 2.9 m (in July) and 5.5 m (in October) with peak periods of the order of 10 seconds and higher (13.2 seconds in November). These waves also always originate from the southeast to south-southeast sectors.

Table 4.1-2 Qamut Block Wave Statistics from the MSC50 Hindcast Data Node M3018543

	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec	Year
Mean Hs [(a)]	0	0	0	0	0	0	0.2	0.7	0.9	1.0	0.3	0	0.2
Dominant Direction	WNW	WNW	WNW	WNW	WNW	SE	SE	SSE	SSE	SE	WNW	WNW	SE
Mean Tp	0	0	0	0	0	0	4.7	6.7	7.2	6.9	7.6	0	6.7
Maximum Hs	0	0	0	0	0	0	2.9	4.5	5.2	5.5	4.9	0	5.5
Direction of Max Hs	S	SW	S	NNW	SSW	WNW	SE	SE	SSE	SSE	SSE	WNW	SSE
Tp of Max Hs[(b)]	0	0	0	0	0	0	8.1	10.6	11.1	10.6	13.2	0	10.6

(a) Hs = significant wave height. Significant wave height is the average of the one-third of the largest individual waves present.

(b) Tp = peak period. This is computed from the wave spectra as the period at which the largest wave energy occurs.

4.1.5 Ice Climatology

4.1.5.1 Sea Ice Environment by Seasonal Period

Northeast Baffin Bay is a marginal ice region, which is partially to completely covered mainly by first-year ice from November to June in all years. Sea ice clearing occurs from the last half of June or into July, depending on the year. Ice formation occurs in October to mid-November depending on the year, with freezing progressing from northwest to southeast. Freeze-up has also been known to start as early as September, but this is rare. By the end of September, ice completely blocks the entrance to Jones Sound (Tang et al. 2004). Freeze-up begins in the fjords and coastal waters. Landfast ice simultaneously forms in northeast Melville Bay and along the northeast coast of Baffin Island. The landfast ice extent in Melville Bay shows high inter-annual variability (Hansen et al. 2004 and StormGEO 2011) and can extend 32 to 112 km out from the coast. A "shear zone" area that eventually becomes an open water corridor when clearing begins in the spring occurs at the transition from fast ice to drifting ice, with many cracks and leads developing along this boundary (Tang et al. 2004).

Break-up and clearing of sea ice in southeast Baffin Bay results from the northward-flowing West Greenland Current which brings relatively warm water over the shelf off northwest Greenland. The late spring and summer wind regime of eastern Baffin Bay is dominated by south-easterly winds which drive sea ice further to the north. The clearing of sea ice in northern Baffin Bay results from the spring expansion of the North Water polynya which is present through most of the winter in Smith Sound and extends into northwest Baffin Bay, as well as into Lancaster and Jones Sounds, during the spring months (Dunbar 1969, Melling et al. 2001). The eastward extent of the North Water polynya expands in the spring and extends into Melville Bay in June (Figure 4.1-16), especially in the past decade with the earlier clearing of sea ice being experienced in Baffin Bay.

Starting as early as May, clearing of the sea ice begins in southeast Baffin Bay and in northwest Baffin Bay, and, in the case of the Qamut Block; it converges on this licence area by mid-June to mid-July. The clearing that occurs from the northwest is due to the North Water polynya, discussed further below. By the end of July, sea ice

clears from both the western and eastern side of Baffin Bay, which has happened in most years recently, in contrast to the past, when full clearing from both coasts has generally taken place later. The early summer clearing pattern leaves sea ice in central Baffin Bay only. This ice is often referred to as the "Middle Ice Pack" or "West Ice".

The annual pattern has been reported by many groups and agencies, including DMI-DTU (2011). It is not discussed further below. The North Water region, however, is described in more detail, as is the linear polynya-like feature or "shear zone" area that becomes an open water corridor off the coast, due to their proximity to the northeast Baffin Bay licence areas, and importance from a biological point of view.

The ice clearing in southeastern Baffin Bay results from the northward flowing West Greenland current which brings relatively warm water over the shelf areas of northeastern Baffin Bay, as well as melt waters from ice sheet runoff off southwestern coast of Greenland. The late spring and summer wind regime of eastern Baffin Bay is dominated by southeasterly winds which drive the sea further to the north. The clearing of sea ice in northern Baffin Bay results from the spring expansion of the Northwater Polynya which is present through most of the winter in Smith Sound and extends into northwestern Baffin Bay, as well as into Lancaster and Jones Sounds, during the spring months (Dunbar, 1969, Melling et al., 2001). The eastward extent of the Northwater Polynya expands in the spring and extends into Melville Bay in June especially in the past decade with the earlier clearing of sea ice being experienced in Baffin Bay (as discussed elsewhere).

The thermodynamics and various forcing functions that establish and maintain the North Water polynya have been studied extensively over the past 30 years by shipboard measurements (e.g. Melling et al. 2001) and modelling work (e.g. Yao and Tang 2003; Biggs and Dumont et al. 2011). Strong northerly winds blow the ice downstream of an ice bridge that forms at narrow constriction points between Greenland and Ellesmere in Nares Strait, leaving behind an area of open water downstream of the ice bridge. Both latent heat and sensible heat processes are thought to play a role in formation and maintenance of the polynya as well as the mechanical clearing of ice due to the wind. Melling et al. (2001) estimated that latent heat is the dominant mechanism by a factor of three or more as compared to sensible heat. Dumont et al. (2011) showed through high resolution numerical modelling that the mean circulation may transport Atlantic-derived deeper and warmer Baffin Bay water to the north end of Smith Sound during specific wind events.

Concurrent with the expansion of the North Water polynya, a linear polynya-type feature or "shear zone" area appears to develop off Upernavik. The favourable winds and warm current along Greenland's west coast open this coastal lead or open water corridor. It can extend north of Disko Island by the end of May and reaches lat. 74° N toward the end of June. During the last week of July, it joins the North Water polynya (Tang et al. 2004).

An excellent source of sea ice extent with a maritime or shipping-related focus is the Canatec ICE06 database, which contains digitized ice charts for a large number of years. The general pattern of ice conditions historically was examined and verified with this database for northeast Baffin Bay. A number of these charts are presented in Appendix C, which show average ice conditions for various ice regimes in the region lat. 72° to 76° N, 55° to long.70° W, on a weekly basis for the period May to November. The charts are derived for the period 2001 to 2010 and depict ice conditions for typical ships having "open water" hulls not suited for contact with sea ice during operations in northeast Baffin Bay.

The likelihood of entry into these areas, for this class of ship (with no ice class, or low ice class only), is based on absence or presence of sea ice. The colours pink to red indicate that an open water type vessel cannot safely operate in the given mean sea ice regime unless some form of ice management or other support occurs. The various shades of green indicate that it is safe for an open water type vessel to operate in the given regime without this assistance. The charts indicate that areas along the west coast of Greenland have earlier occurrences of "open water entry" due to earlier melting of sea ice, compared to parts of northeast Baffin Bay (including Melville Bay) further to the north. These results corroborate the findings by Boertmann et al. (2009) and Tang et al. (2004) among others. Glacial ice in various forms will always be found in these waters.

4.1.5.2 Regional Sea Ice Thickness

Winter sea ice in Baffin Bay is composed of new ice up to 10 cm thick, young ice 10 to 30 cm thick, thin ice 30 to 70 cm thick, and medium ice 0.7 to 1.2 m thick (up to 100 km from the Greenland coast). Medium and thick (120 to 200 cm) first-year ice dominates the central and western sections of Baffin Bay (NERI 2009a). The average thickness of level ice increases from about 70 cm to 1.75 m from southeast along the Greenland coast to

northwest across Baffin Bay. Snow cover on the ice can reduce its ultimate winter thickness by 10% to 20%. The North Water polynya during winter contains a large amount of young ice to thin first year ice over 30 cm thick, and is less than 10% leads and cracks. Fast ice in Melville Bay is often 130 to 180 cm thick, while drift ice can reach 120 to 150 cm thick by the end of the winter in a severe season (Tang et al. 2004). Overall, ice thickness is controlled by winter conditions and export rate through the Davis Strait. The winter conditions, in turn, are controlled by the North Atlantic Oscillation index, discussed earlier in Section 4.1.1.2. It is not currently known what effect, if any, climate change may have on NAO (DMI 2011).

4.1.5.3 Regional Multi-Year Sea Ice Occurrence

While first-year ice is dominant in Baffin Bay and the Davis Strait throughout the winter (PAL 2011), small amounts of multi-year ice can drift into Baffin Bay from Smith Sound, Jones Sound, and Lancaster Sound. The occurrence of multi-year ice is limited to the summer and fall when the landfast ice bridges are not present in Nares Strait, which block multi-year ice in the Lincoln Sea from entering Smith Sound via this passage. Glacial ice in the form of ice shelf or ice island fragments, in the past, has entered Smith Sound along this corridor as well. In some years, greater amounts of multi-year ice can drift south from Nares Strait, leading to small areas of 5:10 to 9:10 multi-year ice in the northeast part of Baffin Bay (Tang et al. 2004). This multi-year ice has thicknesses in the range of 240 to 320 cm. Ridging, rafting, and hummocking are widespread. However, this multi-year ice does not usually reach northwest Greenland inshore and shelf areas (NERI 2009a).

4.1.5.4 Regional Sea Ice Dynamics

The drift of sea ice in northeast Baffin Bay has large seasonal variations. During summer and early fall, starting with ice clearing and through the open water season, the ice drifts largely under the influence of the surface winds. Ocean currents in northeast Baffin Bay, other than the direct wind-driven component, are generally low in speed and variable in direction with a weak overall net flow to the north along the west Greenland shelf and slope, turning to the northwest and then to the west in Melville Bay. This weak pattern is an extension of the West Greenland Current, but it is highly variable in time and space (Tang et al. 2004). While there are few direct measurements of sea ice velocities in northeast Baffin Bay, the response of sea ice drift to geostrophic winds will be similar to that observed in other areas of the Arctic. The ice drifts at about 2% of the wind speed with the ice drift direction approximately 45 degrees to the right of the wind direction in summer when internal ice stresses are small and away from major ocean circulation features (Thorndike and Colony 1982).

From late fall through to spring, ice concentrations are much higher. Ice drift is constrained due to internal ice stress, to values typically less than one percent of the wind speed (Thorndike and Colony 1982). The internal ice stress results in heavy deformation of the sea ice, including ridging, which produces large (deep) ridge keels that can be as much as 20 m or greater in draft. This is more than 10 times larger than the level first-year ice thickness values in late winter of 1.6 m (Amundrud et al. 2004, Tang et al. 2004). Some of these very deep keels will persist for some time into the break-up and clearing period, but will eventually melt.

The drifting or mobile ice in northeast Baffin Bay contains a large variety of floe sizes and concentrations. Thick individual ice floes formed as pressure ridges have horizontal sizes of < 20 to 100 m, and rubble or hummock ice features can have widths of hundreds of meters. Floes that have been pushed and frozen together can have composite diameters of hundreds of metres to tens of kilometres. High storm activity tends to keep the landfast ice extent in Melville Bay at the lower end of its range, and increases dispersion of ice floes in the fall. The northern part of this Bay reaches nearly complete ice coverage during December through April of 8:10 to 10:10 concentration, with annual maximum coverage in March of 9+/10:10 concentration (ERM 2011a).

4.1.5.5 Regional Iceberg Dynamics

Most Baffin Bay icebergs calve from glaciers along the west coast of Greenland during the summer and fall, north of lat. 68° N, with most originating north of Disko Island in Disko Bay and Uummannaq Fjord, as well as in other fjords and bays further north along the coast, including Melville Bay (Figure 4.1-17). Iceberg, bergy bit, and growler production occurs throughout the year.

Icebergs calving from glaciers along the coast north of Disko Island are often entrained in the West Greenland Current, and drift northward and counter-clockwise around Baffin Bay, transiting Melville Bay en route (Mosbech et al., 2004). Glaciers in Uummannaq Fjord and Disko Bay produce 10,000 to 15,000 icebergs per year (95 km^3), with total production at 25,000 to 30,000 or even 40,000 icebergs per year in Baffin Bay and northern Davis Strait (Boertmann et al. 2009, Valeur et al. 1996). Until recently, it was thought that the annual volumetric iceberg

production has not varied appreciably (NERI 2009), but the production rate may be increasing due to the rapid changes in the Greenland Ice Sheet (Box et al. 2011). Some of the icebergs being transported by the West Greenland Current periodically ground on banks, or become constrained, or "frozen in", by landfast ice during winter. If they do not melt or fracture during transport, these icebergs drift into northwest Baffin Bay, and continue drifting south along the east coast of Baffin Island. Some of them drift into Lancaster Sound. Iceberg residence time in Baffin Bay can be up to two or three years (Diemand 2001).

Historical measurements of iceberg distributions conducted in northwest Greenland reveal that the highest densities of iceberg occur north of lat. 75° N and east of long 60° W within approximately 50 to 100 km of West Greenland. Icebergs were also measured at much greater distances of 100 to 500 km from the coast but beyond 150 km, and they occur only occasionally and almost always as large icebergs (Valeur et al. 1996).

4.1.5.6 Iceberg Distribution and Mass

The mean sail height of Baffin Bay icebergs is 60 m, and the mean width is 100 m (Diemand 2001). The average draft observed away from the caving grounds has been reported as 187 m. The largest icebergs ever observed in the region had drafts of 250 to 300 m, but exceeding 230 m draft depth is rare because bathymetry near the calving fronts limits draft depths (NERI 2009). Based on detailed observations made in 1997, the largest icebergs in the region had drafts deeper than 260 m, were up to 90 Mt, and more than 1,400 m in length.

The most recent survey of icebergs in the northeast Baffin Bay licence areas took place from mid-August to mid-September 2011 in Melville Bay. Iceberg population and aerial density were estimated from satellite imagery (C-CORE 2011). Of the many thousands of icebergs present in the region (upwards of 100,000), 175 icebergs were documented in terms of length, mass, and drift velocity (GEMS 2011a). Numbers and sizes of bergy bits and growlers were not recorded. However, it was noted that their concentration tends to be highest in the immediate vicinity of icebergs. The aerial density of icebergs varied from >0.4 icebergs/km^2 in nearshore areas to no more than 0.1 icebergs/km^2 50 to 100 km offshore (CCORE 2011). Median iceberg mass was found to be 1.08 Mt, and the largest iceberg documented was estimated to be 92.6 Mt. Drift direction was generally toward the west, west-northwest, and west-southwest, with significant variations due to tidal currents (GEMS 2011b). During surveys in September to October 1968, iceberg frequency was found to be greater than 0.24 icebergs/km^2 (Wolford, 1981). Other details on iceberg distribution and mass are found in Appendix C.

4.1.5.7 Iceberg Drift Speeds and Other Properties

The 2011 iceberg survey of the region found an instantaneous maximum drift speed on radar of 0.5 to 1 m/s in an "iceberg corridor" immediately to the south and southwest of Cape York (GEMS 2011a) off the northwest part of Qamut Block. The C-CORE 2011 report described a mean speed of 0.13 m/s and a maximum speed of 0.67 m/s for 601 icebergs. A re-analysis of the 2011 data found a mean drift speed of 0.175 m/s overall and a maximum of 0.615 m/s (GEMS 2011b). Icebergs in the nearshore area, within 15 km of Cape York, drifted faster (the mean drift speed was calculated at 0.35 m/s) than icebergs farther offshore.

The iceberg survey conducted in late summer 2011 in Melville Bay (GEMS 2011a) recorded the largest iceberg at 860 by 416 m in horizontal extent, with a peak sail height of 99 m, a draft of 275 m, and a mass of 92.6 million tonnes. The median iceberg mass was 1.08 million tonnes, median waterline length was 130 m, median sail height peak was 37 m, and median draft depth was 84 m. The majority of the icebergs had a mean waterline length of less than 400 m. Two icebergs had a waterline length of more than 1,000 m, with the longest recorded at 4,244 m (GEMS 2011a).

Fifteen percent of the icebergs observed during the 2011 survey were greater than 5 Mt and it should be noted that icebergs this large cannot be towed (GEMS 2011a). Data from 118 icebergs observed during the 2011 survey were used as the basis for the following statistics:

- with respect to mass, there is a 100% chance of an iceberg being larger than 104 tonnes, a 50% chance of an iceberg being larger than 106 tonnes, and an 8 to 9% chance of an iceberg being larger than 107 tonnes;
- with respect to length at waterline, there is a 100% chance of an iceberg being longer than 30 m, a 50% chance of a length longer than 140 m, and a 10% chance of a length longer than 240 m;
- with respect to width at waterline, there is a 100% chance of an iceberg being wider than 27 m, a 50% chance of a width greater than 100 m, and a 10% chance of a width greater than 200 m;

- with respect to sail height, a 100% chance of an iceberg possessing a peak sail height larger than 5 m, a 50% chance of a sail height larger than 36 m, and a 10% chance of a sail height larger than 60 m; and
- with respect to draft, a 100% chance of an iceberg having a draft deeper than 32 m, a 50% chance of a draft deeper than 84 m, and a 10% chance of a draft deeper than 130 m.

The predominant drift pattern for larger icebergs differs from that of sea ice because of the much larger drafts of icebergs. Iceberg drifts depend on the combination of sail versus keel profiles. The predominant wind directions in the Qamut licence area are from the southeast in August and September. Along the coast at around lat. 74° N, to the northwest of Qamut wind directions tend to be more northerly and east-northeast (StormGeo 2011). Icebergs with larger drafts and/or reduced sail heights tend to be influenced more by surface (and near-surface) currents, especially those currents below the largely wind-driven mixed layer. Iceberg drift studies in northeast Baffin Bay (Valeur et al. 1996) indicate that most icebergs move erratically with little mean drift. Velocity rarely exceeds 0.2 m/s, which is in generally good agreement with direct field measurements in the summer of 2011. During periods of higher or greater sea ice cover, from late fall through most of spring, iceberg drift is greatly constrained by the movement of surrounding sea ice. The icebergs generally move at the same speeds as drifting sea ice, or, if caught in landfast ice areas along the coast, movement ceases until sea ice clearing occurs.

4.2 Biological Environment

4.2.1 Plankton

Plankton are small (often microscopic) plants and animals floating, drifting or weakly swimming in bodies of fresh or salt water. In general, plankton can be sub-divided into two groups: phytoplankton and zooplankton.

4.2.1.1 Phytoplankton

Phytoplankton perform the majority of primary production, or the formation of organic particulate matter through photosynthesis (UNESCO 1973). Forming the base of the marine food web, phytoplankton provide essential nutrients and energy to higher trophic level organisms ranging from zooplankton to marine mammals.

In northeast Baffin Bay, where stratification is largely controlled by salinity (Carmack and Wassmann 2006, Carmack 2007), a single intense phytoplankton bloom in late spring, immediately after ice break-up, which may last for several months, is typical. An exception to this trend is observed at polynyas where elevated nutrient availability tied to upwelling events during early ice break-up can result in locally high productivity on a confined scale (DCE 2011). The ice-free period in northwest Greenland typically lasts three to four months but may extend beyond six months in polynya regions (DCE 2011). The North Water polynya, located in northern Baffin Bay, is the world's largest polynya and one of the most biologically productive marine areas in the Arctic (Deming et al. 2002). It is also regarded as a "biological hot spot" by DCE and GINR.

The distribution of phytoplankton biomass and primary production has been studied off the coast of northwest Greenland from lat. 65º N to 72º N. Chlorophyll *a* concentration and primary production were found to be generally higher at sites above lat. 69º N (Jensen et al. 1999).

4.2.1.2 Zooplankton

Zooplankton communities in West Greenland waters are dominated by copepods, which constitute 86% of the zooplankton biomass in this region (GINR 2003). The majority of these copepods are of the genus *Calanus* (including larval stages), which occupy the top 100 m of the water column in spring and summer and feed exclusively on algae. They constitute an important prey item for the higher trophic levels in the Arctic marine ecosystem, including fish, baleen whales (primarily bowhead whales), and seabirds (e.g. the little auk is a specialised *Calanus* feeder) (Karnovsky et al. 2003). Calanoid copepods also play a key ecological role by supplying benthic communities with high quality food (Söderkvist et al. 2006). Consequently, a great deal of the biological activity in Greenlandic waters (e.g. fish spawning, bowhead foraging) is synchronized with the life cycle of *Calanus*.

In Melville Bay, the dominant copepod species are: *Calanus glacialis, C. hyperboreus and C. finmarchicu* (Herman 1983, Head et al. 1985). Present knowledge on zooplankton in eastern Baffin Bay is too limited to designate critical zooplankton habitat in this area. The highly productive eastern margin of the North Water polynya has been identified as a region that would be especially sensitive to oil spills (DCE 2011).

4.2.2 Invertebrates

Benthic communities are an important ecosystem component on the West Greenland continental shelf. They provide an important food source for fish, marine mammals, and invertebrates. Scallop, snow crab, and northern shrimp serve as the basis for commercial fisheries in this region.

The highest benthic biomass occurs in the shallow coastal region (10 to 100 m in depth) where a few large species are dominant (e.g. bivalves, gastropods and sea urchins). At greater depths (100 to 1,000 m), communities are dominated by polychaetes which are often present in high abundances. In general, benthic macrofaunal species are an important component of the marine ecosystems. They consume a significant portion of available primary production and, in turn, serve as an important food source for fish, seabirds and mammals. Benthic surveys conducted in eastern Baffin Bay have shown that the benthic community structure varies considerably as a function of location and depth. Benthic zonation is often accompanied by an exponential decline in benthic diversity along a shelf-slope-basin gradient. In addition to depth, additional factors such as sediment heterogeneity, disturbance, food availability, geographical setting, sea-ice cover, particle load from land, and hydrographic regime also influence benthic diversity and species composition (DCE 2011). Benthic invertebrates are important because they represent a significant fraction of the biodiversity in the region. Existing knowledge on the distribution, diversity, and abundance of benthic invertebrates in northwest Greenland is presently too incomplete to identify critical habitats or important conservation areas with the exception of established commercial fishing grounds for snow crab and northern shrimp (Section 4.3.1).

4.2.2.1 Northern Shrimp (Pandalus borealis)

Northern shrimp live on or near the seabed (epibenthic) with highest densities observed at depths between 150 and 600 m (DCE 2011). Northern shrimp spawn in July to September with females carrying the fertilized eggs until spring (March to May). Larvae undergo several pelagic stages before maturing and settling to the seafloor far from their release site (Pedersen et al. 2002)

4.2.2.2 Snow Crab (Chionoecetes opilio)

Snow crab in northwest Greenland are expected to occur regularly in eastern Baffin Bay, preferring deep, cold water conditions and sandy seafloor at depths between 350 and 1,500 meters (NAFO 2007). They are slow to mature, taking more than five years to reach harvestable size. Their maximum lifespan is approximately 12 to 13 years (NAFO 2007). Major predators of snow crab include groundfish, seals and other snow crab.

4.2.3 Marine Fish

A total of 269 fish species are known to occur in the Greenland Exclusive Economic Zone (EEZ), of which 79 are commonly found off the coast of northwest Greenland (Møller et al. 2010). Jørgensen et al. (2005) sampled 105 trawl stations in Baffin Bay and identified seven unique bottom fish communities based on differences in species composition and habitat type. Of these, four communities were unique to Baffin Bay with 44 bottom fish species identified in total. Greenland halibut (*Reinhardtius hippoglossoides*) was the dominant species observed. Other species caught in notable numbers were polar cod (*Boreogadus saida*), Arctic cod (*Actogadus glacialis*) and the Arctic skate (*Raja hyperborea*).

4.2.3.1 Greenland Halibut (Reinhardtius hippoglossoides)

Greenland halibut are an abundant and commercially valuable species in Baffin Bay. They are typically found in deep water along the continental slope, as well as at the interface of warm and cold water masses at temperatures of one to two degrees Celsius (Bowering and Brodie 1995). Spawning takes place in Davis Strait from December to April in water depths of 800 to 1,000 m (Smidt 1969). Larvae are pelagic during the months of March to June (Smidt 1969) where they drift north from Davis Strait along the coast in the West Greenland Current. They settle as semi-demersal juveniles in southern Baffin Bay and later migrate further north in the vicinity of the Qamut Block. Tagging studies suggest that mature fish later migrate back to spawning areas in Davis Strait (DCE 2011). No spawning events have been recorded in Baffin Bay, either offshore or inshore.

The Greenland halibut is considered an important food source for narwhal, particularly during winter. An estimated 50,000 narwhals from two separate wintering grounds were estimated to consume approximately 790 tonnes of Greenland halibut per day, assuming a diet of 50% of Greenland halibut (Laidre et al. 2004).

4.2.3.2 Arctic Cod (Arctogadus glacialis)

Arctic cod are endemic to the Arctic Ocean with a circumpolar distribution along the coasts of Siberia, Alaska, Canada, and Greenland (Aschan et al. 2009). They are believed to spawn in the late fall or early winter, and are most common on surface and near-surface waters, but can occur at depths below 900 m. In ice-free waters, Arctic cod are often found in large schools consuming large amounts of plankton. In ice-covered waters, they prefer rough, under-ice surfaces (multi-year ice) over smooth under-ice conditions for refuge.

Cod are considered a primary food source for narwhals, belugas, ringed seals, and seabirds, and are also preyed upon by Arctic char (*Salvelinus alpinus*), Atlantic salmon (*Salmo salar*) and Greenland halibut. The estimated stock size of Arctic cod in northwest Greenlandic waters is presently unknown.

4.2.3.3 Polar Cod (Boreogadus saida)

Polar cod have a circumpolar distribution, occupying high latitude waters of Russia, Alaska, Canada, and Greenland (Craig et al. 1982). They are a pelagic/semi-pelagic species most commonly found in the upper water column, but occasionally recorded in water depths up to 900 m. Polar cod are known to frequent estuarine environments (river mouths) and tend to group in large schools when in ice-free waters. They feed mainly on plankton and krill (DCE 2011).

Polar cod spawn during winter in ice-covered waters (November to February) with the larvae hatching in late spring (Cohen et al. 1990). They provide an important prey for many marine mammal and seabird species, notably ringed seal, harp seal, thick-billed murre, northern fulmar, black-legged kittiwake and Ivory and Ross's gulls (DCE 2011). There is no information available on polar cod stock size in the Baffin Bay/Melville Bay area.

4.2.3.4 Arctic Skate (Raja hyperborea)

The Arctic skate occurs in cold, polar waters at depths ranging from 260 to 2,500 m in Baffin Bay, and along the west, south, and east coasts of Greenland and eastward to Iceland, the Barents Sea, and northern Norway. This species appears to prefer cold water temperatures from hatching stage through to maturity (Bigelow and Schroeder 1953).

The Arctic skate is thought to feed on a wide variety of benthic organisms (Stehmann and Burkel 1984). The species is oviparous, laying less than 100 eggs annually. Eggs are successfully incubated in water temperatures as low as 0°C. Arctic skate presently have no commercial value in Greenland.

4.2.4 Seabirds

There are three Important Bird Areas (Figure 4.2-1) located directly north of the Qamut Block: Parker Snow Bay, Appat Appai, and the coastline between Appaliarsulissuaq and Kap Atholl (Birdlife International 2011). During ice free-periods, seabirds are abundant in the Baffin Bay area (DCE 2011). The results of seabird-at-sea surveys in Baffin Bay show low densities of seabirds in spring (April to May) when ice is still widespread, and higher densities of seabirds in summer from June to December (DCE 2011). Some species (auks, puffins) spend the majority of their time at sea, except when breeding. A summary of the important seabird species occurring in the Baffin Bay area is provided in Table 4.2-1.

Sixteen seabird species are known to breed in the Eastern Baffin Bay region. Most of these are colonial and are dispersed along the Greenland coastline southeast of the Qamut Block (Figure 4.2-1). The breeding colonies are primarily concentrated on the mainland coastline and in archipelagos located in southern Baffin Bay between Holm Island and Upernavik, and also north of Cape York (DCE 2011). These colonies vary in size from several pairs to several million pairs (DCE 2011).

High concentrations of foraging seabirds occur on the waters adjacent to these colonies, but some species (e.g., little auks) may range up to 100 km offshore (DCE 2011). Many species are piscivorous, while others feed on large zooplankton or benthic invertebrates. The majority of these species use common productive foraging areas where some catch prey by deep diving (e.g., murres, cormorants, auks) while others feed at the surface or by plunge diving (e.g., kittiwakes, terns).

Large concentrations of foraging seabirds can also occur in open water areas, such as polynyas and along ice edges (DCE 2011, Figure 4.2-1). Early ice break-up in northeast Baffin Bay, including costal areas where shear zones are located, may create open water used by seabirds for foraging or resting. Important offshore feeding

areas may also occur where upwelling events are recurrent, and in areas where commercial fisheries occur (DCE 2011).

When the breeding season is over, populations of seabirds from both Canada and Greenland move southwards through the Qamut Block toward overwintering areas off southwest Greenland and Newfoundland/Labrador (DCE 2011). For some species (e.g., thick billed murres), this migration includes extended periods of swimming on the surface by immature individuals and moulted adults (DCE 2011). It is estimated that at least 100 million adult and juvenile seabirds migrate annually through the greater Baffin Bay area during September and October (DCE 2011).

4.2.5 Marine Mammals

There are 20 species of marine mammals that may be present within the Qamut Block for variable periods of time and at different times throughout the year. This includes 14 species of cetaceans, four species of pinnipeds, walrus, and polar bear.

4.2.5.1 Cetaceans

Narwhal (*Monodon monoceros*)

Narwhals in West Greenland and Eastern Canada make long-distance migrations each year between their northern summering grounds and southern wintering grounds (Dietz et al. 2001, Heide-Jørgensen et al. 2003). During the open-water season in summer (July through September), narwhals occur in inshore areas off northwest Greenland and the Eastern Canadian Arctic (Born et al. 1994b, Dietz et al. 1995, Kingsley et al. 1994). In Baffin Bay, narwhals tend to congregate in large numbers at two main summering grounds: Melville Bay and Inglefield Bredning (Figure 4.2-2). When fast ice begins to form along the coast in fall, narwhals migrate south along traditional migratory routes (Dietz and Heide-Jørgensen 1995, Dietz et al. 2001, Heide-Jørgensen et al. 2002, Heide-Jørgensen et al. 2003a) to deep-water wintering areas in central Baffin Bay and northern Davis Strait where they remain for at least five months of the year (Koski and Davis 1994, Laidre and Heide-Jørgensen 2011). The wintering grounds are associated with dense offshore pack ice where large numbers of whales remain concentrated in specific regions with water depths up to 2,300 m. Individuals have been shown to use the same summering and wintering grounds in consecutive years (Heide-Jørgensen et al. 2003a). In early spring, narwhals travel along ice edges off the east coast of Baffin Island (Koski and Davis 1994) and off West Greenland, concentrating in the North Water polynya in late spring prior to entering Inglefield Bredning and Melville Bay in early summer (Born et al. 1994b, Heide-Jørgensen 2004).

The narwhal diet is restricted to a limited number of species and changes throughout the year. The majority of their food reserves are put on during winter, when narwhals target Greenland halibut and squid (Gonatus sp.) found in deep-water offshore areas in Baffin Bay and Davis Strait. Food intake appears to be limited during summer, with prey selection focusing on Arctic cod, polar cod, and squid at this time (Laidre et al. 2003).

The abundance of narwhals at the summering grounds in Inglefield Bredning and Melville Bay was estimated in 2007 at 8,368 and 6,024 respectively (DCE 2011).The northeast margin of the Qamut Block overlaps with the western margin of Narwhal Protection Zone I (NPZ-I).

Beluga (*Delphinapterus leucas*)

Belugas whales may be present in the Qamut Block for a brief period during the spring (May to June) and fall (October to November) when these whales migrate between their summering grounds in Canadian Arctic waters and their wintering grounds off Western Greenland (Heide-Jorgensen et al. 2003b). There are two established core wintering grounds in the Baffin Bay region where whales tend to congregate at the edge of the sea ice (DCE 2011) (Figure 4.2-3). They include the North Water polynya and the near shore waters off central West Greenland (south of Upernavik) at the eastern edge of Baffin Bay pack ice (the “West Ice”).

The total abundance of belugas in West Greenland in 2006 was estimated at 10,595 individuals (Heide-Jørgensen et al. 2010b). The population appears to be increasing as a result of decreased hunting effort over the last several years (Heide-Jørgensen et al. 2010b). Both wintering ground areas are located outside the Qamut Block.

Table 4.2-1 Overview of Seabird Species Found within the Qamut Block

Common Name	Species	Seasonal Occurrence	Distribution	Other Relevant Information	Greenland Red List Status	IUCN Listed Status	Importance Of Assessment Area to Population[a]	VEC
Fulmar	*Fulmaris glacialis*	summer	coastal / offshore	none	LC	LC	high	yes
Great cormorant	*Phalacrocorax carbo*	summer	coastal	large majority of Greenland population occurs in Baffin Bay	LC	LC	high	yes
Greenland white-fronted goose	*Anser albifrons flavirostris*	May – September	coastal	endemic to Greenland, small, declining population breeds exclusively in western Greenland	EN	LC	medium	no
Snow goose	*Anser caerulescens*	May – September	coastal	significant concentrations of snow geese occur in the Baffin Bay area	LC	LC	low	no
Brent goose	*Branta bernicla*	spring and fall	coastal	**national responsibility species**: Internationally important concentrations occur through Baffin Bay during migrations in May/June and August/September	LC	LC	high	no
Common eider	*Somateria mollissima*	summer	coastal	breeding population previously in decline	VU	LC	high	yes
King eider	*Somateria spectabilis*	July - September	coastal	do not breed in assessment area; however, large numbers of moulted individuals assemble in coastal areas and are flightless for three weeks	LC	LC	high	yes
Long-tailed duck	*Clangula hyemalis*	summer	coastal	none	LC	LC	medium	yes
Red-breasted merganser	*Mergus serrator*	summer	coastal	none	LC	LC	low	no
Red-necked phalarope	*Phalaropus lobatus*	spring and fall	coastal	none	LC	LC	low	no
Grey phalarope	*Phalaropus fulicarius*	spring and fall	coastal	none	LC	n/a	low	no
Arctic skua	*Stercorarius parasiticus*	summer	coastal	none	LC	LC	low	no
Black-legged kittiwake	*Rissa tridactyla*	summer	coastal / offshore	west Greenland population has declined since mid-1900s, and is a preferred quarry for hunters in the area	VU	LC	high-medium	yes
Glaucous gull	*Larus hyperboreus*	summer	coastal / offshore	none	LC	LC	low	no
Iceland gull	*Larus glaucoides*	summer	coastal / offshore	none	LC	LC	low	no
Great black-backed gull	*Larus marinus*	summer	coastal / offshore	none	LC	LC	low	no
Sabines gull	*Larus sabinii*	summer	coastal / offshore	none	NT	NT	low	no
Ivory gull	*Pagophila eburnea*	spring and fall	coastal / offshore	most individuals in Baffin Bay are from the Canadian population which has declined by more than 80%	VU	NT	medium	yes
Arctic tern	*Stena paradisea*	May - September	coastal / offshore	west Greenland population = declining (possibly due to over harvesting of eggs)	NT	LC	high	yes
Thick-billed murre	*Uria lomvia*	summer	coastal / offshore	west Greenland population = declining; some entire breeding colonies in assessment area have been abandoned; 15% of global population and >90% of the Greenland population occur in the assessment area in summer	VU	LC	high	yes
Razorbill	*Alca torda*	summer	coastal / offshore	none	LC	LC	high	no
Atlantic puffin	*Fratercula arctica*	summer	coastal / offshore	population is of national concern as approximately 25% of Greenland population breed in Baffin Bay	NT	LC	high	yes
Black guillemot	*Cepphus grylle*	summer	coastal / offshore	**national responsibility species**: very large portion of global population breeds in Greenland with majority of the Greenland population breeds within Baffin Bay	LC	LC	high	no
Little auk	*Alle alle*	summer	coastal / offshore	**national responsibility species**: >80% of global population breeds in Greenland with majority of Greenland population in Baffin Bay	LC	LC	high	yes

.

Bowhead Whale (*Balaena mysticetus*)

Bowhead whales are closely associated with sea ice. They are the only baleen whale known to remain year round in Arctic waters (DCE 2011). Individuals that occur in West Greenland are part of a population that extends from Foxe Basin through the Canadian high-Arctic archipelago, Hudson Bay and Hudson Strait, and along the east coast of Baffin Island (Heide-Jørgensen et al. 2006).

Although some individuals have been reported to winter in the North Water polynya, core wintering areas for this population are located in Disko Bay, with animals arriving in February and concentrating near Disko Island. In late spring (May to June), whales begin their movement north following a migratory corridor that extends in a northwest direction across Baffin Bay, with animals likely using leads and cracks in the pack-ice (Heide-Jørgensen et al. 2003d, 2006). It is at this time of the year when migrating bowhead whales may be present within the Qamut Block. In July, the majority of the population resides in waters off the east coast of Baffin Island. In August, whales begin their migration westwards to the Canadian Arctic archipelago and northern Hudson Bay and Foxe Basin (Figure 4.2-4).

Although considered one population, there is evidence of considerable age and sex segregation between the Hudson Bay and Foxe Basin region and the northwest Greenland region. Adult whales are the dominate sex observed in Baffin Bay and Disco Bay during winter (Heide-Jørgensen et al. 2010b), while mothers with calves and juveniles occur almost exclusively in the Foxe Basin region. Mating is believed to occur in March to April in Disko Bay (Reese et al. 2001).

Bowhead whales are highly specialized filter feeders of small zooplankton prey (Burns et al. 1993). They are seasonally dependent on substantial concentrations of zooplankton. Studies on the diet of bowhead whales indicate that they feed almost exclusively on calanoid copepods (Laidre et al. 2007, Heide-Jørgensen et al. 2010b).

The number of bowheads that migrate through Baffin Bay to their Canadian summering grounds was estimated in 2001 to 2002 at 6,344 (IWC 2008). Despite recent signs of recovery (Heide-Jørgensen and Laidre 2010), the present population size in Baffin Bay is likely much lower than its original size (Allen and Keay 2006).

Bowhead whales may be present within the Qamut Block from late May through June during their spring migration between Disko Bay and Arctic Canada.

4.2.5.2 Pinnipeds

Hooded Seal (*Cystophora cristata*)

Hooded seals are a highly migratory species. During spring (March to April), they concentrate in whelping areas off Newfoundland and in Davis Strait where breeding occurs on the pack-ice (Stenson et al. 1996). In late April to May, the majority of the population migrates to southeast Greenland to moult in June and July (DCE 2011), with some seals also dispersing into eastern Baffin Bay at this time. Following the moult in late July, most seals off southeast Greenland migrate to deep water areas off Davis Strait and Baffin Bay. Here, they forage along steep sections of the continental shelf, mainly preying on large fish (e.g. polar cod, Greenland halibut) and squid at depths of up to 1,500 m (Andersen et al. 2009). During these foraging excursions, seals rarely haul out, even when spending time in coastal areas. Hooded seals may be present in the Qamut Block at any time during the open water season (DCE 2011).

Harp Seal (*Pagophilus groenlandica*)

Harp seals are a highly migratory species and breed in similar areas and times of year as hooded seals. Whelping areas are found off Newfoundland where seals give birth on pack ice in March and undergo moulting in April. Following the moult, seals disperse between the eastern Canadian Arctic and the east and west coasts of Greenland. Seals in the Qamut Block and surrounding areas increases in numbers through the summer and early fall. Once sea ice begins forming in the late fall, these seals migrate back to waters off Newfoundland. They feed mainly on capelin (*Mallotus villosus*), polar cod, krill (*Thysanoessa sp*.) and amphipods (Kapel 1995). Any harp seals found in the Qamut Block belong to the West Atlantic population.

Ringed Seal (*Pusa hispida*)

Ringed seals are abundant throughout the year in eastern Baffin Bay (including the Qamut Block). They prey upon polar cod, Arctic cod, snail fish (Liparis sp.) and amphipods (Siegstad et al. 1998). During winter, adult

seals occupy lairs in fast ice where they maintain breathing holes and establish underwater territories while juveniles typically occupy pack ice areas. Pupping occurs during spring (March) with lactation lasting up to seven weeks (Hammill et al. 1991). Moulting occurs in June when seals spend extended periods hauled-out on the ice and are rarely seen in open water areas (DCE 2011). Average seal densities on the ice in June are 1.3 to 2 seals per square kilometre (Kingsley 1998). Post-moulting studies demonstrate that seals either move offshore to areas with 40% to 80% ice coverage, or remain close to shore near glacial fronts (Freitas et al. 2007).

Bearded Seal (*Erignathus barbatus*)

Bearded seals are widespread throughout the Arctic in shallow areas where they prey on fish and benthic invertebrates in water depths up to 100 m (Gjertz et al. 2000). They can be found in all parts of Eastern Baffin Bay throughout the year, including the Qamut Block.

During winter, bearded seals are typically found in recurring leads, or in polynyas. The breeding season occurs in spring (April to May). Females giving birth on pack-ice or along the ice edges with access to open water (DCE 2011).

4.2.5.3 Walrus (Odobenus rosmarus rosmarus)

Walrus off northwest Greenland are generally confined to continental shelf waters and localized, shallow banks (less than 100 metre deep) where they can access their preferred prey items – benthic bivalves (Mya sp., Macoma spp. and Hiatella Arctica). In winter, walrus have a restricted habitat for feeding and mating and congregate in leads and polynyas.

Two main wintering stocks exist in the Baffin Bay region. The majority of the Baffin Bay wintering stock is found in the North Water polynya where open water provides access to shallow bank feeding areas (Born et al. 1995). Walrus also winter in several areas close to the mainland coast (West Greenland wintering stock) along leads in the shear zone between fast ice and Baffin Bay pack ice (near Upernavik and Uummannaq). The latter wintering grounds are located east and southeast of the Qamut Block (Figure 4.2-5). In summer, most of the population is found along the coasts of the eastern Canadian Arctic (Ellesmere and Baffin Island), where groups of walrus haul-out at traditional sites on land in close proximity to shallow feeding grounds. Recent aerial surveys estimate walrus abundance during winter at 2,300 to 3,000 for the North Water stock (NAMMCO 2009), and 2,700 for the West Greenland stock (Heide-Jorgensen et al. 2010d).

4.2.5.4 Polar Bear (Ursus maritimus)

Polar bears in the Qamut Block belong to the Baffin Bay subpopulation (Taylor et al. 2001). Home ranges for this population are large, and combined, equal about 192,000 km^2 (DCE 2011). This is shown in Figure 4.2-6. The distribution of polar bears in Baffin Bay is linked closely with the presence of sea ice (Wiig et al. 2008). The annual land fast ice along the coast of Baffin Island and northwest Greenland begins to form in October and remains stable until July. Polar bears rely heavily on sea ice during this time as a platform for travelling, hunting, mating and resting (Stirling 1993, Taylor et al. 2001). They are particularly attracted to the edge of landfast ice (Ferguson et al. 2000) which provides habitat for several of their prey species, in particular the ringed seal and the bearded seal (Wiig et al. 2008). Polar bears have also been observed utilizing a major lead that forms each winter in a recurring shear zone between Holm Island and Cape York (Born et al. 2011, DCE 2011, Taylor et al. 2001). This lead is frequented by ringed seals, and also serves as a spring migratory corridor for other prey species such as narwhals and belugas.

During late spring, when consolidated pack ice in central Baffin Bay is diminished, the majority of polar bears follow the retreating ice westward to spend the open-water season on Eastern Baffin Island (NERI 2009a, Taylor et al. 2001). Some polar bears have also been reported in Melville Bay during the open water season when ice has remained in this region over the summer (DCE 2011).

The Baffin Bay subpopulation was estimated in 1997 at 2,074 individuals (Taylor et al. 2001). This number is thought to have recently declined due to over-exploitation (DCE 2011).

Table 4.2-2 Overview of Marine Mammal Species found within the Qamut Block

Common Name	Species	Seasonal Occurrence	Habitat	Occurrence in Project Area	Greenland Red List Status	IUCN Listed Status	Importance of Qamut Block and surrounding area to population[a]	VEC

4.2.6 Protected Areas

Measures have been taken by the Greenland Government as well as international organizations to identify, evaluate and protect areas of biological importance in Greenland's marine and coastal environment. This section provides an overview of internationally and nationally protected areas located in eastern Baffin Bay in relation to the Qamut Block. These areas are shown in Figure 4.2-7.

The Government of Greenland has identified several "Areas Important to Wildlife" where mineral and petroleum exploration and extraction activities are regulated in accordance with the Mineral Extraction Act. These areas include polar bear protection areas within Melville Bay, seasonal protection areas for narwhals in relation to seismic activities, and protective boundaries for seabird colonies (moulting areas and adjacent buffer zones).

The Greenland Government passed regulations for polar bear management as part of the 'Greenland Home Rule Executive Order no. 21 of 22 September 2005 on the Protection and Hunting of Polar Bears.' Under this legislation, the Melville Bay Nature Reserve is designated a wildlife protection zone, where restrictions have been placed on hunting, fishing, egg collecting, passage, sailing, and air transport below 500 metres altitude. Only permanent residents from the municipalities of either Upernavik or Avanersuaq with valid status as occupational hunters are permitted to conduct traditional[1] hunting and fishing in the outer boundary of the reserve (Protection Border I). Within the Reserve, it is prohibited to hunt females accompanied by one or more cubs, or to disturb denning polar bears. The quota system dictates the permitted harvest level and hunting period within this area. The northeast boundary of Qamut Block is roughly 30 to 40 km west of the Melville Bay Nature Reserve (closest or nearest portion).

Four Narwhal Protection Zones (NPZ) have been designated in the Baffin Bay region (DCE 2011). These zones are shown in Figure 4.2-7. The northeast margin of the Qamut Block overlaps with the western margin of NPZ-I.

No bowhead whale protection zones have been designated in the Baffin Bay region. However, the winter feeding and mating grounds in Disko Bay are considered one of the most important bowhead whale habitats worldwide (DCE 2011). Bowhead whales may transit through the Qamut Block in late May during their spring migration from Disko Bay to the Eastern Canadian Arctic.

There are no designated protection zones for seals in eastern Baffin Bay (DCE 2011). However, stable ice during the whelping/nursing period is considered critical habitat for all four seal species in Greenland.

Protection zones for walrus in Eastern Baffin Bay are limited to two established wintering grounds located north of the Qamut Block in the Qaanaaq region.

Eleven sites throughout Greenland have been identified by the Government of Greenland for inclusion in the Ramsar list of Wetlands of International Importance (Ramsar sites) (DCE 2011). None of these sites occur within the Qamut Block. Six protected seabird breeding sanctuaries have been identified along the coast of northwest Greenland, in accordance with Greenland's Bird Protection Executive Order. Additional protection zones have also been designated around critical nesting areas (e.g., murre and eider colonies) and moulting sites along the coastline (Figure 4.2-7). None of the protected areas occur within the Qamut Block. It is possible individuals from the colonies may transit through the area during foraging and migratory trips. Eighteen Important Bird Areas (IBA)[2] also occur in eastern Baffin Bay. None of these occur within the Qamut Block, although three IBAs are located north of the proposed survey area: Parker Snow Bay, Appat Appai, and the coastline between Appaliarsulissuaq and Kap Atholl (Birdlife International 2011; Figure 4.2-7).

1 Traditional methods include taking or hunting of marine mammals, fish, birds, and eggs using small boats or dogsleds for transportation. The use of aircraft, helicopters, snowmobiles, and other motorized vehicles or vessels over 20 GRT/15 GT are prohibited. The use of traps, spring guns, or poison is prohibited. Firearms must have a minimum calibre of 7.62 mm.

2 Important Bird Areas (IBA) are sites recognized as being globally important habitat for the conservation of bird populations, as designated by Birdlife International, an international bird protection organization.

4.2.7 Species of Concern

Greenland Red-Listed Species potentially occurring within the Qamut Block include eight bird species and five marine mammal species, as described in Table 4.2-2. Species of National Responsibility[3] potentially occurring within the Qamut Block include six bird species and three marine mammal species (Table 4.2-3).

Table 4.2-3 Summary of Species of Concern Potentially Occurring in the Qamut Block

Common Name	Species	Species of National Responsibility	Greenland Red List Status	IUCN Red List Status

4.3 Land and Sea Use

Greenland residents have a strong connection to the environment through hunting and fishing locally-available renewable resources. These practices have endured historically as part of the Greenlandic culture, and provide the basis for food production and economic benefit at both the household and commercial level. Fishing and hunting are the main industries in Greenland (Kolte S. 2011), although employment in these trades is limited to about 2,500 people (including fish processing facilities). The hunting and fishing industry in Greenland is regulated under the Department of Fisheries, Hunting and Agriculture in which hunting and fishing quotas are set annually by the Greenland Government (Greenland Government 2011).

The Qamut Block in Eastern Baffin Bay covers an area of 9,392 km$^{2.}$ The nearest community is Savissivik, located about 60 km north of the Qamut Block and about 110 km south of the US Air Force Base at Thule. Savissivik has a population of about 58 residents. The main source of income in the community comes from hunting and fishing.

4.3.1 Commercial Fisheries

Commercial fisheries represent the most important export industry in Greenland, with northern shrimp, Greenland halibut and snow crab fisheries accounting for 77% of Greenland's total domestic export revenue in 2006 (2.3 billion DKK) (DCE 2011). The commercial fishing industry supports approximately 1,500 jobs in the fish processing industry, as well as many other jobs in affiliated sectors including retail, tourism, and service industries.

3 Those species where the majority of a species' global population resides in Greenland and local management practices are vital to the overall population.

Fishing is administered by the Government of Greenland through quotas and licenses regulating the total allowable catch (TAC) for commercial fish species in Greenlandic Waters. The annual TAC is set based on scientific advice from GINR and several international organizations (e.g., North Atlantic Fisheries Organization (NAFO), North East Atlantic Fisheries Commission (NEAFC), International Council for the Exploration of the Sea (ICES)), as well as consultation with local Greenlandic stakeholders (e.g. KNAPK - Organization for Fishermen and Hunters in Greenland). The TAC is distributed in the form of quotas to individual units of the fleet. In West Greenland, commercial offshore fisheries are conducted by a limited number of operators, including four Greenlandic operators (nine vessels in total), one vessel from the European Union (EU), one vessel from the Faroe Islands and an unknown number of vessels from the Russian Federation (likely less than four vessels due to limited quotas allocated to these ships) (GFLC 2011).

The most important fisheries in Greenland are northern shrimp and Greenland halibut. From 2008 to 2010, annual revenue for the commercial northern shrimp fishery averaged 685 million DKK per year, while annual revenue for the Greenland halibut fishery averaged 204 million DKK per year (Figure 4.3-1) which is equivalent to approximately 62% and 18% of Greenland's total fish export revenue, respectively (Statistics Greenland 2011). Commercial fisheries for Greenland halibut and northern shrimp in West Greenland take place from late June until late September. Annual catch estimates for northern shrimp in Greenlandic waters is over 120,000 tonnes (Statistics Greenland 2011). The fishery mainly occurs along the banks of Davis Strait (west Greenland) and in southern Baffin Bay. In West Greenland, 57% of the TAC for northern shrimp is allocated to the offshore fleet with the remaining 43% allocated to the in-shore fleet (Statistics Greenland 2011). From 2004 to 2006, less than one percent of the total northern shrimp fishery in Greenland occurred in waters north of 71° latitude, compared with up to 30% in previous years (1985 to 1988) (DCE 2011). However, GFLC has observed a northward shift in both fisheries in recent years, with the Greenland halibut fishery presently focused between Disko Island and the Svartenhuk Peninsula and the northern shrimp fishery focused between Sisimiut and Upernavik (GFLC, 2011). No commercial fishery for Greenland halibut or northern shrimp presently exists in the Qamut Block (Figure 4.3-1).

The commercial snow crab fishery in Greenland takes place between 62 to 72° latitude, with the catch limited to large males. The snow crab fishery peaked in 2001 with an annual catch record of 14,247 tonnes (Statistics Greenland 2011). The fishery has declined in recent years potentially due to overharvesting, with the 2008 catch record reported at 2,169 tonnes (Statistics Greenland 2011). No commercial snow crab fishery presently exists in the Qamut Block.

Based on available fisheries records from DCE and GFLC, no commercial fisheries exist north of Nuussuaq. A test fishery for Greenland halibut was carried out west of the Qamut Block between 2005 and 2007. The halibut catch locations identified west of the Qamut Block in Figure 4.3-2 represents halibut test fishing locations and not commercial fishery activities.

4.3.2 Subsistence Fishing

Subsistence fishing is considered an important contribution to the daily household, especially in the settlements. Fishing takes place all year and are concentrated in inshore waters of local fiord systems close to the settlements. During winter (December to May) when dog sleds or snowmobiles can be used for travelling on the sea ice, long lines and nets are used for fishing Greenlandic halibut along ice edges or through holes in the ice. In the open water period (summer), fishing for Greenlandic halibut is supplemented with a fishing for wolfish (*Anarchicas minor*), Atlantic cod, and to a lesser degree, Arctic char. Salleq Island, located south of Savissivik, is the southernmost limit for local subsistence fishing (Qaasuitsup kommunia 2011).

4.3.3 Subsistence Hunting

The Greenland Ministry of Fisheries, Hunting and Agriculture set the annual harvest quotas for whales, walrus, and polar bear for each of its municipalities. Quotas are based on international agreements and biological advice from GINR (Statistics Greenland 2011). Whale quotas are as follows: 310 narwhal whales, 310 beluga whales, 230 mink whales, 10 fin whales, 2 bowhead whales and 9 humpback whales (APNN 2011). Hunting and fishing regulations within Greenland's land and sea territory are described in the Greenland Parliament Act No. 12 dated 29 October 1999. According to Section 4 of the government document, only persons with permanent attachment to Greenland and with appropriate documentation can be granted a recreational or commercial hunting permit/license (APNN 2011). As well, only occupational hunters are allowed to participate in the whale quota

harvest for species such as humpback whales, fin whales (NANOQ 2011). Several seal and bird species, as well as reindeer and musk ox, can also be hunted with a recreational licence.

In the period 2005 to 2010, an annual average of 153,000 seals, encompassing all species, were caught in Greenland. Of this harvest, roughly 34% were caught in the Eastern Baffin Bay area between Upernavik and Qaanaaq (Piniarneq 2012), indicating the importance of this resource in the area. Seals are considered one of the most important resources in Greenland contributing to the local household income and the maintenance of remote settlements. While seal skins are either sold for further processing or used by hunters for clothing, their principle use is for household consumption (KNAPP 2011).

The current population of seven to eight million seals (all species) is considered to be higher than historic levels (Hammill and Stenson 2010). The majority of seals hunted are juveniles (Christiansen 1983) with a peak in hunting observed in late summer in areas north of 74° latitude (DCE 2011).

Ringed seals are the most commonly hunted seal in Greenland. The present annual harvest of ringed seal in northwest Greenland is considered sustainable with a catch of approximately 50,000 seals per year. Harp seal are the second most important hunted seal in the Eastern Baffin Bay area, with annual catches in the order of approximately 10,000 animals. A limited number of bearded seals and hooded seals are also caught every year (< 5,000 pcs) (Piniarneq 2012).

Walrus numbers are estimated at 2,300 to 3,000 for the North Water polyna stock (NAMMCO 2009) and 2,700 individuals for the West Greenland stock (Heide-Jorgensen et al. 2010d). Most walrus are hunted on their wintering grounds or during spring when animals move along the ice edge. Annual harvest quotas for the North Water polynya stock during the period 2007 to 2009 were 90, 80 and 75, respectively (DCE 2011). Annual harvest quotas for the West Greenland stock during the period 2007 to 2010 were 80, 65, 38 and 61, respectively (DCE 2011). Recent satellite telemetry studies indicate that walrus in the West Greenland area and south-eastern Baffin Island area are part of the same population, which is hunted in both Greenland and Nunavut (NAMMCO 2009, Dietz et al. 2010).

Marine mammals are legally hunted along the coast in the Savissivik area. Polar bears are the species most valued by residents. Hunting generates more household income than fishing in this community, although the latter has become more common in recent years. During spring, hunters typically target ringed seal and bearded seal. In summer, narwhal and beluga are taken by hunters in kayaks as boat hunting is not permitted in this region. The 2012 annual quota for the Savissivik region is 18 narwhal and an unidentified number of belugas. Polar bear and occasionally walrus are hunted during winter when ice conditions permit travel by dog sled or snowmobile.

4.3.4 Other Vessel Traffic

Non-Project vessel traffic in or adjacent to the Qamut Block is expected to be low during the summer/fall period, but some aspects of this traffic are not predictable at this time, and may not be known before they occur (specifically, voyages related to military operations). Other non-Project vessels may include: cruise ships operating in Greenlandic waters only, or calling at ports in Greenland en route to or from destinations to the west via the Northwest Passage; merchant ships en route to or from destinations in Arctic Canada; merchant ships heading to or from ports along the West Greenland coast; Danish military (naval) ships; US Military Sealift Command vessels heading to and from the US Air Force Base at Thule, or US Navy ships (including submarines) operating in northeast Baffin Bay for other purposes, US Coast Guard or Canadian Coast Guard ships transiting to or from areas to the west via the Northwest Passage; and commercial fishing vessels.

Shell Kanumas A/S and Maersk Oil Kalaallit Nunaat A/S will be operating a number of ships in northeast Baffin Bay during the 2012 summer/fall navigation period. It is possible that some of the vessels under charter to Shell Kanumas A/S may transit Qamut Block en route to (stratigraphic drilling) locations to the north.

4.3.4.1.1 Cruise Ships

The number of cruise ships in Greenland waters has increased in recent years, including vessels operating in Greenlandic waters only, and vessels calling at Greenland ports en route to or from the central or western Canadian Arctic. The majority of these ships visit Greenland during summer (June to September), and transit

along designated traffic corridors. Most cruise ships visit a number of Greenlandic ports during these voyages. In 2011, approximately 110 landings were made at various ports in the Disko Bay and Melville Bay regions. Approximately seven landings are scheduled for 2012 near the Qamut Block, including one landing in Savissivik and six landings near Qaanaaq/Siorapaluk.

4.3.4.1.2 Merchant Ships

Royal Arctic Line (RAL) A/S is a Greenlandic shipping company headquartered in Nuuk and owned by the Government of Greenland. The RAL operates international cargo services from Nuuk and Aalborg, as well as domestic passenger/cargo vessels between the towns and villages of Greenland. The transportation of goods to and from Qaanaaq, Savissivik, Siorapaluk, Qeqertaq and Pituffik takes place once a year during summer using a vessel from Nuuk. Detailed information on RAL shipping activities for 2011 is provided in RAL's master schedule (RAL 2011). No information is available on foreign-flag cargo ships transiting to or from the US Air Force Base at Thule (Pifuffik).

4.3.4.1.3 Naval Ships

Island Command Greenland/MRCC Grønnedal has a number of naval vessels which act as patrol ships in Greenland territorial waters. A single offshore patrol vessel (OPV-class) is typically assigned to northern Baffin Bay and Melville Bay region during the open-water season, patrolling waters up to Nares Strait and Kane Basin. Vessel patrol activities are strongly influenced by local ice conditions (MRCC 2012 pers. comm.).

Various ships owned or under charter to the US Military Sealift Command, transport cargo to the US Air Force Base at Thule (Pituffik). This cargo includes jet fuel, diesel fuel, other petroleum products, shipping containers, heavy equipment and vehicles, building and construction materials, and secret or classified items. It is possible that cargo will be shipped from Thule, as "back haul", to ports in the United States or other countries. US Coast Guard ships, in addition to US Navy ships, have visited Thule in the past, and these vessels could do that again during the 2012 navigation period. If any of these ships call at Thule in 2012, it is possible they will transit Qamut Block en route to or from this location, depending on ice conditions to the north and northwest, and mission profile at time of passage.

4.3.4.1.4 Other Vessels

No commercial fisheries (Greenland halibut, northern shrimp, or snow crab) presently exist in the Qamut Block (Figure 4.3-2); it is therefore unlikely that commercial fishing boats will be operating in the Qamut Block during the summer "open water" period.

One GINR research ship will operate in the Eastern Baffin Bay/Melville Bay area during the open-water season conducting scientific work (halibut test fishery/noise buoy deployment) with the program scheduled to run until late September (GINR, 2012).

5 Methods Used for the Environmental Impact Assessment

5.1 Purpose and Approach

The purpose of an EIA is to determine whether the Project will have an effect on the environment, to identify the extent of these effects and to develop or specify the means to mitigate, or reduce where possible, the identified effects. Possible effects of the environment on the Project (for example local and regional marine conditions) are also addressed.

The environmental assessment methodology for the proposed Project has been developed to meet BMP regulatory requirements for hydrocarbon exploration and exploitation activities in offshore Greenland (NERI et al. 2011). The methodology entails a structured approach, which includes the following steps:

- Develop the scope of assessment, including: selection of Valued Ecosystem Components (VEC), identification of Project activities with potential to interact with a VEC, and establishing temporal and spatial boundaries for the Project.
- Predict and evaluate potential impacts of the Project on selected VECs.

- Identify mitigation measures and monitoring procedures that have been developed and incorporated in the Project design to eliminate or reduce potential adverse impacts to the selected VECs.
- Determine a level of residual impact significance based on the combined effect of an outcome or consequence of the Project activity on the VEC and the probability that this event may occur.
- Provide the means by which the mitigation measures will be implemented and residual impacts managed, through the provision of an Environmental Protection Plan (EPP). This includes the development of monitoring plans and a mechanism for audit, review and corrective action.

5.2 Scope of Assessment

The environment considered for assessment purposes is described as follows:

- Physical Environment – physical oceanography, ice climatology (sea ice and glacial ice), marine air quality.
- Biological Environment – plankton, invertebrates, fish, seabirds and marine mammals (whales, seals, walrus, and polar bears).
- Land and Sea Use – subsistence hunting and fishing, commercial fisheries, tourism, other human activity, and other ship operations.

5.2.1 Selection of Valued Ecosystem Component

While all components of the environment are important, it is neither practical nor necessary to assess all plausible effects of the Project on every component of the environment. The assessment focuses on the environmental components that have the greatest relevance in terms of environmental value and sensitivity and which are most likely to be affected by the Project.

To achieve this focus, specific Valued Ecosystem Components (VECs) have been identified and selected as endpoints for the assessment. VECs are defined as components of the environment (e.g. species, population, biological event or other environmental feature) that are considered important to the local ecology and human population, have a national or international profile, and, if altered, would be of concern to regulators, general public, indigenous peoples, and other stakeholders (DCE 2011). The VECs that have been identified and assessed in the EIA are presented in Appendix E, Table E-1.

Belugas and narwhals were identified as VECs for the Project, as they are both listed species and their presence in Greenlandic waters is well documented (DCE 2011). For the purpose of the assessment, both species served as ‘indicator’ species for all toothed whales with associations to the Project area. As such, results from the effects assessment, and the mitigation measures proposed, are applicable to all toothed whale species potentially occurring in the Project area during the open-water season.

Similarly, bowhead whales were selected as an ‘indicator’ species for baleen whales for the same reasons. Results from the effects assessment, and the mitigation measures proposed, are thus applicable to all baleen whale species potentially occurring in the Project area during the open-water season.

5.2.2 Interaction of Project with the Environment

In the scoping stage of the assessment, Project activities were examined in order to identify those most likely to interact with the environment and potentially result in an adverse or positive impact. The potential for project interactions with VECs was based on a comprehensive review of the literature, information provided by the proponent including a summary of project-related activities; an appraisal of the environmental setting; temporal and/or spatial overlap; and professional judgment. Assessed activities included routine activities and unplanned (accidental) events.

Interactions carried forward in the assessment (Section 7) are identified in Appendix F, Table F-1. Negligible Project interactions are identified as such and are not considered further in the assessment.

5.2.3 Temporal and Spatial Boundaries of the Assessment

Spatial boundaries considered in the assessment include those areas within which VECs are likely to interact with, or be influenced by Project activities. The assessment considers two levels of spatial boundaries: the local study area (LSA) and the regional study area (RSA):

- the LSA includes those areas used in assessing Project-specific effects; and
- the RSA includes those areas used in assessing Project combined and cumulative effects.

The study areas selected were determined according to the spatial extent of the Project effects and the distribution and mobility of VECs. Some Project effects such as discharges and air emissions from the seismic survey vessel and chase or support ships, have the potential to affect a larger geographic area, whereas others, such as sound from the seismic operation, may affect a smaller area only, or a larger area, depending on the sound source and acoustic conditions at the time of survey. The cumulative effects of multiple seismic surveys that happen at the same time in northeast Baffin Bay, discussed in Section 5.3, including the seismic survey described in the EIA, apply to a large region

Delineation of the spatial boundaries for the assessment of underwater sound was based primarily on the potential zone of impact from Project-generated sound in water (sea) and associated activities. The LSA was defined as all waters within the License Block plus 10 km buffer zone, as this encompasses the acoustic zone of direct impact for potential physical injury (coincident with the 180 dB rel 1 µPa rms ensonificaiton zone) and potential behavioural effects (coincident with the 160 dB rel 1 µPa RMS ensonification zone). The RSA, coincident with all waters under Greenlandic jurisdiction in Baffin Bay, considers indirect as well as far-field regional effects of the Project on VECs, particularly Greenland Red-listed marine mammals.

Temporal boundaries considered in the assessment include the period from when seismic and support vessel(s) first arrive in the Qamut Block until the time all Project vessels have departed, following completion of the survey. Project activities have been assessed during the full life-cycle of the Project. The proposed period of operations is early August to mid-September, with an option of extending to mid-October if the seismic survey is delayed by weather conditions, ice conditions, sea conditions or other factors.

5.2.4 Determining Impact Significance

Following identification of the Project interactions with the environment and in consideration of mitigation measures including all Best Environmental Practices (BEP), the level of impact (impact significance) that may result from each of the interactions with the VEC's was assessed. In assessing impact significance, two main elements were considered: consequence and probability.

The consequence of an impact was categorized as: Negligible; Minor; Moderate; or Severe. It was determined from a number of parameters that describe the nature of the impact, including magnitude, geographic extent, duration, and frequency. Where possible, impact ratings were quantitatively described. Rankings used for each of these parameters are defined in Appendix G, Table G-1. A "decision tree" is used to demonstrate how the individual assessment measures are combined to yield a consequence rating (Appendix H, Table H-1).

Along with consequence, the second variable used to establish impact significance of an effect upon the environment was probability. Probability was defined as the likelihood of the impact occurring during the life of the Project after mitigation has been applied. The probability of impact occurrence was determined, and placed in one of the following categories: Certain (100% probability); Likely (50% to 99% probability); Unlikely (10% to 49% probability); and Rare (0% to 9% probability).

Impacts were rated based on the incorporation of Project mitigation measures to avoid or reduce potential effects. The assessment addresses those effects predicted to exist after mitigation, i.e., residual effects. To determine overall impact significance, impact consequence and impact probability were combined in a risk matrix, as shown in Table 5.2-1. The end result was an overall significance value ranging from 1 to 4: 1-Negligible, 2-Low, 3-Moderate, and 4-Significant. Impacts of negligible consequence were assigned the lowest significance value (1), regardless of impact probability. Effects rated as significant (those rated 4) require additional mitigation to reduce the impact to an acceptable level.

Table 5.2-1 Matrix Combining Impact Consequence and Probability to Determine Overall Impact Significance

Probability	Consequence			
	Negligible	Minor	Moderate	Severe
Certain (100%)	1	2	3	4
Likely (50%-99%)	1	2	3	4
Unlikely (10%-49%)	1	2	2	3
Rare (0-9%)	1	1	1	2

In the impact assessment Section, the assessment of each Project effect is presented separately. This includes information on the Project effect, involving VEC interactions, applicable mitigation measures, summarized in Section 8, Appendix I and Appendix J) and impact criteria rankings (based on impact significance).

6 Potential Impacts and Project Mitigation

6.1 Effects of Airborne Emissions from Project Vessels

The main sources of atmospheric emissions from the Project are exhaust gases from the diesel engines of the seismic survey vessel (MV *Princess*) and the two support vessels (MV *Thor Beamer* and MV *Thor Supplier*). Ancillary equipment (e.g., incinerators, compressor generators, other generator sets, etc) on these vessels will also result in emissions to the atmosphere. However, these emissions are expected to be intermittent and of smaller magnitude, compared to emissions from any vessel's main engines, and therefore, are not considered further in the assessment.

Table 6.1-1 presents an estimate of the fuel consumption for all Project vessels during survey operations in the Qamut Block, periodic refuelling voyages, and positioning to and/or from the Qamut Block. For the purposes of this estimate, the average operating speed and daily fuel consumption of each vessel was used to calculate the total fuel consumption. It was assumed that all Project vessels will be running on Marine Diesel Fuel.

During active seismic operations, all vessels were assumed to be operating 24 hours per day, 7 days per week. This period will be up to 45 days in length; it would begin in early August, and end by 1 October. A 15-day contingency was added to the 45-day survey period for assessment purposes only. This period does not include mobilization or demobilization time from last or next port (coming on or off charter).

The fuel capacities of the vessels identified for the Project imply, based on the survey period and option of extending into October if delayed, that some or many of the vessels may need to complete one voyage to Nuuk to re-fuel. It is also possible that the *Princess* will bunker, or re-fuel, by vessel-to-vessel transfer from one of the support vessels. This possibility was not taken into account for air emission calculations. For both the seismic vessel and support vessels, the transit time between Nuuk and Qamut Block was assumed to be 5 days round-trip (750 nautical miles x 2). Based on these assumptions, the total fuel consumption for the Project is estimated to be roughly 1,631 m^3 (Table 6.1-1).

Table 6.1-1 Estimated Fuel Consumption for Seismic Survey and Support Vessels during the Proposed 2012 Program

Vessel Activity	Vessel Name	Average Operating Speed [knots]	Daily Fuel Consumption [m^3]	Total Fuel Consumption [m^3]
Seismic Survey (60 days)	MV *Princess*	4.0	14.0	840.0
	MV *Thor Beamer*	6.0	1.1	66.0
	MV *Thor Supplier*	4.0	5.0	300.0
Mobilization / demobilization between Nuuk and survey Block (one 5-day round trip per vessel)	MV *Princess*	12.5	15.0	75.0
	MV *Thor Beamer*	12.5	6.5	32.5
	MV *Thor Supplier*	12.5	21.0	105.0
Fuel / resupply trip to Nuuk (one 5-day round trip per vessel)	MV *Princess*	12.5	15.0	75.0
	MV *Thor Beamer*	12.5	6.5	32.5
	MV *Thor Supplier*	12.5	21.0	105.0
Total				**1,631.0**

Table 6.1-2 provides an estimate of the air emissions from all Projects vessels during survey operations in the Qamut Block, periodic re-fuelling voyages, and the assumed positioning to or from the survey area. Table 6.1-3 provides an estimate of greenhouse gas emissions for the Project. Emission factors were used for calculating the associated emissions from the diesel engines based on fuel type and consumption (IVL SERI 2002, Environment Canada 2011). Actual emissions will vary between vessels (different engine types, age and condition, servicing and maintenance history) and change according to vessel speed and operating mode (e.g., transiting, manoeuvring during the survey, maintaining or keeping station, etc).

Table 6.1-2 Total Air Emissions for the Proposed 2012 Program

Emission Parameter	Emission Factor [kg emitted / tonne fuel consumed][(a)]	Total Emission during Seismic Program [tonnes]
PM	1.2	1.92
SOx[(b)]	30.0	48.00
NOx	87.0	139.20
VOC	2.4	3.84
CO	7.4	11.84

(a) Assumes fuel density for marine diesel fuel of 0.981 g/ mL or 0.000981 tonnes/L for calculations (EC 2006)

(b) Assumes sulphur content of 1.5% (maximum allowable sulphur content based on BMP guidelines, 2011).

Notes: CO = carbon monoxide; NO_X = nitrogen oxides; PM = particulate matter; SO_X = sulphur oxides; VOC = volatile organic compounds.
PM, SO_X, NO_X, VOC and CO emissions are calculated using Lloyds Register Engineering Services (1995) for slow speed diesel engines (Lloyds Register Engineering Services 1995 in IVL Swedish Environmental Research Institute Ltd 2002, Table II).

Table 6.1-3 Total Greenhouse Gas Emissions for the Proposed 2012 Program

Greenhouse Gas Parameter	Emission Factor [g emitted / L fuel consumed]	Total Emission During Seismic Program [tonnes]
CO_2	2,663.00	4,343.35
CH_4	0.15	0.24
N_2O	1.10	1.79
CO_2e^a	-	4,904.66[(a)]

(a) The greenhouse gas emissions have been combined and presented in terms of how much CO_2 would be required to produced a similar warming effect. The 100-year Global Warming Potentials (GWP) have been taken from Environment Canada, 2011: CO_2 GWP of is 1, CH_4 GWP of 21, and N_2O GWP of 310.

Notes: CO_2 = carbon dioxide; CH_4 = methane; N_2O = nitrous oxide; CO_2e = Carbon dioxide equivalent.
CO_2, CH_4, and N_2O emissions are calculated using Environment Canada's (2011) Emission Factors for Marine Heavy Fuel Oil Ships (Annex 8, Table A8–11 of EC 2011).

Proposed Mitigation and Best Practices

Project vessels will comply with local and international pollution prevention regulations and best practices, including, but not limited to, the Minerals Resources Act of 2009, the Act on the Protection of the Marine Environment (1993) of Denmark and, where practical, best practices of the International Convention for the

Prevention of Pollution from Vessels (1973) as modified by the Protocol of 1978, MARPOL 73/78 (Annex VI), and various BMP Guidelines that govern the survey and other activity in Qamut Block.

The mitigation measures that will be adopted to reduce the potential impacts of Project vessel emissions on air quality include:

- Diesel engines, incinerators and other equipment onboard Project vessels will be maintained and operated efficiently.
- Ozone-depleting substances will not be used, except in refrigeration equipment where closed recovery systems are employed.
- Project vessels and equipment will use fuel with a sulphur content less than 1.5% (by weight).

Residual Effects and Environmental Significance

The impact assessment indicated that the effects of Project emissions on air quality will be negligible. Table 6.1-4 summarizes the impact ratings classifications for the residual effects of Project-related emissions on marine air quality. The magnitude of any effects is regarded as negligible because the emissions will be dispersed relatively quickly in the atmosphere. Emissions, including particulates in exhaust gases, could be transported outside the LSA by prevailing winds, but it is not likely these emissions will be detectable at any significant concentration by the time they reach the RSA. The frequency of occurrence, however, is continuous, but it is short-term, and therefore, the impact significance will be negligible (1).

Table 6.1-4 Summary of Impacts from Airborne Emissions on Air Quality

VEC	Potential Impact	Planned Mitigation	Impact Assessment Criteria				Consequence	Probability	Overall Significance
			Magnitude	Geographic Extent	Duration	Frequency			
Air Quality	change in ambient air quality concentrations of PM, SO_X, NO_X, VOCs and CO	Section 8.0 & Appendix I Table I-1	negligible	beyond regional	short-term	continuous	negligible	certain	1 (negligible)

No residual effects of emissions are expected beyond the RSA when the proposed mitigation measures are followed, and consequently, no further mitigation will be required.

6.2 Effects of Discharges from Project Vessels

The main sources of potential discharge from the Project are: liquids, including grey water (domestic wastewater), black water (sewage), drainage from decks and exposed (above waterline) structure due to spray and precipitation, cooling water, ballast water, and bilge water: and waste in solid form, including kitchen waste (organic waste and packaging materials), medical waste, potentially hazardous waste (including batteries), non-hazardous waste, and miscellaneous vessel's garbage. Table 6.2-1 summarizes the types of discharge and solid or liquid waste that could be generated on the seismic survey vessel (MV *Princess*) and the two support vessels (MV *Thor Beamer* and MV *Thor Supplier*).

Marine water quality in the Qamut Block should be characterized by low levels of pollutants and other contaminants, due to its remote location and distance from shore (at least 40 km), and the very small amount of maritime activity in this region, notwithstanding comments about vessel traffic under Land & Sea Use in Section 4.3. It is unlikely that unintended discharges to the sea during the Project, or any of allowed or regulated discharges, will affect water quality directly, or marine ecology indirectly, in a long-term fashion.

Table 6.2-1 Types of Waste Potentially Generated from the Project Vessels

Waste Type	Waste Stream	Potential Source	Potential Contents	Comments
Liquid Wastes	grey water	kitchen liquid wastes, bathing water, laundry facilities, deck drains and other non- oily waste water	detergents, soaps, chlorine	disposed at sea
	black water	sewage	microorganisms, nutrients, suspended solids, organic material, chlorine	treated onboard before disposal at sea to standards set out by Annex IV of Marpol
	potentially hazardous waste	waste lubricating oil, hydraulic oil, cable oil	hydrocarbons, heavy metals	stored onboard until proper disposal at the home port
Solid Wastes	medical waste	used first-aid materials, medication	bio-hazardous materials, sharp needles, glass, plastic	stored onboard until proper disposal at the home port
	kitchen waste	culinary activities, unused/uneaten foods	cooked and raw food	macerated and disposed at sea (at least 12 nautical miles/23 km from the coast)
	potentially hazardous waste	batteries, oil drums, filters	heavy metals, acids	stored onboard until proper disposal at the home port
	miscellaneous garbage	packaging, other materials	plastic, paper, glass	sorted by type, compacted where practicable and stored or incinerated onboard until disposal at a certified garbage or recycling reception facility at the home port

It is estimated that 15.2 m^3 of grey water and 1.9 m^3 of black water may be produced and discharged daily from the three Project vessels. These estimates assume that grey water and black water are produced at a rate of up to 254 litres and 32 litres per person per day respectively, based on average usage rates for cruise line operations (EPA 2008) and a probable (maximum) onboard complement of up to 60 persons (all vessels). These estimates are conservative; actual discharges are expected to be lower.

Grey water will be discharged directly to the sea during the Project as treatment of grey water is not required before release under MARPOL (73/78). This discharge may contain residual concentrations of chlorine, but in low or very low concentrations. Residual chlorine will react with organic matter in the upper part of the water column, and become inactive.

Black water (sewage) may contain harmful microorganisms, nutrients, suspended solids, organic material and residual chlorine from treatment. It will disperse and degrade in the environment. Discharge of black water and food wastes will increase Biological Oxygen Demand (BOD), but it is unlikely this will have any appreciable effect on dissolved oxygen content of seawater in the LSA, compared to natural conditions.

Ballast water may contain invasive (exotic) species in the water itself or on particulate. Release of ballast water is strictly regulated under the IMO Convention for the Control and Management of Vessel's Ballast Water and Sediments of 2004 (subject to its full ratification by 2016). This subject is addressed in Section 6.2, and not discussed further below.

Proposed Mitigation and Best Practices

All vessels will follow the Project-specific Waste Management Plan that is identified in the EPP as a supplementary or complimentary plan. Preparation of this plan has not been finished by ConocoPhillips, and it is not attached to the EIA.

Solid waste will be sorted by type, compacted where practical, and stored or incinerated onboard until it can be disposed of at a certified landfill or recycling reception facility in another country. ConocoPhillips will ensure that it is not be transferred to shore, and left at any location in Greenland. Disposal will occur at the home ports of the vessels involved when the Project is finished or at the first port of calling after these vessels leave waters under Greenlandic jurisdiction.

It is remotely possible that emergency waste disposal may be required at a port in Greenland. As a last resort, and with BMP permission, suitable facilities would be identified in Nuuk, and used for temporary handling and storage. ConocoPhillips would remove any waste handled and stored on an emergency basis as soon as practical, and inform BMP when this action is taken.

Food waste will be macerated and disposed at sea at least 12 nautical miles (approximately 23 km) from the nearest point of land. This will be done in accordance with the Act on the Protection of the Marine Environment (Part 7, 22-1, 1993), and Annex V of MARPOL (73/78) for "Special Area", given the sensitive nature and low likelihood of pollution in this region.

Sewage waste, as well as kitchen waste that cannot be macerated, will be treated onboard by all vessels prior to discharge, and will meet IMO standards, Annex IV of MARPOL (73/78).

Some capacity may exist on some vessels for collection and holding of drainage water in limited amount, but drainage from many elements of vessel's structure (above waterline) into the sea cannot be avoided. Decks will be kept clean to prevent drainage from mixing with oil stains, chemical stains, granular material or other residue on the surface of the deck. Bilge water, and any collected drainage water, would be routed through an oil-water separator, and monitored for oil concentration prior to discharge. This process would comply with the best practices of Annex I of MARPOL. Cooling water is part of a closed loop system, and water pumped or taken onboard for this purpose will not be contaminated or mixed with water from other sources before it is returned to the sea during normal operations.

A detailed account of the proposed mitigation measures for managing the effects of discharges to the marine environment is provided in the EPP (Section 8.0) and summarized in Appendix I.

Residual Effects and Environmental Significance

Solid waste (other than organic kitchen waste that can be macerated) will not be discharged into the marine environment. Consequently, no impacts on the environment will occur during normal operations, and hence, no impacts are expected.

The impact assessment indicated that the effects of vessel discharges on marine ecology will be negligible. Table 6.2-2 summarizes the impact rating classifications for the effects of discharges from vessels on VECs. These discharges will occur intermittently or frequently over the course of the Project into an offshore environment when sea ice is absent. The surface water involved in being transported to the west or northwest by the West Greenland Current in this region. It will be well-mixed during transport, even though the water column is more stratified during summer compared to winter. The effects of various discharges on BOD are considered to be negligible. The low amounts of residual chlorine and other harmful material, if any, in treated black water will be dispersed and diluted relatively quickly by mixing and other processes in the surface layer. It is not believed any discharges will result in measurable water quality changes compared to background levels in the LSA or RSA, recognizing that the properties involved have likely not been investigated or reported on in the past, and are not accurately known at this time. However, subsequent indirect adverse effects to marine ecology are not expected. The magnitude of the impact is considered negligible for all VECs, with a short-term duration over a local geographic extent and intermittent to regular frequency, depending on the discharge in question. The consequence is considered negligible. Although the probability of the activity resulting in the effect is rated as likely, the overall impact significance will be negligible. Since residual effects from discharges are expected to be negligible, no further mitigation is required.

Table 6.2-2 Summary of Impacts from Discharges on VECs

VEC	Potential Impact	Planned Mitigation	Impact Assessment Criteria				Consequence	Probability	Overall Significance
			Magnitude	Geographic Extent	Duration	Frequency			
Water Quality	deterioration of water quality	Section 8 (Waste Management Plan) & Appendix I Table I-1	negligible	local	short-term	regular	negligible	likely	1 (negligible)
Marine Fish	indirect effects from the deterioration of water quality		negligible	local	short-term	regular	negligible	likely	1 (negligible)
Seabirds	indirect effects from the deterioration of water quality		negligible	local	short-term	regular	negligible	likely	1 (negligible)
Marine Mammals	indirect effects from the deterioration of water quality		negligible	local	short-term	regular	negligible	likely	1 (negligible)

6.3 Effects of Underwater Sound on the Marine Environment

6.3.1 Introduction

The potential impacts from underwater sound from the seismic survey, ship's engines and onboard activities on marine invertebrates, marine fish, marine birds, and subsistence hunting and fishing are assessed in this section.

There is little known about the ambient (natural) acoustic conditions in northeast Baffin Bay. Measurements on ambient sound are not available in the public domain, or have not been obtained or published to date. It is believed that ambient sound levels are relatively high due to the break-up and movement of sea ice, iceberg calving, iceberg behaviour during transport (including fracturing and degradation, as well as scouring or gouging and grounding), sound from marine mammals, and sound from the existing pattern of maritime activity in these waters, including the commercial fishing fleet, the coastal trade, and other shipping.

6.3.2 Overview of Sound Terminology

Underwater sound can be described through a source-path-receiver model. An acoustic source emits sound energy that radiates outward and travels through the water and the seafloor as pressure waves. The sound level decreases with increasing distance from the acoustic source as the sound pressure waves spread out under the influence of the surrounding environment. The amount by which the sound levels decrease between a source and receiver is called transmission loss. The amount of transmission loss that occurs depends on the source-receiver separation, the frequency of the sound, the properties of the water column and the properties of the seafloor layers, as described in Section 4.1.4.8 (Physical Environment). An animal senses the sound at a level that is dependent on the amount of transmission loss between the source and the receiver. The potential for impact depends on the received sound level and the frequency content of the received sound signal relative to the hearing abilities of the animal and the level of natural background sound. Potential effects range from subtle changes in behaviour at low received levels to strong disturbance effects to temporary hearing impairment and permanent hearing or physical damage at high received levels. Effects from sound exposure scale with the received sound level. Figure 6.3-1 provides a diagram of sound to receiver interaction.

Several metrics are commonly used to characterize sound pressure levels from impulsive sound sources such as airguns. For the present assessment, sound is quantified using the primary sound level metrics of peak sound pressure level (peak SPL), 90% root-mean-square sound pressure level (rms SPL), and sound exposure level (SEL). Underwater sound levels are expressed in decibels (dB) which is a logarithmic ratio relative to a fixed reference pressure of 1 µPa (equal to 10^{-6} Pa or 10^{-11} bar). Cumulative sound exposure level (cSEL) was also used in the assessment criteria for marine fish. cSEL provides a conservative measure that does not account for any hearing recovery that may occur between pulses.

Details of calculation methods used to determine SPL, peak SPL, peak to peak SPL, SEL and cSEL are provided in Appendix D.

6.3.3 Project Sound Sources

The Project sound sources assessed included activities surrounding the seismic survey and vessel sound. The two sources were assessed for marine mammals; however, only seismic activities were assessed for marine invertebrates, marine fish, marine birds, and subsistence hunting and fishing. Details of the Project sources and mitigitation applied can be found in Section 3.1, Section 8 and Appendix D and Appendix I.

6.3.4 Acoustic Behaviour in Arctic Waters

In Arctic waters, sound will attenuate quickly at the surface and then refract and travel at different speeds depending on water currents, water temperature and salinity structure, ocean surface, and chemical processes in the water (Figure 6.3-2). A complete discussion of acoustic behaviours in northeast Baffin Bay is discussed in Section 4.1.4.8 Physical Environment: Acoustic Conditions and Appendix D.

6.3.5 Underwater Acoustic Modelling

Two complementary acoustic models were used to predict the underwater sound field, surrounding the seismic airgun array: JASCO's Airgun Array Source Model (AASM) and JASCO's Marine Operations Sound Model (MONM). The AASM was used to model the airgun array pressure signatures and directional source levels (SL)

(MacGillivray 2006). The MONM was used to model the sound fields. Computed transmission loss values were then combined with the AASM source levels to generate received sound levels over a 3D grid. These models, methodology and results of the modelling are described in (Appendix D).

Full-area acoustic modeling was conducted using AASM and MONM for the full 3,940 in^3 airgun array proposed for use during the seismic survey (results provided in Acoustics Technical Report). Sound levels were modeled over a 305 km by 225 km grid for three different scenarios in August. These locations were chosen to sample the ranges of water depth in the area. The sources and source locations for each scenario are provided in Appendix D.

The modelled received levels were processed to provide sound level isopleth maps in terms of SEL, rms SPL, and peak SPL values. Tables showing distances to specific received sound levels were generated for m-weighted SEL, rms SPL and peak SPL values. Full model results for all the scenarios are found in the Acoustics Technical Report. The radii corresponding to the NMFS exposure criteria, in rms SPL, have been used in this assessment. Radii are presented here as computed in two ways: (1) R_{max}, the maximum range at which the given sound level was encountered in the modelled field grid; (2) $R_{95\%}$, the maximum range to a grid point at which the given sound level was encountered after exclusion of 5% of the farthest such points.

Based on the results from all of the scenarios considered, the maximum range (R_{max}) to an rms SPL of 180 dB re 1 μPa rms is 840 m (710 m $R_{95\%}$) for the full airgun array operating at Site 2. The R_{max} radii to 190 and 160 dB re 1 μPa rms are 230 m and 7,700 m (210 m and 6,400 m for $R_{95\%}$) respectively.

Impacts to the marine environment are discussed below. Only marine fish and marine mammals have acoustic criteria; therefore, the modelling discussed in this assessment applies mainly to those sections.

6.3.6 Marine Invertebrates

Hearing Abilities and Effects of Sound to Marine Invertebrates

Information on the hearing abilities of aquatic invertebrates is limited. Most available data for invertebrates is based on studies conducted on crustaceans and cephalopods (squid and octopods). It is generally thought that invertebrates are not capable of detecting sound given their lack of sound pressure-sensitive organs. However, cephalopods have special sensory structures that are considered to serve primarily for detecting acoustic stimuli (Budelmann 1992 Nixon and Young 2003). Cephalopods have been shown to respond to frequencies in the 100 Hz to 1,500 Hz range (Mooney et al. 2010, Hu et al. 2009). Crustaceans have been shown to be most sensitive to frequencies below 1,000 Hz (Budelmann 1992, Popper et al. 2001); although can detect sound as low as 40 Hz (Tautz et al 1981) and as high as 3,000 Hz (Lovell 2005, 2006).

Marine invertebrates, mainly crustaceans, are capable of producing sound by scraping, rubbing or snapping various parts of their bodies. These sounds may be associated with territorial behaviour, feeding, mating or aggression; and range in frequency from 87 Hz to 200 kHz (Au and Banks 1998, Tolstoganova 2002).

A limited number of studies assessing the impact of seismic operations on invertebrates have been reported in literature. These studies have tended to focus on potential impacts to macrobenthic species of commercial importance.

Several key studies have been conducted in this area. Crustaceans appear to have the highest tolerance to seismic sound and vibration. Cephalopods have the least tolerance and may be adversely affected by seismic sound and vibration. More information on the studies can be found in Norris and Mohl 1983, Matishov 1992, McCauley et al. 2000, Soldal and Lokkeborg 1993, cited in Dalen 1994 studies.

Residual Effects and Environmental Significance

Underwater sound generated by the proposed seismic survey will occur at frequencies which are detectable by some marine invertebrates (e.g. crustaceans). It is unlikely that the seismic operations would increase the mortality or injury of invertebrates unless the source is at close range (within 1 m) (Norris and Mohl 1983). Most invertebrates inhabit the benthic zone which is approximately 100 meters from the source (minimum water depths in the LSA). Furthermore, invertebrates are thought to be resilient to seismic activities because they lack internal gas-filled cavities normally susceptible to sound pressure effects. Effects would likely be limited to short-term

behavioural responses that would vary between species. The consequence of the effect of sound on invertebrates was considered to be minor based on a low magnitude impact restricted to the LSA and occurring over a short duration (survey period). The probability of the effect occurring was considered to be unlikely, resulting in a low (2) overall impact significance rating. Table 6.3-1 summarizes the impact rating classifications and overall significance for the effects of seismic sound on marine invertebrates.

6.3.7 Marine Fish

Hearing Abilities and Effects of Sound on Marine Fish

It is well known that fish use sound for communication, detection of predators and prey and learning about their environment (Popper and Fay 1999, Zelick et al. 1999, Fay and Popper 2000, Popper et al. 2003). All fish species can hear with varying degrees of sensitivity within the frequency range of sound produced by seismic sources and other industrial sound sources (Hawkins 1973, Popper and Fay 1973, Tavolga et al. 1981, Fay 1988, Popper and Fay 1993, Fay 2000). The hearing range for most fish is believed to be in the frequency range of 100 to 1,000 Hz (Fay 1988). A smaller number of species can detect sounds to over 3,000 Hz, while a very few can detect sounds to well over 100 kHz. Because of wide differences in hearing capability and morphologies among fish species, behavioural responses and the susceptibility of fish to auditory trauma varies greatly.

There is considerable anatomical and physiological variation amongst fish with respect to hearing structures, suggesting that various species may detect and process sound in different ways (Popper and Fay 1993). Fish can be divided into two broad categories: hearing generalists and hearing specialists (Popper et al. 2003, Ladich and Popper 2004).

Hearing generalists are fish species without any auditory system specializations. They have relatively poor auditory sensitivity characterized by a narrow bandwidth of hearing; typically detecting sounds from below 50 Hz up to 1 or 1.5 kHz (Popper et al. 2003). This includes most bottom-dwelling species such as Greenland halibut. (Popper et al. 2003). The majority of fish species that fall into this category generally do not hear frequencies much above 1 kHz, with peak sensitivities around 300 to 500 Hz (Ladich and Popper 2004). The sound pressure detection threshold can be as high as 120 dB re 1 µPa at the most sensitive frequency (Nedwell et al. 2004).

Hearing specialists have specialized auditory structures connected to well-developed pressure sensitive organs (Popper and Fay 1993). These morphological adaptations allow hearing specialists to detect sound pressure with greater sensitivity (i.e., lowering their hearing threshold) and in a wider bandwidth than “generalists”, and makes hearing specialists generally more sensitive to high-amplitude sound introduced into the marine environment. Polar cod and Arctic cod are both hearing specialist species and are likely to be present in the Qamut Block and surrounding area. Cod fish can detect both sound acceleration and sound pressure over a substantial frequency range, 20 to 150 KHz. Sound pressure thresholds in cod fish in the frequency range 60 to 300 Hz lie in the range 80 to 90 dB re 1 µPa.

Acoustic Impact Criteria for Marine Fish

National Marine Fisheries Service (NMFS) has established interim sound exposure criteria for the onset of direct physical injury in fish exposed to impulsive sound sources (Popper et al. 2006, Stadler and Woodbury 2009). These criteria were developed specifically for impact pile driving activities, although the criteria are based on measurements taken from different types of impulsive sound sources including airgun arrays. For the purpose of this assessment, these criteria were assumed to be representative of impulsive sound from seismic airgun operations.

NMFS criteria use two metrics, peak sound pressure level ($SPL_{0\text{-}peak}$) and cumulative sound exposure level (cSEL), for establishing the onset of physical effects to fish. NMFS sound exposure criteria are as follows: onset of physical injury in fish would be expected if either the peak SPL exceeds 206 dB re 1 μPa^2s, or the cSEL exceeds 187 dB re 1 μPa^2s for fishes 2 grams or larger; or 183 dB re 1 μPa^2s for smaller fishes.

There is no evidence of fish mortality as a result of seismic activity under non-experimental conditions. The threshold peak impulse sound pressure for direct physical trauma in marine fish is generally considered to be >200 dB (McCauley 1994). Except at close range, the effects of seismic sound sources on fishes are thought to be transitory, mainly evoking a startle response and changes in schooling behaviour (McCauley et al. 2003).

Habituation of fish to underwater sound has been shown to occur, with behavioural changes stopping during the exposure period, sometimes within minutes of commencement of surveying (Pearson et al. 1992).

McCauley et al. (2000, 2003) study suggests that exposure to multiple seismic pulses of 180 dB re 1 µPa or greater can result in significant damage to fish auditory structures.

In general, subtle behavioural changes in fish may be expected to occur at received peak pressures of 160 dB re 1µPa, and peak pressures of 180 dB or higher may cause noticeable changes in behaviour (Chapman and Hawkins 1969, Pearson et al. 1992, Skalski et al. 1992) or auditory trauma (McCauley et al. 2003). A number of other experimental studies have been performed to determine physical and behavioural effects of seismic activity on adult fish. The findings of these studies demonstrate that mortality rarely occurs beyond a range of five meters from the seismic source. Internal injuries tend to occur at received SPL of 220 dB µPa (which occurs at close range to the source) and auditory damage tends to occur at received SPL of 180 dB µPa (Turnpenny and Nedwell 1994). The pressure pulse is considered to be the most import contributor to tissue damage in fish.

Several key studies have been undertaken to assess the extent and type of injuries to fish eggs and larvae exposed to airguns. The results of these studies demonstrate that egg and larvae mortality and damage are highest at close range (within several meters of the airguns) and decrease rapidly with distance from the source. No physical effects were identified at distances of over 5 m from the source (Kostychenko 1973).

Residual Effects and Environmental Significance

Based on a review of the literature, it is expected that underwater sound generated by seismic activities will not exceed levels known to cause irreversible damage or death to fish (adults and eggs), except at close range (within approximately 10 m) to the source. Based on sound modelling results, peak sound pressure levels ($SPL_{0\ peak}$) for a single seismic pulse are predicted to exceed the injury threshold for fish (206 dB re 1 µPa) at distances up to 160 meters from the source. Multiple seismic pulses conducted over a 24-hour period revealed cSEL to exceed the injury threshold for fish > 2 grams (187 dB re 1 μPa^2s) at distances up to 1,950 meters offset from the survey line, and up to 4,950 meters from the survey line for fish < 2 grams (183 dB re 1 μPa^2s).

Sounds produced by the proposed seismic survey (100 to 1,000 Hz) coincide with the most sensitive frequency band of fish hearing. The potential for injury from seismic sound is thought to be minimal for Greenland halibut, given their status as hearing generalists and their preference for benthic habitat where sound effects would be less pronounced; however, they may exhibit behavioural responses (McCauley 1994). Polar cod and Arctic cod are more likely to be effected by seismic sound in the Qamut Block and surrounding area, as both species are hearing specialists and tend to occupy the upper to mid-water column. This is where sound effects would be greater due to the closer proximity to the sound source. As well, the frequency of seismic pulses fall in the peak hearing sensitivity for cod, at frequencies between 80 and 200 Hz with a sensitivity threshold of 80 to 100 dB re 1 µPa (Mitson 1995).

For all fish VECs in the Qamut Block and surrounding area, the magnitude of the effect of seismic sound was considered to be moderate because sound levels will likely exceed established thresholds for the onset of injury and behavioural changes. However, effects are not anticipated at the population level, as fish and ichthyoplankton (fish eggs and larvae) are generally widely distributed, and recovery, in terms of both diversity and abundance, occurs rapidly in response to localized impacts. Seismic sound impacts will be restricted to the LSA and will occur over the short-term (survey period) at a continuous frequency (assuming 24-hour shooting). The consequence of the effect of seismic sound on marine fish was thus determined to be minor for physical effects and moderate for behavioural effects for all fish VECs. With the application of mitigation (ramp-up), the probability for injury or mortality of fish was considered to be unlikely due to avoidance behaviour, and likely for behavioural effects, resulting in a low (2) and moderate (3) impact significance rating, respectively. In summary, effects will likely be limited to short-term behavioural responses (startle, displacement, and schooling behaviour), that will vary by species and hearing group, and will be dependent on the properties of the received sound. Table 6.3-1 summarizes the impact rating classifications and overall significance for the effects of seismic sound on marine fish.

Table 6.3-1 Summary of Impacts from Seismic Sound on Marine Invertebrates, Marine Fish, Seabirds, and Subsistence Hunting and Fishing

VEC	Potential Impact	Planned Mitigation	Impact Assessment Criteria				Consequence	Probability	Overall Significance
			Magnitude	Geographic Extent	Duration	Frequency			
Invertebrates	physical effects	Section 8.0 & Appendix I Table I-1	low	local	long-term	continuous	minor	unlikely	2 (low)
Marine Fish	physical effects	Section 8.0 (ramp-up procedures) & Appendix I Table I-1	moderate	local	long-term	continuous	minor	unlikely	2 (low)
	behavioural effects[(a)]		moderate	regional	short-term	continuous	moderate	likely	3 (moderate)
Seabirds	behavioural effects[(a)]	Section 8.0 (MMSO & PAM), Appendix I Table I-1 and Appendix J	negligible	local	short-term	continuous	negligible	rare	1 (negligible)
Subsistence Hunting and Fishing	declines/ species displacement	Section 8.0 & Appendix I Table I-1	moderate	regional	short-term	continuous	moderate	rare	1 (negligible)

(a) Includes displacement, avoidance and tolerance.

6.3.8 Marine Birds

Effects of Underwater Sound on Marine Birds

Limited experimental data has been collected on the reaction of birds to seismic operations. Based on studies available, it is generally assumed that seabirds are not sensitive to seismic surveys because they are able to avoid the seismic sound source (DCE 2011, Evans et.al. 1998, Lacroix et.al. 2003, Greene and Richardson 1988). Although some species dive underwater for prey, the majority of their time is spent on the water's surface or in flight, where they would not be affected by underwater seismic sound effects. Little information is known on the underwater hearing abilities of diving birds; however, it is likely limited to lower frequencies, and outside the ultrasonic range (DCE 2011). Diving birds may suffer damage to their ears if diving occurs very close to the airgun array. The presence of the seismic vessel itself will likely result in avoidance behaviour and therefore minimize this potential risk. Furthermore, the sensory cells of the inner ear in marine birds can regenerate following incidences of acoustic trauma causing hearing impairment, even after intense exposure (DCE 2011).

Residual Effects and Environmental Significance

The consequence of the effect was considered to be negligible based on a negligible magnitude impact (no measurable effects over baseline); restricted to the LSA and occurring over a short duration (survey period) and continuous frequency. The probability of the effect occurring was considered to be rare, resulting in a negligible (1) significance rating. Since the overall significance of the residual effect is negligible to marine birds, no further mitigation is required. Table 6.3-1 summarizes the impact rating classifications and overall significance for the effects of seismic sound on marine birds.

6.3.9 Commercial Fisheries

Effects of Underwater Sound on Commercial Fisheries

Seismic surveys may result in indirect effects on commercial fisheries in northeast Baffin Bay by potentially displacing or harming fish, and thus affecting catch rates.

Several studies have demonstrated that seismic operations can result in a reduction in fish catch rates. The results of these studies indicate that fish may avoid areas of seismic activities thereby affecting the catch rates of commercial fish species. It has been demonstrated that commercial fish species, including cod, tend to be displaced from fishing grounds when exposed to seismic sound. The extent of fish displacement is, however, considered to fall within the typical distance individual fish travel within their home range (Ryan 1979, Svendsen 1995, Arnold et al. 1994, Lokkeborg and Fernö 1999, Epseland et al. 2007) and vertically within the water column

(Arnold and Walker 1992, Godo and Michalsen 2000, Benoit et al. 2010). Recovery of pre-seismic catch levels have been demonstrated over a relatively short period of time (Lokkeborg 1991, Lokkeborg and Soldal 1993).

There is some evidence that exposure to seismic sound may drive some pelagic and demersal species to the seabed, rendering them more catchable by bottom trawling methods and thus having a positive effect on commercial fisheries (Lokkeborg 1991, Lokkeborg and Soldal 1993, Turnpenny and Nedwell 1994).

Residual Effects and Environmental Significance

There is presently no commercial fishery for any species in or near Qamut Block. Consequently, the effect of underwater sound on commercial fisheries in this region was not assessed during the EIA.

6.3.10 Subsistence Hunting and Fishing

Effects of Underwater Sound on Subsistence Hunting and Fishing

Seismic surveys can result in indirect effects on subsistence fisheries and hunting by potentially displacing fish and marine mammal species harvested by Greenlandic fishers and hunters. The Qamut Block and suurounding area does not overlap with traditional subsistence fishing areas, which mainly occur within coastal and fjord areas. The proposed seismic operations are therefore not anticipated to impact subsistence fishing activities in Northeast Baffin Bay.

In eastern Baffin Bay, belugas, narwhals, walruses, seal (ringed, harp, bearded and hooded), and polar bear are hunted at various times of the year (see Secton 4.3.3). The proposed entry date for the seismic operations is 01 August. The seismic program is predicted to take four to six weeks to complete. In Qaanaaq and Melville Bay, narwhals are caught in summer and hunters are restricted to using kayaks (boat hunting is not permitted in this region). The timing of the proposed seismic survey could overlap with the limited beluga and narwhal hunt that occurs in Melville Bay. The proposed seismic operations are not predicted to result in mortality or physical injury to marine mammals due to the proposed mitigation measures in place (see Appendix I and J). Airgun sound may; however, result in behavioural effects such as displacement of animals from traditional hunting grounds in Melville Bay.

Residual Effects and Environmental Significance

Due to spacing in time and location, no project sound effects are foreseen on local subsistence fishing as there is presently no subsistence fishing activities occurring in the Qamut Block. The environmental consequence of the effect of sound on subsistence fishing is considered negligible and the probability of this effect is rare, resulting in an overall impact significance rating of negligible (1).

The environmental consequence of underwater sound effects on subsistence hunting is considered minor (moderate magnitude, short-term duration, continuous frequency, and local geographic extent as sound will not travel outside the defined LSA at levels above the established NMFS behavioural threshold (160 dB re 1µPa rms). The probability of this effect occurring is considered unlikely based on a statistical review of historical catch rates as a function of seismic activity (see Appendix L), resulting in a low (2) impact significance rating. No adverse effects are expected on the ability of Greenlandic hunters to conduct subsistence hunts for beluga and narhwhal during the open-water season of 2012.

Table 6.3-1 summarizes the impact rating classifications for the effects of seismic sound on subsistence hunting and fishing.

6.3.11 Marine Mammals

The potential impacts of underwater sound to marine mammals depend, to a degree, on the type of marine mammal involved. The potential zone of impact of a man-made sound is also influenced strongly by the properties of ambient sound (Richardson et al. 1995). There is a large volume of literature concerned with the description of various impacts of underwater sound on marine mammals (McCauley 1994, Richardson et al. 1995, Davis et al. 1998, Gisiner 1998, Hildebrand 2005). Generally, these impacts are measured through observations of behavioural responses to sounds. These responses are used as a surrogate measure for sensitivity or susceptibility.

Extensive research efforts have been undertaken by the oil and gas industry, governments and other research institutions to understand the possible effects of seismic exploration activities on marine mammals (for a full review see Richardson et al. 1995, Gordon et al. 2004, Thompson 2000, Simmonds et al. 2004, Southall et al. 2007). A number of extensive reviews have drawn on limited experimental and observational data to indicate that additional studies are required. As the effects of seismic surveying on marine mammals are not fully understood, a precautionary approach is generally adopted for their protection, with mitigation measures aimed at preventing injury and minimizing the risk of biologically significant behavioural changes.

When considering the possibility for underwater sound to impact marine environments, the following factors were considered: 1) the species of interest must have a receptor system for detecting an sound signal; 2) for a sound signal to have a measurable effect on a receptor, the frequency content of that sound must overlap with the hearing range of the species of interest; 3) different types of sound (e.g. pulsed, intermittent, continuous) may have different effects; and 4) different effects may be elicited from an approaching sound source as compared to a stationary or departing sound source; and 5) the scale of the sound disturbance needs to be considered (e.g, number of sources, source levels, and duration of exposure).

6.3.11.1 Hearing Ability and Vocal Behaviour in Marine Mammals

Marine mammals are acoustically diverse, with wide variations in ear anatomy, frequency range, and amplitude sensitivity (Ketten 1991). An animal's sensitivity to sound varies with frequency. Response to sound likely depends strongly on the presence of and level of sounds in the frequency bands or range of frequencies to which the animal is most sensitive (Richardson et al. 1995). The general trend is that larger species, such as bowhead whales, tend to have better hearing sensitivities at lower frequency ranges than smaller species, such as belugas and narwhals. Hearing abilities are generally only well understood in certain captive species where audiograms (plots of hearing threshold at different sound frequencies) have been developed based on behavioural response studies (reactions to sound) and electrophysiological experiments (measuring auditory evoked potentials) (Erbe 2002).

Toothed Whales (Belugas and Narwhals)

The hearing abilities of belugas and narwhals at high frequencies are exceptionally well developed. This is likely related to their use of high frequency sounds for echolocation. Audible frequencies for toothed whales range from 80 Hz to 150 kHz, but they are most sensitive to sounds in the frequency range of 8 to 90 kHz (Richardson et al. 1995).

Belugas are considered 'mid-frequency cetaceans' (Southall et al. 2007); meaning their most sensitive hearing range occurs in the mid-frequency range. Using sound for foraging, navigation and social purposes, they are a highly vocal species with call types consisting of echolocation clicks, pulsed tones, whistles and noisy vocals. Echolocation clicks are produced in the 40 to 60 kHz and 100 to120 kHz range, with source levels reported at 206 to 225 dB re 1 µPa at 1 meter (Au 1993). Non-echolocation calls (e.g., whistles) are centered on frequencies below 6 kHz, but may sometimes attain frequencies up to 14 kHz (Schevill and Lawrence 1949, Sjare and Smith 1986), with dominant frequencies ranging between 400 Hz and 8.3 kHz. Belugas can detect frequencies as low as 40 to75 Hz; however their sensitivity at this range is quite poor (Awbrey et al. 1988). Beluga whales have been documented to communicate with one another at distances of over 300 to 500 meters (Bel'kovich and Shchekotov 1992).

No behavioural or electrophysiological audiograms are available for narwhals. Their vocalizations include echolocation clicks, pulsed tonal calls, and whistles. Narwhal echolocation sounds have been recorded at 40 kHz with source levels reported at 218 dB re 1 µPa at 1 meter (Mohl et al. 1990). Pulsed tones are produced in the 500 Hz to 5 kHz range and whistles have been reported in the 300 Hz to18 kHz range with dominant frequencies occurring at 300 Hz to10 kHz (Ford and Fisher 1978).

Baleen Whales (Bowhead Whales)

On a comparative basis, the baleen whale auditory system does not appear as specialized as that of toothed whales (Ketten 1997). Audiograms are not available for baleen whales due to the lack of these animals in captive settings which is required (based on current technology) in order to conduct behavioural and electrophysiological hearing studies. Hearing thresholds and frequency sensitivities in baleen whales are thus inferred from anatomical ear structure, vocalizations, and behavioural studies in the wild (Richardson et al. 1995). In general,

most baleen whale species have been shown to react to frequencies below 1 kHz (Richardson et al. 1995). They have an estimated auditory bandwidth of 7 Hz to 22 kHz (Southall et al. 2007).

Hearing in bowhead whales can be inferred indirectly by the frequency at which they vocalize and the levels of sound at which behavioural reactions occur. Bowhead whales have been shown to react to sound with dominant frequencies between 50 to 500 Hz (Richardson et al. 1995). Avoidance behaviour has been reported when bowheads were exposed to low broadband sounds of 90 dB re 1µPa (Richardson and Greene 1993). The majority of the sounds produced by bowhead whales are low frequency-modulated calls with reported frequency ranges of approximately 25 to 900 Hz (Ljungblad et al.1982, Clark and Johnson 1984, Cummings and Holliday 1987). Bowhead vocalizations include pulsive and tonal sounds, the latter either descending, ascending, constant, or inflecting in frequency (Clark and Johnson 1984). The duration of bowhead vocalizations range from short 0.5 second signals to long and melodic 4 to 5 second tones (Clark and Johnson 1984). Most single-note tones carry little sound energy above 400 Hz (Wursig and Clark 1993). Source levels from tonal moans and pulsive sounds range from 128 to 185 dB re 1 µPa at 1 m, with some vocalizations recorded by hydrophones up to 20 km away from calling whales (Clark et al. 1986).

Singing behaviour is considered to be an advanced form of vocalization in baleen whales (Clark 1991). Songs are composed of units, phrases, and themes; units sung in a sequence form phrases, a repetition of a phrase is a theme, and several themes combined create a song that can last several minutes (Payne and McVay 1971). Songs have been documented to change within and between seasons (Clark and Johnson 1984, Würsig and Clark 1993, Tervo et al. 2007).

Pinnipeds (Seals and Walrus)

Underwater hearing sensitivity in seals and walrus falls in between that of baleen and toothed whales with an estimated auditory bandwidth between 75 Hz and 75 kHz. Phocinid seals, such as the ringed and bearded seal, have underwater hearing thresholds between 60 and 85 dB re 1µPa, with flat audiograms between 1kHz and 30 to 50 kHz (Mohl 1968, Terhune and Ronald 1972, 1975, Terhune 1981). Some phocinids have been documented to be able to detect very high frequency sounds up to 180 kHz, although, their sensitivity to sounds above 60 kHz is poor and frequencies cannot be discriminated (Mohl 1968).

Ringed seal vocalizations include barks, clicks, and yelps, all of which occur in the 400 Hz to 16 kHz frequency range, with dominant frequencies concentrated above 5 kHz (Stirling 1973, Cummings et al. 1984). Source levels are between 95 and 130 dB re µPa, considerably lower in energy than other marine mammal vocalizations, and likely the reason why ringed seal vocalizations are generally only detectable within 1 km of the source (Cummings et al. 1984).

Bearded seals vocalize in the form of ‘songs’ that are presumed to be associated with territoriality and courtship (Ray et al. 1969, Budelsky 1993). Songs have been recorded at between 20 Hz and 6 kHz, with dominant frequencies occurring at 1 to 2 kHz, and source levels of 178 dB re 1µPa at 1 m (Ray et al 1969, Stirling et al 1983, Cummings et al. 1983). Unlike ringed seals, bearded seal vocalizations can be detected as far as 25 km from the source (Cleator et al. 1989).

Few studies have measured the audiogram of the walrus. In general, walrus have relatively sensitive hearing to low frequency sounds (Kastelein et al. 2002). A study of an 18-year-old captive walrus reported an optimal hearing range between 1kHz and 12 kHz, with maximum sensitivity (67 dB *re* 1 µPa) occurring at 12 kHz (Kastelein et al. 2002). Hearing sensitivity fell gradually below 1 kHz and dropped off sharply above 12 kHz (Kastelein et al. 2002). Walrus vocalizations include bell tones (male-specific), clicks, taps, knocks, rasps and grunts. The dominant frequencies of most vocalizations occur between 400 and 1200 Hz (Ray and Watkins 1975). Clicks and taps are produced in the 100 Hz to 10 kHz range, with dominant frequencies concentrated below 2 kHz. Rasps are produced in the 200 to 600 Hz range, with dominant frequencies occurring between 400 and 600 Hz. The dominant frequencies of grunts occur below 1 kHz (Scheville et al. 1966, Ray and Watkins 1975, Stirling et al. 1983). Vocalizations in walrus are typically associated with herd organization and coordination behaviour (Richardson et al. 1995).

Polar Bear

Little is known on underwater hearing abilities in polar bears. In-air hearing has been studied on captive subjects (using auditory evoked potentials to produce audiograms) demonstrating that polar bears can likely hear in-air at a slightly wider range of frequencies than humans (up to 25 kHz) and have absolute hearing thresholds below 27 to 30 dB re 20 μPa (Nachitgall et al. 2007).

6.3.11.2 Acoustic Impact Criteria

Standard injury and disturbance criteria are used to assess the potential for seismic survey sound to impact marine species. Assessment of the potential for seismic survey sound to impact marine mammals requires sound level thresholds against which received sound levels can be compared. The safety and disturbance sound threshold criteria currently applied to most Arctic marine seismic surveys in Canada and the United States are based on the rms SPL metric as adapted for impulsive sound sources (NMFS) (NMFS 1998). The safety threshold criterion for cetaceans is 180 dB re 1μPa (rms) and for pinnipeds is 190 dB re 1μPa (rms).

The National Marine Fisheries Services (NMFS) thresholds are intended to represent levels at which there is potential for auditory injury. Commonly, the 160 dB re 1μPa (rms) threshold has been used as a behavioural disturbance criterion for all marine mammals. Behavioural responses are not necessarily predictable from the level (loudness) of the sound source and may vary depending on factors such as age, status of the animal, type of activity it is engaged in, and social context (McCauley et al. 2000).

These criteria are understood to be conservative in terms of avoiding auditory injury to marine mammals and have been used throughout this assessment for determining potential for injury from exposure to single airgun pulses and from exposure to sound from the hydrographic survey. These criteria as they are expressed in rms pressure, they do not prevent exposure to high peak pressures (Madison 2005). They also do not take into account certain important attributes of the exposure such as duration, frequency, or repetition rate; nor do they account for the frequency-dependent hearing sensitivity of specific species. Sounds are less likely to disturb or injure animals if they are at frequencies where the animal has low hearing sensitivity. A recent panel report suggests that frequency dependence of hearing ability should be considered when establishing safety and disturbance sound threshold criteria (and corresponding safety radii) for seismic surveys (Southall et al. 2007).

In order to take into account the differential hearing capabilities of various groups of marine mammals, the M-weighting frequency weighting approach described by Miller et al. (2005) is commonly applied. M-weighting is similar to C-weighting (used for loud impulsive sounds on humans) in that it is a filtering system. M-weighting is used to present sound levels in a way that accounts for the hearing abilities of different marine mammals, by filtering out sound at frequencies outside of the most sensitive hearing ranges. The M-weighted levels characterize sound as it would be perceived by different animals. The M-weighting method accounts for sound frequencies extending above and below the most sensitive hearing range of marine mammals within each of five functional groups: low frequency cetaceans, mid-frequency cetaceans, high frequency cetaceans, and pinnipeds in water. The method to calculate M-weighting is provided in Appendix D.

Based on a review of available literature on marine mammal hearing and on the physiological and behavioural responses of marine mammals to man-made sound, Southall et al. (2007) have recently proposed alternative criteria for injury and behavioural disturbance in marine mammals. These alternative criteria are based on both peak pressure and sound exposure level metrics and take into account the type of sound (non-pulse, single-pulse, or multi-pulse), as well as the broad hearing capabilities of the marine mammals involved. These so-called "dual-criteria" are based on both the zero-to-peak SPL of the acoustic wave, expressed in dB re 1 μPa, and the total SEL, expressed in dB re 1 $\mu Pa^2 \cdot s$. A received sound exposure is assumed to cause injury if it exceeds either the peak SPL or the SEL criterion, or both.

For a multi-pulse source such as an airgun array, the injury criteria proposed were SPL: 230 dB_{peak} re 1 μPa (flat-weighted) for cetaceans, 218 dB_{peak} re 1 μPa (flat-weighted) for pinnipeds and SEL: 198 dB re. 1 μPa^2-s (M-weighted) for cetaceans, 186 dB re 1 μPa^2-s (M-weighted) for pinnipeds. A detailed description of the flat-weighted and M-weighted calculation methods used to determine injury criteria for cetaceans is provided in Appendix D.

The SEL criteria must take into account the cumulative effect of multiple exposures in the case of a multi-pulse sound source such as an airgun array. The cumulative effect of exposure to repeated airgun pulses is presented in the Cumulative Effects section of this report (Section 7.0). Southall et al. (2007) sum multiple exposures to produce a single exposure "equivalent" value by assuming that there is no recovery of hearing between sound pulse exposures.

In the case of a multi-pulse source such as an airgun, no single criterion for behavioural impacts was found to be suitable across multiple marine mammal groups. Instead, the likelihood of behavioural modification must be assessed for a given scenario based on available data for the type of sound source and the marine mammal species involved (Southall et al. 2007).

6.3.11.3 Seismic Airgun Survey

Seismic surveys introduce high-amplitude sound into the marine environment (200 to 250 dB re 1 µPa rms at 1 m) with the potential to impact large ocean areas for extended periods of time (Gordon et al. 2004). Most of the sound produced from seismic surveys consists of low frequency pulses at frequencies below 250 Hz with the strongest energies centered in the 10 to 120 Hz range (Goold and Fish 1998). However, it is acknowledged that the spectral distribution of sound from airgun arrays does extend to higher frequencies (>250 Hz) (Madsen et al. 2006, DeRuiter et al. 2007). For example, in the upper surface layer where sound velocity is often reduced (low velocity surface duct), some sound energy at the surface can exceed 500 Hz. (DeRuiter et al. 2007). These high frequency components contribute to the transient, direct-path, first arrivals of received airgun signals.

The acoustic modelling conducted during the EIA took emitted frequencies up to 2 kHz and 1/3-octave band sound levels for the airgun into account. Modelling was done over this frequency range. The high-frequency airgun transients are of short duration and low duty-cycle compared to the lower-frequency, reverberant part of the received signal (Madsen et al. 2006). Due to the short duration of the first arrival in the received signal, the authors concluded that the high-frequency transients are not likely to result in significant masking problems for mammals that are sensitive to high-frequencies. The dominant low frequency pulses emitted during seismic surveys fall below the sensitive hearing range for beluga and narwhal, but are within the sensitive hearing range for bowhead whales, seals, and walrus (Richardson et al. 1995). Possible effects from seismic sound on marine mammals include: physical effects (mortality, hearing impairment), behavioural effects (displacement, avoidance, tolerance), and acoustic masking. This section assesses the potential impacts of those effects to marine mammals.

Physical Effects

There is no direct evidence of sound from seismic surveys resulting in acute physical damage to marine mammals in their natural marine setting, with the possible exception of a report by Gary and Waerenbeek (2011) in which aberrant behaviour was observed in a single pantropical spotted dolphin in close proximity (600 m ahead of the airgun array) to 3D seismic explorations. Hearing impairment effects have only been documented under experimental conditions, and include: permanent hearing loss (known as permanent threshold shift, or PTS), and temporary hearing loss (known as temporary threshold shift, or TTS). TTS and PTS can potentially occur when marine mammals are exposed to high-amplitude impulsive sound (Goold and Coates 2006); with TTS demonstrated in certain captive toothed whales and pinnipeds exposed to loud sound sources (Southall et al. 2007). Prolonged or repeated exposure to sound levels sufficient to induce TTS without recovery time can lead to PTS (Southall et al. 2007). To date, there is no record of either of these effects occurring in marine mammals as a direct consequence of exposure to airgun pulses under natural field conditions.

TTS was observed in belugas after exposure to single pulses in the order of 186 dB re 1 μPa^2-s (SEL) and hearing returning to normal within several minutes of exposure. The study demonstrated that, for very short impulsive sounds, higher sound pressures may be required to induce TTS than for multiple pulsive sounds of longer duration.

TTS has been shown to occur in harbour porpoise at received peak levels above 200 dB re 1 µPa (SPL_{peak}) and sound exposure levels of 164 dB re 1 μPa^2-s, when exposed to 4 kHz signals (Lucke et al. 2008). These values were lower than those reported for other toothed whales (Finneran et al. 2002).

Little is known about the potential for seismic sounds to induce auditory trauma in baleen whales. If physical effects do occur, they would likely be limited to close ranges from the sound source (Richardson et al. 1995). Studies have suggested that higher sound levels may be needed to trigger TTS in baleen whales compared to toothed whales (Southall et al. 2007). Baleen whales are likely to avoid approaching airguns before being exposed to levels high enough for hearing impairment to occur, incidences of TTS or PTS in baleen whales are not expected during the Project.

In pinnipeds, TTS thresholds associated with exposure to brief pulses (single or multiple) of underwater sound have not been measured. Initial evidence from prolonged (non-pulse) sound exposure experiments suggest that some pinnipeds may incur TTS at lower received levels than small toothed whales exposed to similar prolonged non-pulse sounds (Kastak et al. 1999, 2005, Ketten et al. 2001). The TTS threshold for pulsed sounds has been indirectly estimated at an SEL of approximately 171 dB re 1 μPa^2 s (Southall et al. 2007), which would be equivalent to a single pulse with received level approximately 181 to 186 dB re 1 µPa (rms), or a series of pulses for which the highest rms values are a few dB lower.

There is limited information on the physical effects of seismic sound on walruses and polar bears. During the open-water season, both species occur in either pack-ice areas or remain close to shore. Project vessels will be avoiding both of these environments. Furthermore, walruses and polar bears are not expected to be encountered in the Qamut Block during the programs.

Behavioural Effects

The majority of studies conducted on the effects of seismic sound on marine mammals focus on behavioural responses (OSPAR 2011). A wide range of conclusions have been drawn from these studies, which has led to a general lack of consensus in the scientific community on the occurrence, scale and significance of such effects. The following section provides a brief summary on some of the main findings of studies observing the behavioural effects of seismic surveys on marine mammals.

Baleen whales

In general, baleen whales are thought to be the most reactive to airgun sound because they hear well in the low frequency range (Richardson et al. 1995). Baleen whales have been shown to avoid active seismic operations, and have been reported to move away, stay close to the surface, or change their orientation when exposed to seismic sound sources (Richardson et al. 1986). Studies of bowhead, humpback, and gray whales have demonstrated that seismic pulses with received levels of 160 to 170 dB re 1 µPa (rms) seem to elicit avoidance behaviour in the majority of animals exposed (Richardson et al. 1995). Low received sound levels can have subtle effects on surfacing and respiration patterns (Richardson et al. 1986, Koski and Johnson 1987, Ljungblad et al. 1988, Malme et al. 1988, Richardson 1998, Brownell 2004, Gordon et a. 2004). However, under certain circumstances, baleen whales have also been shown to be quite tolerant of low- and moderate-level acoustic pulses from distant seismic surveys (Reeves et al. 1984, Koski and Johnson 1987, Richardson and Malme 1993). Grey whales and bowheads have been shown to continue their normal activities when exposed to pulses at received levels as high as 150 dB re 1 µPa (Richardson et al. 1995). Male humpback whales have demonstrated either toleration or attraction to seismic sources while female humpback whales, by contrast, have shown avoidance behaviour in response to seismic sound (McCauley et al. 2000).

For bowheads in particular behavioural responses are shown to be quite variable and appear to be dependent of the type of activity the whale is engaged in (e.g. foraging vs. migrating). During migratory movements in the Alaskan Beaufort, individual bowheads have demonstrated avoidance behaviour up to 30 km distance from seismic vessels where levels can be up to130 dB re 1 µPa (rms) (Miller et al. 1999, Richardson et al. 1999). During the summer feeding season, bowhead whales appear to be less sensitive to seismic sound, showing no obvious reactions to seismic pulses at distances of 6 to 99 km where sound levels can be up to 107 dB (rms) (Richardson et al. 1986, Miller et al. 2005, Harris et al. 2007). It has been suggested that whales may be tolerant to such increased sound levels due to prioritized foraging requirements (Beale and Monoghan 2004. Baleen whales only demonstrate avoidance behaviour during feeding when sound levels reach up to 178 dB re 1 µPa (rms) (Ljungblad et al. 1988, Richardson et al. 1995, Miller et al. 2005). Bowhead whales in Alaska have also demonstrated tolerance / habituation to seismic activities over extended time scales, with individual whales observed regularly in traditional summering areas despite ongoing exposure to underwater pulsive sound from nearby seismic operations (Richardson et al. 1986, 1987a). Bowhead whales continue to use

the same westward migration corridor through the Beaufort Sea each fall, despite recurring annual seismic operations in this region which coincide with the fall migration period (Miller at al. 1991).

Toothed Whales

Toothed whales seem to adopt different strategies for responding to sound disturbances from seismic surveys (Stone 2003). Some toothed whales have been shown to respond to seismic surveys at considerable ranges (Bowles et al. 1994, Mate et al. 1994). In contrast, several studies have indicated that toothed whales exhibit tolerance behavior (limited response) in response to seismic sound and are not excluded from habitat areas by active seismic surveys (Rankin and Evans 1998, Swift 1998). Rankin and Evans (1998) could not demonstrate that seismic surveys had a negative impact on large-scale distribution of delphinids in the Gulf of Mexico. Swift (1998) conducted acoustic monitoring to determine the relative abundance and distribution of sperm whales before, during, and after a three week seismic survey west of Scotland. Acoustic detection rates were actually higher during the seismic survey period than the weeks before or after the survey. Swift (1998) also found no significant difference in detection rates between 'shooting' and 'non-shooting' periods during the seismic survey itself, suggesting a lack of short-term responses. Madsen et al. (2002) studied the acoustic behaviour of sperm whales in an offshore canyon located in arctic waters (northern Norway) in response to a distant seismic survey. Results demonstrated no changes in vocal activity in response to airgun pulses and no evidence of displacement was observed, as reported by local whale watch operators. Similarly, Stone (1998, 2000) reported that sperm whales sighting rates did not differ significantly as a function of seismic surveys.

Sperm whales in the Gulf of Mexico have been exposed to seismic surveys for many years; visual surveys (Gordon et al. 2006) and satellite tagging studies (Winsor and Mate 2006) have not been able to detect changes in the animals' behaviour. Preliminary conclusions from recent controlled exposure experiments with tagged animals have suggested possible responses to sound exposure in terms of foraging activities (Miller et al. 2006). The same authors found that during exposure, one animal stayed at the surface for an unusual amount of time, and they interpreted that behaviour as potential vertical avoidance (Miller et al. 2006). While most whales in their study continued their normal dive patterns, a behavioural response was inferred from the reduced fluke pitch and vocalisation buzz rates during the dive. However, the animals showed no avoidance behaviour in a 1 to 13 km range from the sound source at received levels of 152 to 162 dB (peak to peak) re 1 µPa (equivalent to 147 dB (rms) re 1 µPa or 115 to 135 dB re 1 μPa^2s). Miller et al. (2006) suggested that the 'observed' foraging might have been related to behavioural reactions of the sperm whale prey to airgun sound, or may simply be an artefact of the habituation of these animals to seismic surveys.

Another study by Gordon et al. (1998) in inshore waters around Orkney, UK, reported on both experimental exposures of harbour porpoises to a small seismic source (approximatley 228 dB re: 1 µPa zero-to-peak@ 1 m), and on harbor porpoise detection rates made during commercial seismic surveys. No changes in the rate of sound contact were observed during two hour periods before, during, and after the controlled exposure, and harbor porpoises were not shown to be excluded from an area of preferred habitat after short-term exposure to the seismic source. Acoustic monitoring of porpoises was also conducted during full-scale seismic surveys near Shetland (Gordon et al. 1988), in which no significant differences in sound detection rates for porpoises were observed between 'shooting' and 'non-shooting' periods (acoustic monitoring equipment was deployed approximately 1.6 km from the source on a seismic support vessel). Stone and Tasker (2006) reported sighting rates of white-sided dolphins and white-beaked dolphins that were significantly lower during periods of shooting compared with non-shooting periods on surveys with large airgun arrays. However, throughout the course of surveys, sighting rates were not found to differ significantly, indicating that any behavioural responses were short-term in nature.

Belugas are one of the few toothed whale species that seem to be reactive to airgun sound, having demonstrated large-scale displacement behaviour from active seismic operations (Richardson et al. 1995). Aerial surveys conducted in the Beaufort Sea during the summer have shown that sighting rates of beluga whales were significantly lower within 20 to 30 km from an operating airgun array (Miller et al. 2005, Harris et al. 2007). Information on the behavioural responses of narwhals to seismic sound is limited, although it is suggested that they share similarities to belugas in terms of responsiveness to sound (Richardson et al. 1995).

Seals, Walrus and Polar Bear

Very little information exists on the reactions of pinnipeds to sounds from seismic exploration in open water, although it is generally understood that pinnipeds are unlikely to exhibit an avoidance reaction to seismic sound (Richardson et al. 1995). Seals are often sighted at close ranges by observers on seismic vessels, with only minor changes in behaviour observed during seismic operations, and little to no avoidance of active airguns. Visual monitoring from seismic vessels in the Beaufort Sea reported that some ringed seals demonstrate avoidance behaviour up to 100 m from an active seismic vessel, however others remained within 100 to 200 m of the sound source during active shooting (Harris et al. 2001, Moulton and Lawson 2002, Miller et al. 2005).

During controlled exposure experiments, harbour seals and grey seals exposed to airgun pulses (source levels of 215 to 224 dB re 1 µPa; peak to peak) exhibited strong avoidance reactions and immediate, but short-term, startle responses to the initial airgun pulses (Thompson et al. 1998). However, the behaviour of all harbour seals seemed to return to normal soon after the end of each trial, even in areas where disturbance occurred on several consecutive days. Only one harbour seal showed no detectable response to the airguns and approached to within 300 m of the source (Thompson et al. 1998). Avoidance behavior was observed during all trials with grey seals, in which individuals switched from foraging dives to v-shaped transiting dives, and moved away from the source, increased swim speed, and/or dive duration. Excluding two seals which hauled out after testing, those that remained in the water seemed to have returned to pre-trial behaviour within two hours of the end of the experiment (Thompson et al. 1998). In a separate report by Greene et al. (1985), gray seals exposed to sound from airguns showed no strong reaction. No changes in sighting rates of ringed seals were observed between periods with a full array firing, a partial array firing, and no guns firing (Harris et al. 2001). Mean radial distance to the seals observed did increase during full array operations, suggesting some local avoidance.

Seals have also demonstrated considerable tolerance and habituation to very high levels (220 dB re 1 µPa; peak Myrick et al. 1990b) of underwater sound pulses from nonexplosive and explosive scaring devices, with avoidance behaviour waning quickly after repeated exposure (Mate and Harvey 1987). It is thus expected that seals would be rather tolerant of, or habituate to, repeated underwater pulsive sound from distant seismic sources, particularly when these animals are strongly attracted to an area (Richardson et al. 1995).

There is limited information on the behavioural effects of seismic operations on walruses and polar bears. As stated previously, effects on both species are considered to be unlikely due to limited time these animals spend in the water during this time and the limited use by the animals in the Qamut Block.

Acoustic Masking

Auditory masking occurs when sound signals used by marine mammals (e.g. echolocation, communication, and environmental cues) overlap in time and frequency with another sound source, such as seismic sound (Richardson et al. 1995). If little or no overlap occurs, communication is not expected to be disrupted (Abgrall et al. 2008). In the case of seismic surveys, the potential masking acoustic (airgun sound) consists of pulsive sounds with a low duty cycle (repetition rate relative to background sound). Most energy in seismic sound sources is emitted at low frequencies, with strongest spectrum levels below 100 Hz and only limited energy emitted up to approximately 150 kHz (Abgrall et al. 2008). Based on optimal hearing ranges, baleen whales are most susceptible to masking effects from low frequency seismic sources, particularly because low frequency sounds have the potential to transmit long distances and potentially affect large geographic areas (Erbe and Farmer 2000, Gordon et al. 2004). Odontocetes have reduced low frequency hearing and they vocalize at higher frequencies so masking for those species is expected to be less important.

Davis et al. (1998) considered the effect of masking from seismic operations to be of little significance to marine mammals due to the low cycle rate of seismic pulses relative to continuous sounds, such as ship sound. In addition, audibility between pulses does not seem to be compromised when marine mammals are exposed to pulsive sound sources such as seismic sounds (Abgrall 2008). However, sound levels after each airgun pulse are unlikely to return fully to background levels prior to the arrival of the subsequent airgun pulse due to reverberation effects (Koski et al. 2011). Reverberation signals are caused by sound energy that reflects multiple times from the seabed and sea surface, and from sound that is scattered non-specularly from rough bottoms. Reverberation is less significant for steep sound propagation angles experienced close to the source. Reverberation increases and results in longer pulse duration with distance from the source, although the overall sound levels also decrease with distance. Masking can occur if those levels are above background level and above the audible

threshold of marine mammals. It is likely that reverberated sound levels will be above audible thresholds to baleen whales over large distances. Bowhead whale vocalizations have been recorded between airgun pulses during active seismic operations (Green et al. 1999), with vocal activity emitted at a slightly slower rate than observed during non-seismic events (Richardson et al. 1986). Similarly, a recent study by Blackwell et al. (unpublished) showed that bowhead vocalizations decreased with exposures to relatively low sound levels, however, no corresponding changes to bowhead migration patterns were observed. The airgun operations during that study occurred within a relatively narrow bowhead migration corridor of approximately 30 km width. The ConocoPhillips operations will occur in a region with substantially lower bowhead densities.

The frequencies contained in seismic pulses are within the audible range of pinnipeds and walrus, and therefore have the potential to interfere with their communication capabilities. Sound levels during pulse intervals may also exceed background levels and the audible threshold of both pinnipeds and walrus due to reverberation effects (Koski et al. 2011) thus also potentially contributing to acoustic masking."

Proposed Mitigation and Best Practices

In order to minimize the potential physical impacts to marine mammals as a result of seismic survey sound, specific vessel-based mitigation measures and best practices have been developed for the seismic survey program, as summarized in Appendix I and detailed in Appendix J.

Residual Effects and Environmental Significance

Physical Effects

Effects from hearing impairment (PTS and TTS) to marine mammals as a result of airgun sound were assessed. Based on sound modeling results (Appendix D), and NMFS exposure criteria for impulsive sounds, the onset of injury for cetaceans and pinnipeds was predicted to occur at 710 meter ($R_{95\%}$) and 210 m ($R_{95\%}$), offset from the survey line, respectively. This exceeds the marine mammal safety zone radii recommended by JNCC guidelines (JNCC 2010). An 800 meter marine mammal safety zone (offset from the survey line) is thus recommended for the proposed seismic operations, based on the NMFS injury criterion for ceteaceans (180 dB re 1 µPa rms), the more conservative of the two established NMFS injury criteria.

Specific vessel-based mitigation actions (discussed in Section 8.0, Appendix I and Appendix J) will be triggered if marine mammals are observed within the safety zone. With the extended safety zone in place, marine mammals outside the 800 meter safety zone are presumed not to be exposed to harmful levels of sound. The environmental consequence of this effect is thus considered to be minor for baleen whales, toothed whales, pinnipeds and walrus (low magnitude, local effect, long-term duration, continuous frequency), and negligible for polar bears. The probability of airgun sound resulting in physical effects on marine mammals is considered rare given the proposed mitigation, resulting in a negligible (1) overall significance rating for all marine mammal VECs.

Behavioural Effects

Potential behavioural effects in marine mammals from seismic sound are assessed in this section. Table 6.3-2 summarizes the impact ratings classifications for the effects of seismic sound on marine mammals.

NMFS currently uses a criterion of 160 dB re 1 µPa (rms) as the onset of behavioural disturbance in marine mammals. Acoustic modeling results indicate that underwater sound from seismic pulses will exceed the NMFS behavioural threshold for marine mammals (160 dB re 1 µPa (rms) – impulsive) at distances up to 7.7 km from the source (offset of the survey line). ConocoPhillips will implement a marine mammal safety zone of 800 m while completing their operations.

Table 6.3-2 Summary of Impacts from Seismic Sound on Marine Mammals

VEC	Potential Impact	Planned Mitigation	Impact Assessment Criteria				Consequence	Probability	Overall Significance
			Magnitude	Geographic Extent	Duration	Frequency			
Toothed Whales (Beluga and Narhwal)	physical effects	Mitigation for physical effects only – see Section 8.0 (MMSO and PAM), Appendix I Table I-1 and Appendix J	low	local	long-term	continuous	minor	rare	1 (negligible)
	behavioural effects[(a)]		moderate	local	short-term	continuous	minor	likely	2 (low)
	masking		moderate	local	short-term	continuous	minor	unlikely	2 (low)
Baleen Whales (Bowhead Whales)	physical effects		low	local	long-term	continuous	minor	rare	1 (negligible)
	behavioural effects[(a)]		moderate	local	short-term	continuous	minor	unlikely	2 (low)
	masking		moderate	regional	short-term	continuous	moderate	unlikely	2 (low)
Pinnipeds and Walrus	physical effects		low	local	long-term	continuous	minor	rare	1 (negligible)
	behavioural effects[(a)]		moderate	local	short-term	continuous	minor	likely for pinnipeds; unlikely for walrus	2 (low)
	masking		moderate	regional	short-term	continuous	moderate	likely for pinnipeds; unlikely for walrus	moderate (3) for pinnipeds; low (2) for walrus
Polar Bears	physical effects		negligible	local	long-term	continuous	negligible	rare	1 (negligible)
	behavioural effects[(a)]		negligible	local	short-term	continuous	negligible	unlikely	1 (negligible)

[(a)] Includes displacement, avoidance and tolerance.

The effect of seismic sound on bowhead behaviour is considered to be of moderate magnitude as the NMFS behavioural threshold criteria will be exceeded, however no population level effects are anticipated and no disruption of critical activities are anticipated (no critical areas for bowhead whales are present in the Qamut Block and surrounding area). This effect is considered to be limited to the LSA, short-term in duration, and of continuous frequency as airguns will be firing throughout the survey period. The environmental consequence is thus considered to be minor. Because bowhead whales are not likely to be in Baffin Bay during the open-water seismic period, the probability of behavioural changes occurring are predicted to be unlikely, resulting in a low (2) overall impact significance rating.

The effect of seismic sound on narwhal and beluga behaviour is considered to be of moderate magnitude as the NMFS behavioural threshold criteria for cetaceans will be exceeded, although most of the sound energy will be emitted outside the sensitive hearing range for both species (Richardson et al. 1995, Gordon et al. 2004) and therefore no severe disruption of critical activities is anticipated. . This effect is considered to be limited to the LSA, short-term in duration, and of continuous frequency as airguns will be firing throughout the survey period. The environmental consequence of this effect is thus considered to be minor. The probability of behavioural effects in toothed whales (narwhal and beluga) occurring from seismic sound is predicted to be likely, as the Qamut Block overlaps with a designated narwhal protection zone during summer (NPZ-I) and therefore narwhal are anticipated to be in this area during the seismic program. The overall impact significance rating for behavioural effects from seismic sound on narwhal and beluga is predicted to be low (2).

The effects of seismic sound on pinnipeds and walrus behaviour is considered to be of moderate magnitude as the NMFS behavioural threshold will be exceeded. No population level effects and no disruption of critical activities are expected since no critical areas for seals are present in the Qamut Block during the survey period and no walrus summering grounds are present within or near the Qamut Block either. This effect is considered to be limited to the LSA, short-term in duration (45 day program + 15 days contingency) and of continuous frequency as airgun operations will be continuous. The environmental consequence of this effect is considered to be minor. Seals will likely be present in the Qamut Block during the active survey program; however, walrus are likely to be outside the Qamut Block area at their summer herding grounds. The probability of this effect is considered to be likely for seals and unlikely for walrus, resulting in a low (2) overall significance rating for both pinnipeds and walrus.

Because the natural behavioural tendencies of polar bears (e.g. remaining on the ice, at the water surface, or on land) greatly reduces their exposure to underwater sounds, the effects of seismic sound on polar whale

behaviour is considered to have a negligible environmental consequences and a rare probability of occurrence, resulting in a negligible (1) overall significance rating.

Acoustic Masking

The potential masking effects of pulsed sounds on beluga and narwhal calls are predicted to be limited, as both species typically communicate at frequencies outside the dominant bandwidth of seismic survey sound. Furthermore, both species may be able to emit and receive sounds between airgun pulses (Davis et al. 1985, Abgrall et al. 2008). The environmental consequence of masking effects of beluga and narwhal communication is considered to be minor (moderate magnitude, short-term duration, continuous frequency, and local geographic extent), with an unlikely probability of occurrence (as communication frequencies are likely not masked by seismic sound), resulting in a low (2) impact significance rating (Table 6.3-2).

The frequencies emitted by seismic pulses overlap with the communication frequencies used by bowhead whales, pinnipeds, and walrus. Although the cumulative seismic sounds are pulsive, sound levels due to reverberation after each airgun pulse are likely to be above background sound levels, as well as above the audible threshold for these animals over large distances and thus capable of masking their communication (Blackwell et al. unpublished, Koski et al. 2011). The environmental consequence of masking effects on bowhead, walrus, and pinniped communication is thus considered to be moderate, given the impact will be short in duration, continuous in frequency, moderate in magnitude, and regional in geographic extent (masking effects may extend outside the LSA + 10 km buffer zone). The probability of this effect is considered likely for pinnipeds and unlikely for bowheads and walrus, as the latter are not likely to be in Baffin Bay during the open-water season when the seismic programs will be taking place. The resulting impact significance rating for masking effects is therefore assessed as low (2) for bowheads and walrus, and moderate (3) for pinnipeds (Table 6.3-2).

6.3.11.4 Project Vessel Sound

In general, the source level of ship sound increases with ship size, speed, propeller blade size, number of blades, and rotations per minute (Gray and Greeley 1980). The largest component of ship sound comes from propeller cavitations, propeller singing, propulsion and other onboard machinery (Richardson et al. 1995). Broadband source levels specific to the Project vessels are unknown. However, broadband source levels of 170 to 180 dB re 1 µPa at 1 m have been reported for similar size vessels (length 55 to 85 m, diesel, 2 propellers with 4 blades, diameter of 3 m and turn at approximately 160 rpm).

Physical Effects

There is no direct evidence of either PTS or TTS occurring in marine mammals as a consequence of exposure to vessel-generated sound. Underwater sound from shipping generally ranges from 10 Hz to 1 kHz and tends to dominate ambient sound at frequencies from 20 Hz to 300 Hz (Richardson et al. 1995). Above 300 Hz, shipping sounds may or may not be significant depending on the level of wind-dependant ambient sound (Richardson et al. 2005). Most of the sound energy emitted by medium- and large-sized ships such as the seismic and support vessels tends to be concentrated in the low-frequency band, below 1 kHz (OSPAR 2009). The optimal hearing range for toothed whales typically occurs between 1 kHz and 100 kHz; whereas baleen whales (such as bowhead whales) and pinnipeds have better hearing in the lower frequency range: (7 Hz to 22 k Hz for baleen whales and 75 Hz to 75 kHz for pinnipeds) (Richardson et al. 1995, Southall et al. 2007). Expected frequencies from Project vessel sound are therefore more likely to overlap with the functional hearing range of baleen whales and pinnipeds than with toothed whales.

Behavioural Effects and Acoustic Masking

Research has demonstrated that vessel sound can influence physical behaviour of marine mammals and potentially result in masking of their communication space (Richardson et al. 1995). Acoustic responses to vessel sound include alteration of the composition of call types, the rates and duration of call production, and the actual acoustic structure of the calls. Types of behaviour influenced include respiration rates, dive patterns, and swim velocities. These adjustments have, in certain cases, been correlated with numbers of vessels and their proximity, speed, and directional changes. Responses have been shown to vary by gender and by individual. Many toothed whales show considerable tolerance of ship traffic. There is no available evidence of toothed whales permanently abandoning parts of their historical range because of vessel traffic (full review in Richardson et al. 1995 and Gordon et al. 2004).

Toothed whale reactions to vessels range from great tolerance to extreme sensitivity, depending on whale activities and experience, habitat, boat type, and boat behaviour (Richardson et al. 1995). Belugas have been shown to engage in avoidance or escape behaviour when exposed to fast and erratically moving small boats or when directly approached by a vessel (Fraker 1977a, 1977b, 1978). Acute behavioural reactions have also been observed in narwhals and belugas in response to early season icebreaker activity in the Canadian High Arctic (LGL and Greenridge 1986, Finley et al. 1990). Narwhals were shown to exhibit “freeze / silent” behaviour rather than the “flight / alarm” response observed in belugas when exposed to the icebreaking sound. Some evidence of narwhal displacement (~80 km) was also observed when animals were exposed to low levels of sound (94 to 105 dB re 1 µPa) in the 20 to 1000 Hz band, although individuals were shown to return several days later during periods when icebreaker sound levels were even higher (120 dB re 1 µPa) and in the same frequency band (Finley et al. 1990), suggesting potential tolerance or habituation to these sound sources.

Other studies have demonstrated that belugas do not always exhibit avoidance behaviour; in certain circumstances, examples of apparent long-term and seasonal habituation to vessel sound are evident in belugas (Fish and Vania 1971, Frost et al. 1984). Belugas have been shown to be rather tolerant of the frequent passages of large ships traveling in consistent directions in summering ground areas such as the St. Lawrence River (Canada), Cook Inlet (Alaska), and the Beaufort Sea (Fraker 1977b, Macfarlane 1981, Sergeant 1981, 1986, Burns and Seaman 1985, Pippard 1985). Belugas have shown declining vessel avoidance responses and increasing interactive behaviour (approaching vessels) in the St. Lawrence estuary (Blane 1990). Belugas that are hunted from small power boats in traditional gathering areas return each summer even though hunting causes short-term displacement and may change local distribution (Fraker 1980, Reeves and Mitchell 1981, Seaman and Burns 1981, Burns and Seaman 1985, Caron and Smith 1990). Belugas have also been shown to return to annual breeding locations in Northern Quebec even if overhunted (Finley 1982, Finley et al. 1982). The West Hudson Bay population returns annually to the port of Churchill annually despite a harvest of approximately 500 whales per summer (Sergeant 1981). Evidence of tolerance to vessel sound is commonly observed in other toothed whales such as dolphins and porpoises, either by a lack of avoidance behaviour to vessels (Duncan 1985), or by means of active interaction with vessels such as bow riding (Shane et al. 1986, Williams et al. 1992). When avoidance behaviour is observed by toothed whales, it is most commonly in response to vessels of types used to hunt these animals (Richardson et al. 1995). Temporary displacement may result, but there is no evidence of toothed whales abandoning significant parts of their range because of vessel traffic and associated sound (Richardson et al. 1995).

Reactions of baleen whales to vessels also vary considerably (Richardson et al. 1995). Lower frequency (10 to 100 Hz) sounds have been shown to be more influential on behaviour (Frankel and Clark 1998, 2000 and 2002). When receiving low-level sounds from distant or stationary ships, baleen whales both ignore and approach the sounds. If ships approach baleen whales slowly and non-aggressively, baleen whales often exhibit slow and inconspicuous avoidance manoeuvres. In response to strong or rapidly changing ship sound, baleen whales often interrupt their normal behaviour and swim rapidly away. Avoidance is especially strong when a boat heads directly toward a whale (Richardson et al. 1995).

Several cases of apparent tolerance and habituation to vessels have been reported in baleen whales (Norris et al. 1983, Withrow 1983, Dahlheim et al. 1984, Richardson et al. 1995). Low-level sounds from distant or stationary vessels often seem to be ignored by animals, particularly when feeding (Richardson et al. 1995). Baleen whales use shipping lanes in the St. Lawrence estuary and off Cape Cod each year despite frequent exposure to vessels (Mitchell and Ghanime 1982, Beach and Winrich 1989). Vessels in grey whale breeding lagoons have been shown to cause short-term escape reactions, particularly when boats move fast or eratically; however, the proportional incidence of escape / avoidance behaviour has been shown to decrease over the course of the winter, suggesting habituation (Reeves 1977, Swartz and Cummings 1978, Swartz and Jones 1981). Jones and Swartz (1984, 1986) found no evidence of grey whales leaving a lagoon despite increased vessel presence. Shipping and evaporative salt works in Guerrero Negro Lagoon reportedly caused grey whales to abandon the lagoon for several years, although the whales returned after shipping decreased (Reeves 1977, Bryant et al. 1984). Hatler and Darling (1974) reported that grey whales in British Columbia return annually to traditional summer feeding areas despite co-occurrence of high vessel traffic in these regions. Individually recognizable bowheads have been shown to return to feeding locations within one day after being displaced by vessels and associated sound (Koski and Johnson 1987), although it was unknown if they would return after repeated disturbance. A radio-tagged bowhead whale exhibited reduced dive times when approached by a small ship on each of three days when the ship was within 500 m of the whale. However, dive patterns were shown to

revert back to normal in the days following ship disturbance, and the whale remained in the same area for several days while the ship continued operating (Wartzok et al. 1989). Some humpbacks in Alaska show little or no reaction of approaching vessels (Watkins et al. 1981), with animals less likely to react overtly when actively feeding than when resting or engaged in other activities (Krieger and Wing 1984, 1986). In southeastern Alaska, vessel activity was observed to elicit short-term avoidance behaviour, although some humpbacks still remained for several weeks in areas of heavy vessel traffic, and returned to the same area in subsequent years (Baker et al. 1988, 1992). The most extensive data are from summer feeding grounds off Cape Cod, where humpback whales have been shown to spend extended periods in high traffic areas, and return there annually despite frequent exposure to vessel activity (Watkins 1986, Beach and Weinrick 1989, Clapham et al. 1993).

Proposed Mitigation and Best Practices

A list of mitigation measures for managing the effects of vessel sound on marine mammals is provided in the EPP (Section 8.0) and Appendix J. A summary is provided below:

- Project vessels shall regularly maintain propellers to minimize propeller cavitations.
- Project vessels shall avoid rapid acceleration (which causes increases in underwater sound).
- Project vessels shall keep speeds to as low as practical as ship-based sound typically increases with ship speed (Fischer and Brown 2005).
- As safe navigation allows, vessel operators shall take every precaution to avoid harassment of marine mammals by means of the following;
  - Under no circumstances, other than in the case of an emergency, will a Project vessel approach within 300 m of a walrus or polar bear observed on glacial or sea ice.
  - Project vessels shall also maintain a minimum distance of 300 m from marine mammals engaged in feeding activities.
  - For all other marine mammal encounter situations, vessels will not approach or be positioned closer than 100 m to a marine mammal.
  - If marine mammals approach within 100 m of a Project vessel, the Project vessel shall reduce its speed and, if safe to do so, will cautiously move away from the animal(s).
  - If it is not possible for the vessels to move away from or detour around a stationary marine mammal or group of marine mammals, the vessel shall wait until the animals depart the area and are at least 100 m from the vessel prior to resuming operational speed.
  - The vessel shall not be operated in such a way as to separate an individual member(s) of a group of marine mammals from other members of the group. When weather conditions require, such as when visibility decreases, the vessel shall adjust its speed accordingly to avoid the likelihood of ship strikes.

Residual Effects and Environmental Significance

Effects of underwater sound from vessel engines, propellers and other on-board activities on marine mammals are assessed in this section (Table 6.3-4). Bowhead whales were identified as a VEC for the Project as their presence in Greenlandic waters is well documented (DCE 2011). However, results from this effects assessment, and the proposed mitigation for this species, are applicable to all other baleen whales potentially occurring in the Project area during the open-water season.

Underwater sound from Project vessels is not predicted to exceed the injury threshold for pinnipeds or cetaceans. ConocoPhillips operations will avoid protected and critical areas therefore, the effects of Project vessel sounds on marine mammal behaviour and acoustic masking is predicted to be of moderate magnitude.

The magnitude of the effect of vessel sounds on marine mammals is considered to be low with respect to physical effects. NMFS threshold criteria for behavioural disturbance would be exceeded, but effects at the population level are not anticipated. The geographic extent was considered to be regional as the potential for vessel sound effects would exist as vessels move outside the LSA towards shipping channels, when in transit to and from local port facilities. The duration of vessel sound is considered long-term with regards to physical effects

and short-term with regards to behavioural effects and acoustic masking (only present during the Project life, 45 days + 15 days contingency).

The potential for effects from vessel sound to result in physical effects on marine mammals was considered be of minor environmental consequence and a rare probability of occurrence, resulting in a negligible overall significance rating for all marine mammal VECs. The potential for vessel sound to result in behavioural effects and acoustic masking is considered to be of moderate environmental consequence for baleen whales, toothed whales, pinnipeds and walruses; and a negligible consequence for polar bears. The probability of this effect occurring is considered rare in polar bears and baleen whales (e.g. bowhead whales), and unlikely for all other marine mammal VECs. The overall significance rating of this effect is predicted to be negligible (1) for baleen whales and polar bears; and low (2) for toothed whales, seals and walruses.

Based on results from the literature, marine mammals will either habituate to vessel sounds generated during the Project and remain in the Qamut Block, or leave the Qamut Block temporalily and return once the seismic program is completed. No significant effects at the population level are anticipated. Table 6.3-3 summarizes the impact rating classifications and overall significance for the effects of vessel sounds on marine mammals.

Table 6.3-3 Summary of Impacts from Vessel Sounds on Marine Mammals

VEC	Potential Impact	Planned Mitigation	Impact Assessment Criteria				Consequence	Probability	Overall Significance
			Magnitude	Geographic Extent	Duration	Frequency			
Toothed Whales (Beluga and Narhwal)	physical effect	Section 8.0 (MMSO and PAM), Appendix I Table I-1 and Appendix J	low	regional	long-term	continuous	minor	rare	1 (negligible)
	behavioural effects[(a)]		moderate	regional	short-term	continuous	moderate	unlikely	2 (low)

	behavioural effects[(a)]		negligible	regional	short-term	continuous	negligible	rare	1 (negligible)

(a) Includes displacement, avoidance and tolerance.

6.4 Effects of Vessel Traffic

The impact of vessel traffic related to the Project on marine mammals, commercial fisheries, subsistence fishing and hunting, tourism, and to some extent, other shipping, is assessed in this section. All impacts from more ship traffic in Qamut Block due to the seismic survey are “negligible”.

Marine Mammals

It is possible that more ship strikes involving marine mammals will occur in 2012 because of increased vessel traffic related to the Project in the Qamut Block or during passage to or from the licence area. Studies indicate that maritime activity may have adverse effects on marine mammals due to ship strikes. (Moore and Clarke 2002, Laist et al. 2001). These effects include mortality and physical injury. Baleen whales are more susceptible than other marine mammals due to their large size, slower travel and manoeurving speeds, and lower avoidance capability (Laist et al. 2001). Vessel speed and size are an important factor for determining the probability and severity of ship strikes involving marine mammals. Lethal and severe injuries are caused by ships 80 metres or longer travelling at speeds greater than 13 to 15 knots. These speeds are considered to be a critical threshold, below which ship strikes and mortality are less likely to occur (Dolman et al. 2006, Jensen and Silber 2003).

While there have been reports of toothed whales being struck by some types of ships (Wells and Scott 1997, Van Waerebeek et al. 2007), these animals are at relatively low risk due to their speed and agility (Richardson et al. 1995).

All ships involved with the Project are relatively small vessels. The seismic ship has a length overall of 76.2 m. The *Princess* and two support ships will be operating at reduced speed (4 to 5 knots) during the seismic survey, and consequently, imposing reduced speed as a possible mitigation measure to reduce the likelihood of a ship strike is not necessary. Even during transit to and from Upernavik (or Nuuk) for re-fuelling (including any fuel taken and carried for transfer to other vessels offshore) by one of the support ships, if this occurs, ships will be traveling slower than the critical speed threshold identified above.

Proposed Mitigation and Best Practices

A list of mitigation measures for minimizing the potential of vessel collisions with marine mammals is provided in the EPP (Section 8.0) and Appendix J. A summary is provided below.

- Marine mammal monitoring will be performed on the seismic and hydrographic vessels by trained MMSOs. Observers will notify the vessel operator (Survey Party Chief or other) if there is a concern of the ship striking a marine mammal. These personnel will make a decision if actions are required to avoid a possible collision. This may include slowing the ship, if safe to do so, until the animal has traveled clear of the ship's course. During seismic operations, ramping up the airgun array and use of a mitigation airgun during line changes, will assist in deterring marine mammals from approaching the ship and risking the possibility of a ship strike;
- As safe navigation allows, vessel operators shall take every precaution to avoid harassment of marine mammals by means of the following:
  - Under no circumstances, other than in the case of an emergency, will a Project vessel approach within 300 m of a walrus or polar bear observed on glacial or sea ice.
  - Project vessels shall also maintain a minimum distance of 300 m from marine mammals engaged in feeding activities.
  - For all other marine mammal encounter situations, vessels will not approach or be positioned closer than 100 m to a marine mammal.
  - If marine mammals approach within 100 m of a Project vessel, the Project vessel shall reduce its speed and will cautiously move away from the animal(s).
  - If it is not possible for the vessels to move away from or detour around a stationary marine mammal or group of marine mammals, the vessel shall reduce its speed and wait until the animals depart the area and are at least 100 m from the vessel prior to resuming speed.
  - The vessel shall not be operated in such a way as to separate an individual member(s) of a group of marine mammals from other members of the group. When weather conditions require, such as when visibility decreases, the vessel shall adjust its speed accordingly to avoid the likelihood of ship strikes.
- Survey effort and associated vessel activity will be minimized in marine protected areas and areas identified as important to marine mammals (Section 4.2.2 (Protected Areas) and presented on Figure 4.2 7 of the EIA). COP will cease operations and leave the area before the onset of the NPZ-II protection period on October 15.

Residual Effect and Environmental Significance

The lower vessel speeds that prevail during operations will greatly reduce the likelihood of vessel strikes on marine mammals by providing ample time for these animals to avoid oncoming vessels, as well as time for crew and MMSOs to detect and avoid marine mammals during active operations. The circumstances of the Project in Qamut Block have an important bearing on environmental impact significance. With the application of effective mitigation, such as reduced vessel speed (which applies from the outset owing to the kind of operations carried out), and reducing time in NPZ-I to the lowest required number of days to meet seismic data acquisition requirements, ship strikes involving marine mammals are not expected during the survey period, or during transit to and from the licence area.

In the unlikely event that a ship strike occurs, it would likely cause in an injury only, due to reduced ship speed and lower vessel tonnage (Laist et al. 2001). The magnitude of the effect was considered to be low, and the geographic extent was considered to be regional, since the potential for strikes would exist outside the LSA, when ships transit to or from the licence area along routes normally used for passage. The duration of the impact is considered to be short-term, as the effect is only present when ships are in the licence area (45-day survey plus 15 days contingency). The consequence of the effect was thus determined to be minor for all marine mammal VECs. With mitigation in place, the probability for vessel strikes on marine mammals is predicted to be rare. This results in a "negligible" significance rating.

Subsistence Hunting and Fishing, Tourism and Other Shipping

Project vessel traffic will be sharing the sea with other traffic in the Qamut Block during the open water navigation period. Based on Land & Sea Use described in Section 4.3 of the EIA, other maritime activity could involve: boats used for subsistence hunting and fishing, cruise ships, research ships conducting scientific surveys, military vessels, ships involved with annual re-supply and sealift to communities and other sites along the northwest Greenland coast, and possibly, ships en route to or from the Northwest Passage in the Canadian Arctic Archipelago. It will not include any ships from the commercial fishing fleet, since there is no commercial fishery for any species in Qamut Block or adjacent waters at this time.

It is not expected that ship traffic related to the Project will interfere with subsistence fishing and hunting, since the survey area does not overlap with traditional fishing and hunting grounds. These areas are mainly located in coastal regions near Savissivik and Salleq Island, or in the Melville Bay Reserve.

Project vessel traffic could have an effect on marine tourism due to temporary delays experienced by cruise ships. However, this possibility is regarded as remote to minor in importance. Roughly seven landings are scheduled for 2012 near the Qamut Block, including one landing in Savissivik, and six landings near Qaanaaq and Siorapaluk, but the latter are well to the west and north. Any landings at these communities will not affected by operations in the survey region.

Proposed Mitigation and Best Practices

At the discretion of BMP, as a condition attached to Project approval, a Fishery Liaison Officers (FLO) may be required on one or more of the ships. The FLO would act as an advisor, and assist with matters related to the commercial fishing fleet. However, the likelihood of this happening is believed to be very low, since there are no commercial fisheries, at present, in or near the Qamut Block.

The relevant Greenland authorities (e.g., Island Command Greenland / MRCC Grønnedal) will be notified about intended operations before the Project starts in Qamut Block. This notification is standard practice, and allows Island Command Greenland to alert mariners, via normal marine radio broadcasts, to avoid the survey region, or exercise caution during transit of these waters. An exclusion or restricted operations zone, or equivalent, may be implemented. In addition, with respect to coordination and communication between the three operators in northeast Baffin Bay, ConocoPhillips will participate in the preparing and implementing of a Simultaneous Operations Plan, which involves, but is not limited to, management of vessel traffic related to exploration programs in this region.

During active seismic operations, a Notice to Mariners (Efterretninger for Søfarende, abbreviated E.f.S) would be published by the Danish Maritime Authority before the Project begins, and a Navigation Warning would be broadcast on a regular basis by coastal radio stations, informing mariners in the area about current survey location, schedule and other relevant details. If possible, this information will be provided directly to Royal Arctic Line, research organizations, and government agencies with known operations taking place at the time of survey.

Residual Effect and Environmental Significance

With the application of mitigation, the consequence of Project vessel traffic effects on subsistence hunting and fishing, marine tourism, and other shipping (including ships involved with other exploration programs) are negligible (or non-existent, in the case of commercial fisheries). The level of activity related to these VECs is anticipated to be low or very low, with little or any overlap than cannot be managed by normal maritime procedures. The probability of ineffective or unsuccessful vessel traffic management during normal operations in or near Qamut Block is regarded as rare to very rare. Consequently, the impact rating for all VECs is "negligible".

Table 6.4-1 summarizes the impact rating classifications for the effects of vessel traffic on marine mammals, subsistence hunting and fishing, tourism, and other shipping in Qamut Block and adjacent waters. The "other shipping" component, including military vessels, larger merchant vessels, and the coastal trade, is not rated in the table, but impact significance is believed to be "negligible". This is consistent with the assessment logic or reasoning for tourism, which is ship-based in an offshore setting. It involves vessels that are en route only, transiting to other locations; the licence area is not a destination for cruise ships.

Table 6.4-1 Summary of Impacts from Vessel Traffic on VECs

VEC	Potential Impact	Planned Mitigation	Impact Assessment Criteria				Consequence	Probability	Overall Significance
			Magnitude	Geographic Extent	Duration	Frequency			
Marine Mammals	physical effect due to collisions with vessels	Section 8.0 & Appendix I Table II-1, Appendix J	low	regional	short-term	occasional	minor	rare	1 (negligible)
Bids	displacement		low	local	short-term	continuous	minor	unlikely	2 (low)
Subsistence Hunting and Fishing	displacement of targeted species		negligible	local	short-term	occasional	negligible	rare	1 (negligible)
Tourism / Parks and Recreation	displacement of species of interest		negligible	local	short-term	occasional	negligible	rare	1 (negligible)

6.5 Effects of Vessel Lighting

Project vessel lighting during twilight or darkness may affect birds in the Qamut Block and surrounding area by increasing the risk of bird collisions with vessels. Some species of Birds are prone to colliding with ships and offshore structures if they are attracted by lights during operations at night (Wiese et al 2001, Reed et al 1985, Merkel et al. 2011). Migrating birds that fly low and rapidly over the sea (e.g. king eiders) are particularly susceptible (Day et al. 2003, 2005).

A solar calculator can be used to estimate the length of the daylight period, and the period of nautical twilight before sunrise and after sunset. At the latitude and longitude of interest (center of license area), the daylight period on 15 July and 1 August is 24 hours in length. On 15 August, the sun rises at 00:53 local (West Greenland) time (-04 GMT), and sets at 23:23. On 1 September, the rise and set times are 03:51 and 20:36, respectively. On 15 September, the rise and set times are 05:15 and 19:03. Finally, on 1 October, the rise and set times are 06:44 and 17:24. These times were estimated using the ESRL-GMD calculator (NOAA 2012); other calculators produce similar results. There will be extended periods of nautical twilight before sunrise and after sunset at the latitude of Qamut Block. These periods can be estimated with the US Naval Observatory calculator (USNO 2012). The length-of-daylight estimates are sufficient for assessment purposes.

Based on the length-of-daylight estimates above, any effects of vessel lighting on birds will not occur until the last half or last third of the proposed survey period, and are expected to be limited.

The Qamut Block and surrounding region does not overlap with critical bird nesting or molting sites, as noted in Section 4.2 on Biological Environment. However, individual birds from these colonies or other locations may transit through the area.

Proposed Mitigation and Best Practices

External vessel lights will be shielded and/or reduced during twilight and darkness, with the exception of navigation lights, and used only when necessary. Safety on deck is paramount, and will take precedence over mitigation.

Birds that land on vessels during twilight and darkness should be left undisturbed, unless they impede operations or risk being harmed by onboard operations. If possible, an exhausted bird resting on the ship can be moved to a sheltered location until it is able to fly. Crew members will be asked to handle dead, injured or resting birds in an appropriate manner.

Data on bird encounters can be used to help determine factors associated with collision and mortality risks, and may be useful in developing mitigation to reduce these risks. The MMSOs on the *Princess* will be monitoring for seabirds on a regular basis. A Project-specific bird observing manual will be prepared prior to the start of survey, based on the NERI (2011) Guidelines. In addition, all bird encounters will be reported to the MMSO on duty.

Residual Effects and Environmental Significance

The assessment indicated that impacts from vessel lighting on seabirds were negligible. Table 6.5-1 summarizes the overall impact rating classifications for the effects of Project vessel lighting on seabirds. Lighting will not be necessary during operations until late in the survey period. When lighting is used at night, minimizing the amount of light involved has proved effective in reducing seabird mortalities from collisions (Reed et al. 1985). In addition, seabirds tend to fly slower during darkness, further reducing the chance of collision with a vessel (Day et al. 2003, 2004). The distance of the Qamut Block from land and any coastal breeding sites will further reduce the likelihood of collisions at night (Merkel et al. 2011). Even with application of the proposed mitigation, there is still potential for physical injury or death of seabirds as a result of colliding with a Project ship. The magnitude of this effect is thus considered moderate. The geographic extent of this effect is considered to be regional. Some potential for seabirds to collide with Project ships exists outside the LSA during transit to and from the survey region. The duration of the effect was considered to be short-term, or during the survey period only (up to 45 days plus 15 days contingency). The frequency of the activity causing the effect (vessel lighting) was considered to be occasional because vessel lighting would only be used during the latter part of the survey period and for short periods of time per day. With the application of mitigation, the consequence of the effect was thus considered to be minor and the probability rare, resulting in an impact significance rating of negligible.

Table 6.5-1 Summary of Impacts from Vessel Lighting on Seabirds

VEC	Potential Impact	Planned Mitigation	Impact Assessment Criteria				Consequence	Probability	Overall Significance
			Magnitude	Geographic Extent	Duration	Frequency			
Seabirds	physical effects due to collisions with vessels	see Section 8.0 (MMSO and PAM), Appendix I Table I-1 & Appendix J	moderate	regional	short-term	occasional	minor	rare	1 (negligible)

6.6 Effects of Introduced Species from Ballast Water Exchange

It was noted in Section 6.2 that ballast water is a potential discharge from ships in the Qamut Block during the Project, and that it may contain invasive (exotic) species, either in the water, or on sediment that is suspended in it. The possible but unlikely introduction of invasive species from this source, or other potential sources, is assessed below.

The unintended introduction of invasive species from shipboard sources might impact marine ecosystems in Greenland. Possible introduced species include bacteria and other microbes, microalgae, and aquatic plant and animal species in ballast water or sediment. These organisms are invasive or non-invasive in nature. Invasive species can spread rapidly in the absence of natural predators, and dramatically alter local habitats, making them unsuitable for native species (DFO 2011). Introduced species, if invasive, can also have effects on the abundance of native species, due to predation and/or competition for habitat and food resources.

Proposed Mitigation and Best Practices

It is remotely possible that ballast water could be discharged by one or more of three ships during the Project if re-ballasting is needed to reach ice draft or after ship-to-ship transfer of fuel offshore, but ballast water exchange is not anticipated during normal operations. If any release of ballast water is necessary, all ships during the Project will comply with a Ballast Water Management Plan that is identified in the EPP as a supplementary or complimentary plan. This plan will be followed to make the possibility of invasive species being released in ballast water as small as possible. Preparation of this plan has not been completed by ConocoPhillips, and it is not attached to the EIA. However, all mitigation described in the IMO Convention for the Control and

Management of Ship's Ballast Water and Sediments of 2004 will be implemented. Other potential sources of invasive species during the Project could not be identified on any of the ships.

Residual Effects and Environmental Significance

Since ballast water exchange is not expected during the Project, ballast water would not be released in the LSA, or enter the RSA, from a foreign water source during the Project. In the unlikely event that re-ballasting needs to be done by any of the ships, a Ballast Water Management Plan will be followed. Consequently, the Project will not lead to any introduction of invasive species in the LSA or RSA, or other Greenland waters either.

It is recognized that the impact of an invasive species introduced from ballast water or sediment could be detrimental for marine ecosystems in northeast Baffin Bay. It is also possible that the geographic extent of this effect could be "beyond regional", in that an introduced species could potentially expand to waters to the west of Qamut Block as a result of transport by the West Greenland Current. Further, if this species survived and reproduced during this transport, it could potentially reach waters in northwest Baffin Bay, and then waters to the south, along the coast of Baffin Island. However, this situation is not realistic. The circumstances of the Project, including number and type of ships involved, ballast water exchange not expected during normal operations, any release strictly governed by a Ballast Water Management Plan, and the small or very small amount of ballast water involved if any release took place, do not support this possibility either. It was discounted (as not probable) during assessment.

The likelihood of successfully introducing an invasive species from ballast water or sediment during the Project is very low. A series of events would have to occur, including: existence of an invasive species in a ship's ballast water tanks; ballast water exchange taking place in Qamut Block; adaptability of the species to local environmental conditions after a small amount of ballast water containing or carrying it released; ability of the invasive species to out-compete local species when it is introduced; ability of the invasive species to quickly reproduce or colonize (and reach a population size that can be sustained over time); and ability of the invasive species to alter the local ecosystem to make it permanently less suitable for local species. The probability of all these conditions developing in the right sequence is regarded as rare. If a successful introduction of invasive species in a Greenlandic marine ecosystem did occur, it could have a long-term impact (DFO 2011). At a population level, the magnitude of the impact would be moderate. The geographic extent could move beyond the RSA; however, the frequency of the activity causing the effect is considered to be occasional. This indicates a moderate consequence. Since the probability of the event is rare, the overall significance is negligible for all VECs.

Table 6.6-1 Summary of Impacts from Ballast Water Exchange on VECs

VEC	Potential Impact	Planned Mitigation	Impact Assessment Criteria				Consequence	Probability	Overall Significance
			Magnitude	Geographic Extent	Duration	Frequency			
Marine Fish	introduction of invasive species	Section 8.0 (Ballast Water Management Plan) & Appendix I Table II-1	moderate	beyond regional	long-term	occasional	moderate	rare	(1) negligible
	ecosystem change								
Seabirds	ecosystem change		moderate	beyond regional	long-term	occasional	moderate	rare	(1) negligible
Marine Mammals	ecosystem change		moderate	beyond regional	long-term	occasional	moderate	rare	(1) negligible
Subsistence Hunting and Fishing	changes in important species		moderate	beyond regional	long-term	occasional	moderate	rare	(1) negligible

6.7 Effects of Unplanned Events and Accidental Spills

An unplanned event or accidental spill of solid or liquid material could occur during the Project in Qamut Block, or during transit to or from the licence area. Depending on the type of incident, it could have an impact on the

environment. This situation applies to the ship conducting the seismic survey, as well as to the two vessels supporting this vessel.

These incidents could involve a variety of liquid or solid substances, including fuel in tanks, fuel in drums, lubricants, hydraulic oil, chemicals, hazardous or non-hazardous waste, and even well-secured items on deck that might break free during very heavy seas. For assessment purposes, it was assumed that the unplanned event was an accidental (unintentional) spill, and that the volume or amount of material was minor (small) or major (large).

Minor spills that occur onboard during normal operations, which should be infrequent or occasional, based on "best practice" at sea, could lead to a release into the environment if the material involved cannot be contained or controlled by crew members. This situation is very different from a major spill, which might result, directly, from a ruptured fuel tank (or tanks) after a collision, or indirectly, from fire damage or explosion damage, or from worse incidents.

The worst unplanned event is catastrophic loss after collision with another ship (or iceberg) at economy or maximum speed, which is remotely possible during any operation in northeast Baffin Bay. However, this event is regarded as a highly unlikely situation, and it is not valuable for understanding the implications of a less severe event. Consequently, the assessment is based on a less severe, but still major, incident that is focused on the M/V *Princess*, the largest ship chartered for the Project, which carries more fuel than other vessels.

Minor Spill during Project operations

The types of materials typically used on seismic survey ships and support vessels with potential for spillage were noted above. Fuel, in particular, can be spilled during bunkering in port or during ship to ship transfer offshore if a hose ruptures or a valve, coupler or other fitting fails. It was assumed that any small spill involving fuel during the Project would be contained onboard, and not enter the sea. In the unlikely event this fuel spill could not be contained, and it drained overboard, it was assumed that the release would be less than 0.5 m^3 (ERM 2011) in volume, that it remains in the vicinity of the ship, and that an attempt would be made to contain and clean it up if safe to do so. A drum of fuel, for example, contains about 210 litres, and depending on the specific gravity of the fuel involved, it would hold about half the assumed volume.

A Fuel Spill Response Plan will be prepared and implemented to make sure any small fuel spill, onboard only or reaching the environment in limited amount, can be responded to properly. This plan is part of the EPP, described in Section 8 of the EIA.

Major Spill during Project Operations

It was assumed that a major spill would be the result of a severe collision between two ships or between a ship and an iceberg. The hull would be breached, causing multiple tanks to rupture, and fuel would be released to the environment. To prevent or reduce the likelihood of collisions, all Project vessels will be equipped and operated to appropriate Greenlandic, Danish and/or international standard. In addition, given the prevalence of glacial ice in the form of icebergs, bergy bits and growlers in Qamut Block, ConocoPhillips will be developing and implementing an Ice Management Plan for the Project.

This plan is summarized in the EPP (Section 8 of the EIA). It will be followed to make sure seismic operations proceed safely and successfully during the survey period. The primary goal is preventing or minimizing the possibility of collisions or impacts with glacial ice that would compromise safety, cause damage to a ship, or cause damage to towed equipment.

To limit the possibility of collisions between Project ships and other vessels in the area, or during transit along the west coast of Greenland, ConocoPhillips will notify the Danish Maritime Authority before operations begin, notify Island Command when the seismic survey commences, ensure Island Command is informed throughout, and comply with Vessel Monitoring System (VMS) requirements in Greenland.

Marine Diesel Fuel (MDF) was selected for assessment of a major liquid spill in or near Qamut Block. It was assumed that M/V Princess would be carrying the most MDF if an unplanned event occurred. The Princess has a total fuel capacity of 692 m^3 (CCGVeritas 2011). The vessel's port and starboard tank lay-out was not critical

for developing the scenario. It was also assumed that up to one-third or one-half of this capacity (roughly 300 m^3) could be released to the sea during a major spill of fuel.

MDF is not one fuel with a simple composition; these fuels are normally hydrocarbon blends with variable compositions of differing molecular weights, including some heavier components. It has low viscosity, and does not form a "fuel in seawater" emulsion. The lighter fractions show greater solubility and higher toxicity, but have a tendency to evaporate quickly. Dense components spread less rapidly, but tend to remain longer in the water column. Very dense components may sink to the seafloor and assume a tar-like consistency (CONCAWE 1998). In general, MDF is considered to be "persistent" if it enters the sea, and does not dissipate as quickly as more refined hydrocarbons (ITOPF 2002). To understand how MDF propagates in an Arctic marine environment, the Nielsen et al. (2006, 2008) studies were consulted.

It is emphasized these studies are not completely applicable to MDF, since they involved crude oil only, and the releases that were modelled were much larger in volume than 300 m^3. However, they indicate, in part, how hydrocarbons behave in Arctic marine environments, including waters in northeast Baffin Bay, during sea ice free conditions. Other information on this subject is summarized by Sørstrøm et al. (2010).

Nielsen et al. (2006) conducted trajectory modelling on 15,000 or 30,000 tonne spills of crude oil at five sites in eastern Baffin Bay, ranging from the shelf edge to the inner portion of the shelf in Disko Bay during sea ice free conditions. MDF and crude oil are different products, but they have common fractions, and the ocean-atmosphere processes that control behaviour after a spill would be similar or identical. The modelling involved winds from six directions, and indicated that crude oil reached the shore during only three of 24 scenarios. One-third of the released crude oil was predicted to evaporate within the first 24 hours of the release.

SINTEF (Stiftelsen for industriell og teknisk forskning) in Trondheim (Norway) indicated that 50 to 60% of any MDF released during a spill into seawater with a temperature as low as 5^oC will evaporate in a few hours (Daling 2012, pers. comm.). The balance should disperse in the surface layer in a relatively short period of time, depending on wind, wave, and surface current conditions. Since the assumed volume of MDF that could be spilled from the *Princess* is about 2% of the smaller amount that was modelled for the oil spill scenarios, the volume and aerial extent of MDF remaining after evaporation, dispersion, and mitigation of an offshore 300 m^3 spill should be negligible or very small, and difficult to detect.

Additional oil spill model simulations have been done by Nielsen et al. (2008) for locations in northeast Baffin Bay, including two sites just north of 74°N near 60°W and 63°W between the Tooq and Qamut license blocks, and one site (71° 23'N, 58° 20'W) to the south. These results support the comments made above.

The northern part of Qamut Block is located 40 km or more from the coastline of northwest Greenland. The regional wind and current regime, discussed in Section 4.1, indicates that the West Greenland Current is weak in this region, with a tendency for net flow to the west while the winds are predominantly from the southeast through summer and early fall. Tidal currents have some bearing on transport as well, but less so than over banks to the east and south. The seismic survey will be carried out during sea ice free conditions, avoiding a "fuel under sea ice" or "fuel in sea ice" situation. Given the prevailing winds and currents, the net advection of a 300 m^3 spill of fuel from the Princess would be generally west moving roughly parallel to the shoreline. It is unlikely that a fuel spill of this size would reach the coast, given the small volume left after mitigation has been applied, and the large decrease involving evaporation to the atmosphere, followed by dispersion in the water column. If this release of fuel occurred closer to shore, north of the licence area, it could impact the coast, but no operations are planned in those waters.

The seismic survey extends into the west-central part of NPZ-I. ConocoPhillips is aware this region is an ecologically sensitive area. No operations, such as ship to ship re-fuelling, with any possibility of causing or resulting in a fuel spill, will occur in these waters.

Residual Effects and Environmental Significance

The effects of minor unplanned events involving smaller spills that cannot be contained onboard have a "negligible" impact significance rating for all VECs. These results are shown in Table 6.7-1. These events would be infrequent or occasional to start with, not continuous; containing the spill immediately is normal procedure and "best practice" at sea on a competent, well-run vessel. When this mitigation is applied, the magnitude of effects

was regarded as negligible. Geographic extent would be limited to the survey area, in the immediate vicinity of the ship involved. The duration was anticipated to be short-term in most cases, but it could be longer, depending on the spilled material or substance that could not be contained. The consequence was rated as negligible, and probability, as a result of the foregoing, as unlikely for all VECs. Further mitigation is not required.

Table 6.7-1 Summary of Impacts from Minor Unplanned Events and Accidental Spills on VECs

VEC	Potential Impact	Planned Mitigation	Impact Assessment Criteria				Consequence	Probability	Overall Significance
			Magnitude	Geographic Extent	Duration	Frequency			
Sediment Quality	deterioration of sediment quality	Section 8.0 (Spill Prevention and Response Plan) & Appendix I Table I-1	negligible	local	short-term	occasional	negligible	unlikely	1 (negligible)
Water Quality	deterioration of water quality		negligible	local	short-term	occasional	negligible	unlikely	1 (negligible)
Marine Fish	minor toxic effect		negligible	local	short-term	occasional	negligible	unlikely	1 (negligible)
Seabirds	minor toxic effect		negligible	local	short-term	occasional	negligible	unlikely	1 (negligible)
Marine Mammals	minor toxic effect		negligible	local	short-term	occasional	negligible	unlikely	1 (negligible)
Subsistence Hunting and Fishing	minor toxic effect to important species		negligible	local	short-term	occasional	negligible	unlikely	1 (negligible)

The effects of major unplanned events involving larger spills that enter the sea in Qamut Block have a “negligible” impact significance rating for all VECs, with two exceptions where the rating is “low”, taking evaporation, dispersion and application of mitigation into account. These results are shown in Table 6.7-2. Some observations about two of the ratings are provided below. Sediment quality was included as a VEC because of potential effects on substrate in the inter-tidal zone if any fuel came ashore. While these effects are possible, it is very unlikely that water containing any fuel would move toward the coast. Since commercial fishing does not occur, at present, in or near the licence area, it was not assessed.

Effects on seabirds from major spills have a “low” impact significance rating. Birds would be the most negatively affected receptor after this category of unplanned event. The magnitude of these effects, depending on the amount of fuel remaining in the upper part of the water column after evaporation to the atmosphere, application of mitigation, and dispersion or mixing processes, could be high. It may lead to mortality of vulnerable species, such as common eider or thick-billed murre, both species of concern. The geographic extent could be local to regional, and duration, short-term to medium-term. As a result, the consequence of the effects could be severe. The probability is rare; therefore, the overall significance is low (2).

Effects on marine mammals from major spills have a “low” impact significance rating. Depending on the amount of fuel left in the surface layer after evaporation to the atmosphere, application of mitigation, and dispersion or mixing processes, the magnitude of these effects could be high, involving more than one Greenland red-listed animal (narwhals and beluga whales), possible disruption of marine mammal behaviour, possible harm, and possible damage to sensitive habitat areas. The geographic extent could be local to regional, and the duration, short-term to medium-term. The consequence of the effects, therefore, could be severe. The probability is rare; therefore, the overall significance is low (2).

Table 6.7-2 Summary of Impact from Major Unplanned Events and Accidental Spills on VECs

VEC	Potential Impact	Planned Mitigation	Impact Assessment Criteria				Consequence	Probability	Overall Significance
			Magnitude	Geographic Extent	Duration	Frequency

7 Cumulative Effects Assessment

7.1 Introduction

Cumulative effect assessment (CEA) is defined as “the combination of multiple impacts from existing projects, the proposed project, and/or anticipated future projects that may result in significant adverse and/or beneficial impacts on an environmental resource / receptor that would not be expected in case of a stand-alone project” (IFC 2007).

The framework for conducting the cumulative effects assessment (CEA) involved the following steps:

- Identification of residual effects for the ConocoPhillips Project in the Qamut Block.
- Identification of spatial and temporal boundaries for the CEA.
- Identification of other past, present, and reasonably foreseeable future Projects or activities in the CEA study area.
- Prediction and evaluation of potential cumulative effects of the Project on selected VEC in the receiving environment.
- Identification of mitigation measures to eliminate or reduce potential cumulative effects.
- Determination of the significance of any residual cumulative effects after mitigation.

Following the identification of Project-specific residual effects, the assessment of cumulative effects focussed on selective VECs that were most likely to be affected by other projects or activities known to take place at the same time and/or in the same general location (RSA). The VECs selected included fish and marine mammals where underwater sound, as a result of other seismic survey operations, was the focus of the cumulative effects assessment.

An approach for investigating and assessing the cumulative effects of underwater sound on fish and marine mammals from multiple seismic operations concurrently taking place in northeast Baffin Bay, at both local and regional scales, was agreed to, in principle, by BMP, DCE, and the three northeast Baffin Bay operators at a meeting in Copenhagen on 20 January 2012. An approach for in-situ monitoring of cumulative underwater sound levels (using bottom-moored or fixed systems) during the multiple seismic operations in northeast Baffin Bay was also part of this agreement.

The following section provides an overview of the approach used to model aggregate or cumulative underwater cSEL on a regional scale. Detailed information on the modeling approach is presented in the Acoustic Technical Report (Appendix D).

7.2 Methods

Acoustic modeling was conducted on a regional scale by JASCO Research to assess the cumulative effects to selected VEC's from exposure to underwater sound from simultaneous seismic operations in adjacent License Blocks in northeast Baffin Bay. Aggregate sound exposure maps were prepared to illustrate the long-range sound contributions from all projects in this region (Appendix D).

The spatial boundary, in general, is the same as the RSA described in Section 5.2.3. The acoustic modeling related to cumulative effects was conducted for northern Baffin Bay as a whole, extending in the North Water Region, on the north, and towards Disko Island, in the eastern part of central Baffin Bay, on the south. The agreed-on methodology for investigating and assessing the cumulative effects of underwater sound on marine mammals, at both local and regional scale, during multiple seismic surveys in northeast Baffin Bay occurring at the same time was followed throughout.

Projects and activities that were included in the CEA included:

- the proposed 2012 ConocoPhillips 2D-seismic program (Qamut Block);
- the proposed 2012 Maersk Oil Kalaallit Nunaat A/S (MOKN) 3D-seismic program, and hydrographic and shallow geophysics survey (Tooq Block); and
- the proposed 2012 Shell Kanumas A/S (Shell) 3D-seismic program and stratigraphic drilling program (Anu Block and Napu Block).

Two modeling approaches were applied:

- modelling aggregate cSEL in the RSA from all airgun pulses from all activities over a 24-hour time period; and
- modelling sound propagation beyond the RSA for a single airgun pulse from each activity.

As mentioned in JASCO's Acoustics Technical Report, the aggregate cSEL model scenario included simultaneous operation of four seismic surveys and vertical seismic profiling (VSP). Activities from MOKN's hydrographic survey were not included in this analysis because contribution of the sound from this work is expected to be negligible relative to the four seismic surveys. This aggregate model scenario was designed with sources positioned such as to provide a conservative assessment of overall sound exposure in sensitive areas such as Melville Bay. Modeled sound levels for all activities in the aggregate model scenario were summed to provide an aggregate measure of the 24-hour cSEL over a grid of receiver locations at a regional scale.

Sound propagation beyond the RSA was modelled using single transects connecting several source and receiver locations. The source locations included each operator's airgun arrays (four in total) and the vertical seismic profiling array. Receiver locations were located several hundred kilometers away, distributed around the Baffin Bay area. The modelling included sound absorption from the water column, applied constant seafloor and water column properties, and made the cautionary assumption of open water (no sea ice) conditions since the presence of sea ice would give rise to scattering of the sound and reduce received sound levels.

7.2.1.1 Modelled Scenarios

In the aggregate model scenario JASCO computed cSEL for all airgun pulses which could realistically be acquired by each operator (ConocoPhillips, MOKN, and Shell) over a 24-hour time period for the following activities:

- ConocoPhillips: acquisition of one complete seismic survey line in the Qamut block;
- MOKN: acquisition of two complete seismic survey lines in the Tooq block;
- Shell: acquisition of two complete seismic survey lines, using two airgun arrays, in the Anu and Napu blocks;

- Shell: vertical seismic profiling occurring at one site north of the Qamut block.

JASCO Research also modeled sound propagation outside of the RSA along single transects connecting each airgun-array to a set of four receivers: (R1) near the western boundary of the Melville Bay Reserve, (R2) in the southern part of the North Water Region between Greenland and Canada, (R3) at or near the entrance to Lancaster Sound, and (R4) to the south towards Disko Island. The source and receiver locations are shown in Figure 7.2-2.

7.2.1.2 Criteria

SEL is a measure of total sound energy and is a convenient metric for summing sound energy from multiple sound pulses. As such, the cumulative SEL (cSEL) metric is appropriate when assessing effects to marine mammals and marine fish from cumulative exposure to multiple airgun pulses. cSEL is calculated as a straight summation of sound energy over multiple pulses and provides a conservative measure that does not account for hearing recovery between pulses.

The cSEL criteria recommended by Southall et al (2007) are: 198 dB re 1 μPa^2-s for cetaceans and 186 dB re 1 μPa^2-s for pinnipeds. These criteria are intended to be M-weighted to account for the variable hearing abilities of different marine mammal groups. These levels provide thresholds for injury but corresponding cSEL thresholds for behavioural impacts from multiple pulses do not exist. Commonly 160 dB re 1µPa (rms) is considered a threshold for behavioural effects in marine mammals, although migrating bowhead whales have been reported to exhibit behavioural reactions to multiple airgun pulses at received levels as low as 120 dB re 1µPa (rms) (Richardson et al, 1999).

7.3 Results

Maps showing sound level contours resulting from the aggregate cSEL calculations (along with more details of the methodology) are provided in the Acoustics Technical Report (Appendix D). Based on the model results, the total areas in which the modeled cSEL are at or above injury threshold criteria (flat-weighted and M-weighted) are presented in Table 7.3-1 for each M-weighted hearing group and for flat-weighted levels (i.e. not filtered for any particular hearing group). The table also presents the distance offset from the survey line at which the modeled levels exceed the injury threshold criteria. These results provide the quantitative basis for the assessment of cumulative effects on fish and marine mammals.

Full results from the transect modelling completed beyond the RSA are found in Appendix D (Acoustic Technical Report, Section 5.3). For the source positions considered, the highest rms SPL received at each receiver location was: (R1) 127.2 in Melville Bay, (R2) 129.3 in the northern waters, (R3) 128.1 in Lancaster Sound, and (R4) 119.8 towards the south.

Although the total area within which the injury threshold is exceeded for pinnipeds is large, this area is confined to a region within 800 m range from the source (offset from the survey line). Using the most conservative marine mammal injury threshold for cSEL (pinnipeds @186 dB re 1 μPa^2s), seismic sound would extend out to a maximum of 600 m at levels high enough to result in auditory injury. The cumulative SEL calculations assume stationary receivers and the greatest dose of sound energy is delivered to the receiver at that the time the vessel is at its closest point of approach to the animal. Therefore, since the 600 m range within which there is a potential for injury from 24-hours of cumulative sound exposure is within the stipulated 800 m safety zone, the risk for injury from cumulative sound exposure is also mitigated through implementation of the safety zone and associated shut-down criteria.

Table 7.3-1 Areas Affected by cSEL in Qamut Block and RSA

Injury Threshold for cSEL (dB re 1 mPa^2s)	Distance Offset from the Survey Line at which Injury Threshold is Exceeded [m]	Total Area in Qamut Block where Injury Threshold is Exceeded over a 24-hour Period [km^2]	Percent of Total Area Available in Qamut Block (11,600 km^2) [%]	Total Area in all Blocks[(a)] where Injury Threshold is Exceeded Over a 24-hour Period [km^2]	Percent of Total Area Available in all Blocks[(a)] (42,196 km^2) [%]
186 (Flat)	1,750	387.9	4.1%	2,734	6.5%
186 (PINN)	600	105.2	1.1%	892	2.1%
198 (Flat)	100	20.0	0.2%	118	0.3%
198 (LFC)	85	17.5	0.2%	103	0.2%
198 (MFC)	<10	1.8	0.02%	<20	<0.05%
198 (HFC)	<10	0.6	0.01%	<14.8	<0.04%

(a) Includes Tooq Block, Qamut Block, Pitu Block, and Anu Block.

Note: Flat = flat-weighted; PINNm = weighted for pinnipeds; LFC=weighted for low-frequency cetaceans, MFC= weighted for medium-frequency cetaceans, HFC= weighted for high-frequency cetaceans

7.4 Interpretation and Mitigation

7.4.1 Identification of Mitigation Measures

Aggregate or 'cumulative' sound exposure modeling is based on the sound metric cSEL, as this is the only metric that takes into account cumulative sound exposure from repetitive pulses and/or overlapping acoustic fields. 'Behavioral disturbance' protection zones cannot presently be determined from cumulative sound exposure modeling because there are no known behavioral impact thresholds for cSEL. The current cSEL thresholds relate to PTS (186 and 198 dB re 1 μPa^2s; M-weighted for pinnipeds and cetaceans respectively). As such, the cumulative acoustic model of the combined four seismic surveys is only able to provide information for cSEL likely to induce hearing loss (TTS and PTS) in marine mammals, and not behavioral reactions. Based on the acoustic modeling results, cSEL capable of inducing TTS or PTS were not predicted in overlap areas of the sound fields away from the sources. Therefore, the combined seismic operations do not necessitate different protection measures other than those recommended for the individual Project surveys, from an injury prevention standpoint.

Section 6.3 identified potential temporary behavioural effects on fish and marine mammals from non-overlapping sound sources occurring in Qamut Block (the LSA). The same effects are predicted to occur at the regional level. Mitigation measures for non-overlapping Project effects in Qamut Block are described in Appendix I (Mitigation Measures) and Appendix J (Marine Mammal Management Plan) of the Final EIA, and summarized in the EPP (Section 8.0).

In addition to ConocoPhillips applying these known and effective mitigation measures during its operations in Qamut Block (including extended safety zones, ramp ups, pre-shooting surveys, and shut-down / low power procedures), the three operators in northeast Baffin Bay have agreed to prepare and implement a simultaneous operations plan with mitigation added that is related to underwater sound and marine mammals in a regional setting. This mitigation involves planning and coordination related to keeping seismic survey ships positioned as far apart as possible when multiple operations are taking place at the same time. Taking these steps is different than following procedures to keep vessels from approaching too close to each other during acquisition such that quality or integrity of seismic data is affected. The latter is what a simultaneous operations plan is normally designed to do, in addition to addressing safety of shipping when many vessels will be operating in, or transiting to and from, an area such as northeast Baffin Bay.

7.4.2 Determination of Significance

Table 7.4-1 summarizes the impact rating classifications for the cumulative effects of seismic sound on fish and marine mammals in Northeast Baffin Bay.

Table 7.4-1 Summary of Cumulative Impacts from Seismic Sound on Marine Mammals and Fish on a Regional Level

VEC	Potential Impact	Planned Mitigation	Impact Assessment Criteria				Consequence	Probability	Overall Significance
			Magnitude	Geographic Extent	Duration	Frequency			
Marine Fish	physical effects	See Section 8.0 & Appendix I Table I-1	Moderate	Regional	Long-term	Continuous	Moderate	Unlikely	Low (2)
	behavioural effects[(a)]		Moderate	Regional	Short-term	Continuous	Moderate	Likely	Moderate (3)
Toothed Whales (Beluga and Narhwal)	physical effects	Mitigation for physical effects only: Section 8.0 (MMSO, PAM, extended safety zone, etc), Appendix I Table I-1, Appendix J	Low	Regional	Long-term	Continuous	Minor	Rare	Negligible (1)
	behavioural effects[(a)]		Moderate	Regional	Short-term	Continuous	Moderate	Likely	Moderate (3)
	acoustic masking		Moderate	Regional	Short-term	Continuous	Moderate	Unlikely	Low (2)
Baleen Whales (Bowhead Whales)	physical effects		Low	Regional	Long-term	Continuous	Minor	Rare	Negligible (1)
	behavioural effects[(a)]		Moderate	Regional	Short-term	Continuous	Moderate	Unlikely	Low (2)
	acoustic masking		Moderate	Regional	Short-term	Continuous	Moderate	Unlikely	Low (2)
Pinnipeds and Walrus	physical effects		Low	Regional	Long-term	Continuous	Minor	Rare	Negligible (1)
	behavioural effects[(a)]		Moderate	Regional	Short-term	Continuous	Moderate	Likely for pinnipeds / Unlikely for walrus	Moderate (3) for pinnipeds / Low (2) for walrus
	acoustic masking		Moderate	Regional	Short-term	Continuous	Moderate	Likely for pinnipeds / Unlikely for walrus	Moderate (3) for pinnipeds / Low (2) for walrus
Polar Bears	physical effects		Negligible	Regional	Long-term	Continuous	Negligible	Rare	Negligible (1)
	behavioural effects[(a)]		Negligible	Regional	Short-term	Continuous	Negligible	Unlikely	Negligible (1)

(a) Includes displacement, avoidance and tolerance.

Cumulative Sound Exposure on Marine Fish

The potential for physical injury (auditory trauma) or behavioral effects from cumulative sound exposure on all fish VECs is considered to be of moderate magnitude, as sound levels could exceed established cSEL injury thresholds at close range to the individual sound sources, and behavioural changes (avoidance behaviour) are anticipated in the far-field, and may potentially result in a temporary disruption of fish behaviours critical to survival. However, effects are not anticipated at the population level, as fish and ichthyoplankton (fish eggs and larvae) are generally widely distributed, and recovery, in terms of both diversity and abundance, is likely to occur rapidly in response to localized impacts. Physical and behavioural effects will be spatially limited to the RSA (regional geographic extent), and will occur on a continuous frequency (assuming 24-hour operations amongst all operators). Physical effects on fish are considered to be long-term in the case of physical injury (auditory damage), and short-term (limited to the open-water season) in the case of behavioural effects. The environmental consequence of the cumulative effects of underwater sound was thus determined to be moderate for both physical and behavioural effects for all fish VECs. With the application of mitigation (ramp-up), the probability for physical injury or mortality of fish is considered to be unlikely due to anticipated avoidance behaviour, and likely for behavioural effects, resulting in a low (2) and moderate (3) impact significance rating, respectively.

Cumulative Sound Exposure on Toothed Whales (Narwhals and Belugas)

Beluga whales and narwhals were identified as VECs for the Project as their presence in Greenlandic waters is well documented (DCE 2011). However, results from this effects assessment, and the mitigation measures as proposed, are applicable to all toothed whale species potentially occurring in the Project area during the open-water season.

Based on the results in the Acoustic Technical Report (Appendix D), the cSEL injury threshold for mid-frequency cetaceans (198 dB re 1 μPa^2-s, Southall et al. 2007) is predicted to be exceeded at distances up to 10 m offset from the survey line. The potential for auditory damage to beluga and narwhal as a result of cumulative seismic sound exposure is thus considered to have a low magnitude, as the cSEL injury threshold will not extend outside the 800 m safety zone. Moreover, most of the sound energy from airguns is emitted outside the sensitive frequency range for both narwhals and belugas. This effect is considered to be long-term in duration (in the case of PTS) over a regional geographic extent (within the RSA), and of continuous frequency (assuming 24-hour operations amongst all operators). The environmental consequence of this effect is thus considered to be minor. With known and effective mitigation in place, the probability of direct physical injury (auditory damage) in toothed whales from cumulative exposure to seismic sound is considered rare, resulting in a negligible (1) impact significance rating for both beluga and narwhal. It is unknown to what degree indirect physical / physiological effects may occur as a result of cumulative sound exposure due to the limited research conducted on this topic. If mammals remain in an area because it is important for feeding, breeding, or some other biologically important purpose, it is possible that physiological stress may occur as a result of chronic exposure to sound. This might, in turn, have negative effects on the well-being or reproduction of the animals involved, although this linkage remains inconclusive at this time.

The effect of cumulative sound exposure on narwhal and beluga behaviour is considered to be of moderate magnitude, as far-field effects on behaviour are likely, however no population level effects are anticipated, and most of the sound energy will be emitted outside the sensitive frequency range for both species. This effect is considered to be limited to the RSA, short-term in duration (during the open-water season of 2012), and of continuous frequency assuming 24-hour operations amongst all operators throughout the survey period. The environmental consequence of this effect is thus considered to be moderate. The probability of this effect occurring is predicted to be likely as toothed whales (particularly narwhal) are likely to be in the regional area (RSA) during the open-water season given the protected summering ground areas (NPZ-1) identified for this species near Melville Bay. The overall impact significance rating for behavioural effects from cumulative sound exposures from seismic sound sources is predicted to be moderate (3) for beluga and narwhal.

Potential masking effects of cumulative seismic sound exposure on the communication space of beluga and narwhal are expected to be limited, as both species typically communicate at frequencies outside the dominant bandwidth of seismic survey sound. Furthermore, both species may be able to emit and receive sounds between airgun pulses (Davis et al. 1985, Abgrall et al. 2008). The environmental consequence of this effect is thus considered to be moderate (moderate magnitude, regional in geographic extent, short-term duration, continuous frequency), with an unlikely probability of occurrence (as communication frequencies are likely not masked by seismic sound), resulting in a low (2) impact significance rating (Table 7.4-1).

Cumulative Sound Exposure on Baleen Whales (Bowheads)

Bowhead whales were identified as a VEC for the Project as their presence in Greenlandic waters is well documented (DCE 2011). However, results from this effects assessment, and the mitigation measures as proposed, are applicable to all baleen whale species potentially occurring in the Project area during the open-water season.

Based on modeling results in the Acoustic Technical Report, attached in Appendix D, the cSEL injury threshold for low-frequency cetaceans (LFC) (198 dB re 1 μPa^2-s; Southall et al. 2007) is predicted to be exceeded at distances up to 85 meters offset from the survey line. The potential for physical injury (auditory damage) to bowhead whales as a result of cumulative seismic sound exposure is thus considered to have a low magnitude, as the cSEL injury threshold will not extend outside the 800 m safety zone. This effect is considered to be long-term in duration (in the case of PTS), over a regional geographic extent (within the RSA), and of continuous frequency (assuming 24-hour operations amongst all operators). The environmental consequence of this effect is thus considered to be minor. With known and effective mitigation in place, the probability of physical injury to bowhead whales from cumulative exposure to seismic sound is considered rare (particularly as most bowhead whales are likely to be absent from the RSA during the seismic program), resulting in a negligible (1) impact significance rating for this species.

The effect of cumulative seismic sound on bowhead whale behaviour is considered to be of moderate magnitude as far-field effects on behaviour are likely; however no population level effects are anticipated. This effect is considered to be limited to the RSA, short-term in duration (during the open-water season of 2012), and of

continuous frequency assuming 24-hour operations amongst all operators throughout the survey period. The environmental consequence of this effect is thus considered to be moderate. Because bowhead whales are not likely to be in Eastern Baffin Bay during the open-water seismic period, the probability of this effect occurring is predicted to be unlikely, resulting in an overall low (2) impact significance rating for bowhead whales.

The frequencies emitted by seismic sound overlap with those used by baleen whales for communication. Although the cumulative seismic sounds are impulsive, sound levels due to reverberation after each airgun pulse are likely to be above background sound levels, as well as above the audible threshold of bowhead whales over large distances and thus capable of masking their communication (Blackwell et al. unpublished, Koski et al. 2011). The environmental consequence of this effect is thus considered to be moderate (moderate magnitude, regional geographic extent, short-term duration, continuous frequency). However, the probability of this effect occurring is considered unlikely because bowheads are expected to be absent from the RSA during the open-water season, and communication is likely possible during pulse intervals, resulting in an overall low (2) impact significance rating (Table 7.4-1).

Cumulative Sound Exposure on Pinnipeds and Walrus

The cSEL injury threshold for pinnipeds (PINN) (186 dB re 1 μPa^2-s; Southall et al. 2007), based on results in the Acoustic Technical Report (Appendix D), is predicted to be exceeded at distances up to 600 m offset from the survey line. The potential for auditory damage to pinnipeds from cumulative seismic sound exposure is thus considered to have a low magnitude, as the cSEL injury threshold will not extend outside the 800 m safety zone. This effect is considered to be long-term in duration (in the case of PTS), over a regional geographic extent (within the RSA), and of continuous frequency (assuming 24-hour operations amongst all operators). The environmental consequence of this effect is thus considered to be minor. With known and effective mitigation in place, the probability of physical injury to pinnipeds and walruses from cumulative exposure to seismic sound is considered rare (particularly for walrus as they are expected to be absent from the RSA during the seismic program), resulting in a negligible (1) impact significance rating for this species (Table 7.4-1).

The effect of cumulative seismic sound on pinniped and walrus behaviour is considered to be of moderate magnitude, as far-field effects on behaviour are likely; however no population level effects are anticipated and no disruption of critical activities are expected (no critical areas for pinnipeds, such as sea-ice are present in the RSA during the survey period and no walrus summering grounds are present in the RSA). This effect is considered to be limited to the RSA, short-term in duration (during the open-water season of 2012), and of continuous frequency assuming 24-hour operations amongst all operators throughout the survey period. The environmental consequence of this effect is thus considered to be moderate. Based on the likelihood of species occurrence in the RSA, the probability of this effect occurring is predicted to be likely for pinnipeds and unlikely for walruses, resulting in an overall impact significance rating of moderate (3) for pinnipeds and low (2) for walruses (Table 7.4-1).

The frequencies emitted by seismic sound overlap those used by pinnipeds and walrus for communication. Although the cumulative seismic sounds are pulsive, sound levels due to reverberation after each airgun pulse are likely to be above background sound levels, as well as above the audible threshold for these animals over large distances and thus capable of masking their communication (Blackwell et al. 2011, Koski et al. 2011). The environmental consequence of masking effects on walrus and pinniped communication is thus considered to be moderate, given the impact will be short in duration, continuous in frequency, moderate in magnitude, and regional in geographic extent (masking effects will extend outside the LSA + 10 km buffer zone). The probability of this effect is considered likely for pinnipeds, and unlikely for walrus, as the latter are not likely to be in Baffin Bay during the open-water season when the seismic programs will be taking place. The resulting impact significance rating for masking effects is therefore assessed as low (2) for walrus and moderate (3) for pinnipeds (Table 7.4-1).

Cumulative Sound Exposure on Polar Bear

All operators will be conducting seismic operations in sea-ice free conditions. It is therefore anticipated that polar bears will be absent from the seismic survey areas during the open water seismic season due to their close association with sea ice. Moreover, because the natural behavioural tendencies of polar bears (e.g. remaining at the water surface, or on land) greatly reduce their exposure to underwater sounds, the potential for physical injury or behavioural disturbance in this species owing to cumulative seismic sound exposure is considered to have a

negligible environmental consequence. The probability of this effect occurring is considered rare for physical injury and unlikely for behavioural disturbance and acoustic masking, resulting in a negligible (1) impact significance rating with regards to physical, behavioural, and acoustic masking effects.

8 Environmental Protection Plan

8.1 Introduction

This section describes the EPP for the Project. It is an overview or summary of this plan. It is based on the environmental assessment, including mitigation measures designed to manage, reduce or eliminate impacts of the Project on Qamut Block, specifically, and northeast Baffin Bay, in general. ConocoPhillips will implement an integrated approach for environmental protection and environmental protection during the Project. As a result, the EPP includes a number of individual plans, and incorporates elements of others. Many of the plans in the latter category are not complete at this time, and will be provided to BMP 40 days prior to the start of survey operations in Qamut Block.

It is noted that a planning and preparation process, including adoption of pre-survey measures based on approval of the Project, and the scheduling of detailed steps to implement and monitor the mitigation measures described in the EIA, will occur after the Final EIA is submitted to BMP by ConocoPhillips. This process will be subject to conditions, if any, attached to the approval.

The EPP has been has been prepared in accordance with the current version of the Guidelines (BMP 2011), and with the Minerals Resources Act. Consequently, all Project activities are governed by the following requirements:

- identification and assessment of the risk of pollution and any other harmful impacts on the environment with the intention to reduce to the extent possible these impacts;
- implementation of mitigation measures that are in compliance with applicable legislation and good industry practice for waste management, refueling, and notification to other operators within the area, coordinating activities to the extent possible to avoid unnecessary impediment; and
- making all project personnel aware of the standards and controls prior to the commencement of work, and conducting all project related activities in a safe and responsible manner with due consideration to actual field conditions encountered.

8.2 Environmental Policy during the Project

ConocoPhillips has an environmental policy in Greenland that is part of the broader Health, Safety and Environment (HSE) framework of its global parent. It embraces this policy, and is committed to protecting the health and safety of everybody who plays a part in its operations, lives in the communities in which it operates, or uses its products. ConocoPhillips will conduct its business with respect and care for both the local and global environment, and systematically manage risks to drive sustainable business growth. It will not be satisfied until it succeeds in eliminating all injuries, occupational illnesses, unsafe practices and incidents of environmental harm from our activities.

To meet its commitment to these goals, ConocoPhillips will:

- Demonstrate visible and active leadership that engages employees and service providers and manage HSE performance as a line responsibility with clear authorities and accountabilities.
- Ensure all employees and contractors understand that working safely is a condition of employment, and that they are each responsible for their own safety and the safety of those around them.
- Maintain "stop work policies" that establish the responsibility and authority for all employees and contractors to stop work they believe to be unsafe.
- Manage all projects, products and processes through their life-cycles in a way that protects safety and health and minimizes impacts on the environment.
- Provide employees with the capabilities, knowledge and resources necessary to instill personal ownership and motivation to achieve HSE excellence.

- Provide relevant safety and health information to contractors and require them to provide proper training for the safe, environmentally sound performance of their work.
- Measure, audit and publicly report HSE performance, and maintain open dialogue with stakeholder groups and with communities where ConocoPhillips operates.
- Comply with applicable regulations and laws.
- Work with both governments and stakeholders where ConocoPhillips operates to develop regulations and standards that improve the safety and health of people and the environment.
- Maintain a secure work environment to protect itself, its contractors and its assets from risks of injury, property loss or damage resulting from hostile acts.
- Communicate its commitment to this policy to subsidiaries, affiliates, contractors and governments worldwide and seek their support.

By implementation of this policy, ConocoPhillips seeks to earn the public's trust and to be recognized as the leader in HSE performance.

8.3 Standards, Controls, Consultation and Notification

All operations in Qamut Block will be carried out according to all applicable regulations, standards, and “best practice” guidelines in waters under Greenlandic jurisdiction, including, but not limited to:

- MARPOL 73/78 “International Convention for the Prevention of Pollution from Ships”;
- IMO International Convention for the Safety of Life at Sea (SOLAS) 1974;
- IAGC “Marine Geophysical Operations Safety Manual” (published by the International Association of Geophysical Operations);
- IAGC “Environmental Guidelines for Worldwide Geophysical Operations” (most recent edition);
- OGP Guideline: Managing HSE in a Geophysical Contract (Report No. 432);
- Order No. 417 of 28 May 2009, “Order on Technical Regulation on Safety of Navigation in Greenland Waters”;
- Order No. 170 of 17 March 2003, “Ship Reporting Systems in the Waters off Greenland”;
- Technical Regulation No. 169 of 4 March 2009, “Technical Regulation on the Use of Ice Searchlights During Navigation in Greenland Waters”;
- Resolution A.1024 (26) IMO 2010, “ Guidelines for Ships Operating in Polar Waters”; and
- any requirements attached to the authorization from the Government of Greenland, or any other conditions required by the authorities.

ConocoPhillips recognizes the importance of regular communication with BMP, DCE, and other agencies, as well as with communities and local organizations in northwest Greenland, on Project issues, including environmental concerns. Some of this interaction occurred during community visits after the Preliminary EIA was submitted to BMP. Additional interaction will occur after submission of the Final EIA. ConocoPhillips is also familiar with BMP requirements related to notification before, during and after the seismic survey, and will comply with all of these requirements.

The importance of internal Project briefings is also understood by ConocoPhillips. It will ensure all contractors are well-informed about operations-related environmental issues before and during the seismic survey, including conditions, if any, attached to Project approval.

8.4 Plans Included in or Related to the Environmental Protection Plan

8.4.1 Safe Operations Plan

Many parts of this plan are relevant to the EPP. It is being prepared by ConocoPhillips and its contractors, and will cover a wide range of activities, procedures, requirements, and other considerations during the seismic survey in Qamut Block this year. In accordance with the Guidelines (BMP 2011), it will include, but is not limited to:

- Complete description of safety management systems and all bridging documents for the health, safety and contingency systems used by ConocoPhillips and its contractors on ships during the Project, including documentation on crew health and safety training.
- Documentation for compliance with all requirements for safe navigation in Greenlandic waters, including certificates of seaworthiness[4], fire management plan, boarding procedures, and other maritime practices during normal and emergency operations, as well as insurance certificates.
- Description or explanation of health systems and medical emergency preparedness, including actions that will be taken to treat and stabilize patients with injuries or acute conditions, means of consulting with a physician about these injuries or conditions (or bringing this physician aboard), and arrangements that have been made for evacuating the injured or ill person or persons to a hospital or medical facility onshore.
- Description of procedures for responding to environmental incidents, including spills, unplanned discharges, collisions with mammals, and other situations.

The Safe Operations Plan will be submitted to BMP by ConocoPhillips 40 days before operations begin in Qamut Block. It is not attached to the Final EIA. The Emergency Response Plan (ERP), described below, and the Simultaneous Operations Plan (if an agreement is reached between the operators in northeast Baffin Bay to prepare this plan), discussed below as well, may be integrated with the Safe Operations Plan.

8.4.2 Simultaneous Operations Plan

This plan is normally developed and implemented as a “best practice” by companies during offshore exploration when two or more seismic surveys are occurring in a given region. The quality and integrity of seismic data can be affected or become impaired or degraded if the survey ships are too close to each other when airgun arrays are being operated, and seismic data is being acquired.

It was mentioned in Section 7 of the Preliminary EIA that a simultaneous operations plan could become part of regional mitigation related to cumulative effects of underwater sound from multiple seismic surveys that occur at the same time. That is, given the possible impacts of higher sound levels on marine mammals from a cumulative effects point of view, planning and coordination could be done to avoid operational situations where a maximum amount of seismic sound is being generated during multiple programs. This planning and coordination could involve maintaining larger separation distances between seismic vessels than ones related to impairment of seismic data quality or integrity, or making choices about sequencing (when and where operations occur on a given day or during a given week). The types of situations to be avoided would be identified by the operators based on experience during concurrent seismic surveys in other offshore areas. Discussions about preparing a plan took place between the operators before each operator’s Preliminary EIA was submitted to BMP in mid-March 2012.

ConocoPhillips, Maersk Oil Kalaallit Nunaat A/S and Shell Kanumas A/S subsequently agreed to prepare and implement a simultaneous operations plan with mitigation added related to underwater sound and marine mammals in a regional setting. As noted in Section 7, this mitigation involves planning and coordination to keep seismic survey ships operating at greatest distance from each other as often as possible when multiple surveys occur at the same time. Taking these steps is not the same as following procedures to keep these vessels from approaching too close to each other during acquisition such that quality or integrity of seismic data is affected.

[4] The ship’s master will demonstrate familiarity with all rules and regulations to navigation and operations with the Greenlandic EEZ (Exclusive Economic Zone), and will ensure that safe voyage planning includes all information necessary to ensure safe navigation, such as weather, wave and ice conditions, bathymetry, local geography, currents and tide, navigational hazards, operational limits, the ship’s design, and means of communication.

The latter is what a simultaneous operations plan is normally designed to do, in addition to addressing safety of shipping when many ships will be operating in, or transiting to and from, an area such as northeast Baffin Bay. The three operators will exchange operational contact information, enabling all seismic vessels to maintain regular communication with each other at sea during execution of operations. The operators will also share their detailed operational plans with each other before any seismic surveys begin in northeast Baffin Bay, and interact on details in a collaborative way. This sharing and consultation between companies is an opportunity to develop and test, in advance, the steps that will be followed to keep seismic ships positioned as far apart as possible when multiple surveys are underway at the same time.

8.4.3 Waste Management Plan

The waste management strategy of ConocoPhillips during the Project was described in Section 6.2. All material and equipment brought into Qamut Block, with the exception of fuel consumed during operations, and discharges authorized under national regulations or international conventions (e.g., grey water, black water, macerated organic waste, drainage from decks and above waterline ship's structure), will leave the license area at the end of the seismic survey. No waste will be disposed of onshore, whether it is hazardous or non-hazardous. This strategy is consistent with BMP's Guidelines related to waste, and with requirements under the Mineral Resources Act.

Waste will be segregated and stored onboard according to type and MARPOL grouping, prior to disposal at a properly equipped and licensed waste disposal facility at a port in another country. Some non-hazardous waste may be incinerated at high temperature, since at least some of the ships chartered for the Project are equipped with incinerators. Hazardous waste, including batteries, will be safely and securely stowed. Waste management records will be maintained as normal operating practice, including quantities of waste incinerated onboard, and hazardous waste retained for onshore disposal.

Procedures and policies related to waste management will be described in a project-specific Waste Management Plan. ConocoPhillips is developing this plan with its contractors. It will be submitted to BMP 40 days before operations begin in Qamut Block. It is not attached to the Final EIA.

8.4.4 Ballast Water Management Plan

The ballast water management strategy involves no discharge of ballast water during the survey period. If this occurs during the Project, which ConocoPhillips regards as unlikely, though it is possible if re-ballasting to ice draft after re-fuelling (e.g. by the vessel receiving fuel after ship to ship transfer offshore), then it will be controlled by the IMO convention on ballast water management.

A plan describing ballast water management is being prepared by ConocoPhillips and its contractors. It is not attached to the Final EIA. It will cover, as a minimum, the following IMO requirements:

- ballast water exchange will be conducted at least 200 nautical miles from land in waters at least 200 m deep;
- in cases where the above is not possible, exchange will occur at least 50 nautical miles from land in water at least 200 m deep;
- if these requirements cannot be met, other areas may be designated for ballast water exchange;
- sediments from the ballast tanks will be removed and properly disposed of; and
- a ballast water record book (ballast exchanges, treatments, and accidental discharges) will be maintained.

Instances of ballast water discharge, if any, during the Project will be reported to BMP as part of post-program activity. ConocoPhillips will submit a ballast water management plan to BMP 40 days before operations begin in Qamut Block.

8.4.5 Fuel Spill Response Plan

A detailed Fuel Spill Response Plan is being developed by ConocoPhillips and its contractors. It can be submitted to BMP on request. It is not attached to the Final EIA. This plan will include the following elements:

- number, type, contents and location of spill kits;

- crew spill response training and ship's spill response certification information;
- spill response communication plans and contact information; and
- procedure for maintaining an Oil Record Book as required under MARPOL 73/78, International Convention for the Prevention of Pollution from Ships.

It is noted that ships involved with the seismic survey may carry small quantities of chemicals for technical (scientific) or maintenance and repair purposes. It is believed any unintended spills of these chemicals during the Project would be minor in amount or volume. If supplies of liquid or solid chemicals are necessary onboard, they will be selected based on the least environmentally harmful alternative. All associated Material Safety Data Sheet (MSDS) information will be available on the ship in question. Appropriate personal protective equipment (PPE) will be onboard that is suited or rated for using these products.

8.4.6 Marine Mammal and Seabird Observation Program

The MMSO Plan is a key component of the EPP. It is attached in Appendix J as the main element of a Marine Mammal Management Plan for the Project, including supplementary material. The primary issue of concern is the effect of underwater sound from the seismic array on marine mammals, and to a lesser but still important extent, from equipment on the ship performing the other survey that is part of the Project.

Trained and certified marine mammal and seabird observers (MMSOs) will be stationed on seismic ship. Four MMSOs will be joining the CGGVeritas M/V *Princess* for the seismic survey. Resumes and qualifications of the MMSOs on this ship will be submitted to BMP 40 days before operations begin in Qamut Block.

The MMSOs will carry out observations in accordance with the JNCC "Guidelines for Minimizing Acoustic Disturbance to Marine Mammals for Seismic Surveys" and the DCE "Guidelines to Environmental Impact Assessment of Seismic Activities in Greenland Waters", both cited earlier sections of the EIA. This will to ensure compliance with operational requirements and completion of the work based on both sets of guidelines, since the DCE Guidelines take precedence over the JNCC Guidelines, but situations could arise where DCE information is absent or not available. In addition, MMSOs may provide environmental advice, as well as avoidance or mitigation recommendations, to the captain or officers on the bridge of the seismic vessel.

The DCE Guidelines require a watch for marine mammals within 500 m of the seismic source prior to the start of operations. ConocoPhillips will establish an 800 m safety zone during its operations to minimize the effects of the operations on marine mammals. The primary mitigation measure will always be reducing the amount of sound entering the marine environment. Acquisition of seismic data will be suspended if marine mammals are sighted within 800 m of the airgun array when it is operating. Marine mammal observations will occur during daylight hours, and include all marine wildlife, including pinnipeds, birds, and cetaceans. Use of the mitigation gun on the seismic ship, if this gun needs to be used during line changes or other operations, will also be noted. In addition, the four MMSOs on this vessel will work closely with the operator of the monitoring system described below. A daily log of sightings, observation locations and data will be maintained using the forms associated with the NERI guidelines (log forms will be included as appendices), and a final report will be submitted.

8.4.7 Passive Acoustic Monitoring Plan

A vessel-based passive acoustic monitoring (PAM) plan will be implemented will be implemented during the seismic survey, in conjunction with the MMSO plan mentioned above. A designated, certified PAM operator will use a PAM system on the *Princess* for monitoring on marine mammals (instead of visual monitoring) at night, during periods of darkness, periods of reduced visibility (such as fog), and during sea states greater than Beaufort 3. This person will contribute information for the same mitigation measures as the MMSO team, involving the pre-shoot searches, ramp-ups, and shut-down procedures, as well as use of the mitigation gun. Communication procedures will be established between the MMSOs, PAM operator, and airgun operator for transfer of monitoring responsibilities, and how that occurs. This protocol with be outlined in the Project-specific MMSO manual. Supplementary information on the PAM plan is provided in Appendix J, the Marine Mammal Management Plan for the Project.

The PAM system used on the *Princess* for detecting marine mammal vocalizations was described in Section 3 of the EIA. It is manufactured by Seiche Measurements, and has been used extensively world-wide since 2008. The four towed hydrophone elements have a large bandwidth of 20 Hz to 200 kHz, which means a number of

marine mammal species can be detected if the mammals in question are vocalizing when the PAM system is operating. The data can be visualized, and monitored in real-time, with the software that operates the system. Identification of the mammals in range at different frequencies involves recognizing and comparing structure and content of the data with standard signatures for species that occur in Qamut Block and adjacent waters.

8.4.8 Ice Management Plan

An Ice Management Plan is relevant to the EPP because problems with sea ice or glacial ice include the possibility of damage to ships or towed equipment. This outcome could have environmental implications, in addition to operational ones.

Drifting sea ice, even in low concentrations (e.g., in the form of more concentrated strips or patches), and calved glacial ice in the form of icebergs, bergy bits or growlers, can interfere with the single-streamer seismic survey that will occur in Qamut Block, and may require the seismic vessel to deviate from a survey line, or cause difficulty during a line change. The IMP for the Project is a multi-tiered or multiple-level approach for the Project that is focused on management of glacial ice, involving various tasks and responsibilities at different times and scales of interest. This approach is supported by well-proven procedures for safe operations in glacial ice and sea ice environments. Key elements of the Plan are iceberg drift forecasts, understanding likelihood of impact with the vessel or array, and avoidance methods. Ice defence methods, such as towing of bergy bits and small icebergs, will not be used during the survey.

Ice management planning will take into account systems for ice detection, ice surveillance, data reporting, collation, and tactical forecasting. This phase of activity will occur before the Project starts in the licence area, and involves pre-deployment preparation, operational requirements and tactics, ways of capturing lessons learned, and requirements for analyzing success or failure during the post-survey period. Operational requirements and tactics include, but are not limited to:

- Following agreed-on procedures for glacial ice (and sea ice) avoidance; ensuring that equipment needed for these procedures is onboard and functional, and that crew have been trained on this equipment, or have experience with it; and
- defining response roles and responsibilities, as well as the decision-making process onboard.

One of the primary duties of the two support ships during the survey in Qamut Block is ice management. These vessels will be used to locate and defend against glacial ice in the vicinity of the seismic ship, the array, or the streamer.

Supplementary information on ice management is found in Appendix C. The IMP is being prepared by ConocoPhillips and its contractors, and will be submitted to BMP 40 days before the Project starts in Qamut Block. It is not attached to the Final EIA.

8.4.9 Emergency Response Plan

An Emergency Response Plan (ERP) is being developed by ConocoPhillips and its contractors. It is not attached the Final EIA. Some parts of this plan are relevant to the EPP. The ERP is project-specific, and will address potential emergency situations (e.g., man-overboard, injuries to personnel, unintended release of hazardous substances to the environment, ship strikes involving marine mammals, flooding of one or more compartments, fire in a cabin or laboratory, fire in the engine room, collisions with towed equipment, collisions with other ships, collisions with glacial ice, etc) that need to be responded to and managed during the seismic survey or the hydrographic / shallow geophysics survey. It must include clear lines of responsibility at sea and onshore, as well as the communication and notification protocols that need to be followed any accidents or incidents.

The ERP will be submitted to BMP 40 days before the Project begins in Qamut Block. BMP will be notified immediately of any significant situation or event, including loss of life, missing personnel, serious injury, onboard fire, fuel spill, and any threat to crew, ships or the environment. As soon as practical after this notification, ConocoPhillips will prepare and send a written report to BMP on the situation or incident.

8.4.10 Fisheries Impact Management Plan

There is no commercial fishery in Qamut Block that currently happens for any species. However, BMP may decide that a Fishery Liaison Officer (FLO), as a condition of approval, should be stationed on M/V *Princess* (or on one of the two support ships) to address any fisheries-related issues that develop during the seismic survey. If so, a fisheries impact management plan will be prepared by ConocoPhillips. It would be sent to BMP on request.

The FLO would transmit survey-related information to any fishing vessel that enters Qamut Block, establish grievance procedures (if needed), maintain records of all fisheries-related communication, events or incidents, and other interaction with this fleet (if any), and prepare reports for ConocoPhillips when the survey is finished. These reports will be submitted as part of post-program activity. A fisheries impact management plan is a framework for planning and organizing this work, and guiding delivery.

8.4.11 Environmental Studies Plan

The plan will be based on the suggestions in Section 8 of the EIA, and specifically, will also include research programs that are relevant to Qamut Block and adjacent waters that DCE, GINR, and other agencies would like to carry out with Strategic EIA funding from the northeast Baffin Bay operators in 2012 and subsequent years. When the Project is approved by BMP, this plan will be finalized, and submitted by ConocoPhillips. It is not attached to the Final EIA.

8.4.12 Mitigation Reporting/Oversight Plan

The strategy for mitigation during the Project will be following all mitigation measures identified in the EIA that reduce or eliminate impacts of the seismic survey on the environment. A reporting/oversight plan for mitigation will be prepared by ConocoPhillips before the work begins. It can be provided to BMP on request. This plan will consist of a table that describes the mitigation measures (Appendix I, Table I-1), including some of the plans mentioned above, and procedures for monitoring or evaluating, and then reporting on, the success of implementing the mitigation strategy.

9 Study Limitations and Future Research

Available information from ConocoPhillips, other northeast Baffin Bay operators, BMP, DCE, other EIAs prepared on projects in northeast and eastern Baffin Bay, universities and other organizations, and publications in the open literature was obtained and referred to during the EIA. While, in general, this information was sufficient for assessment purposes, the amount of analysis or interpretation that could be done on some topics was limited by missing data, or lower quality or deficient data. ConocoPhillips understands that offshore Greenland is an emerging or developing exploration area, that scientific research continues, and that the situation described in not unusual or negative. This section of the EIA describes some of the limitations related to assessment, and provides suggestions for research and other activity in the future.

9.1 Study Limitations and Data Gaps

The following list provides the limitations identified during assessment of the Project and preparation of the Preliminary and Final EIA Reports. That is:

- The acoustic modelling conducted by JASCO Research, used the best available bathymetry in the public domain (the International Bathymetric Chart of the Arctic Ocean, or IBCAO, data set) at regional scale, and bathymetry derived from seismic surveys provided by ConocoPhillips, at licence or block level. Absent or limited information included seafloor properties (sediment type, sediment distribution, upper structure of sediment column, seabed morphology, etc) and seasonal water column structure (specifically, temperature and salinity) in Qamut Block.
- Measurements of ambient sound levels in northeast Baffin Bay would improve modelling and contribute to better interpretation of results. It is not clear what the natural background is (and what it consists of) in these waters at different times of year. Some data on ambient acoustic conditions will be collected during a project proposed by DCE and GINR during summer and fall 2012. Other data should be collected on a broader basis (over a larger region), including far-field locations. Existing sediment and seabed characteristics are not well documented in current literature. Additional research on sediment geochemistry, extent and depth

of scouring by iceberg keels (including re-working or “re-moulding” of scoured soils), contaminants (including persistent organic pollutants, various hydrocarbon compounds, bioavailable metals, other trace metals, etc) at representative shallow and deeper locations, and seasonal and annual changes in benthic ecology, for example, would be helpful for future EIAs.

- In addition to a shortage of temperature and salinity data on the water column in Qamut Block at different times of the year, current measurements with bottom-moored systems on the shallow bank in the central part of the licence area, on the flanks of this bank, and on deeper parts of the shelf are absent. Obtaining this information would be valuable in the future.
- Data on the distribution and characteristics of icebergs is not as thorough as it should be on Qamut Block and adjacent waters. Additional data could to be collected in the future. This information would contribute to safe operations during future activities in the area, improved environmental assessment, and also to planning and engineering design.
- The offshore biological environment is one area of marine science that is most studied for Greenland. Invertebrates, marine fish, seabirds and marine mammal species are relatively well-known. However, there are data gaps related to certain species, and more information, in general, is required on marine ecosystems in northeast Baffin Bay, since it is the least studied region off the west coast of Greenland. For example, detailed understanding of marine mammal migration patterns in relation to timing of sea ice break-up and clearing, and residency in summer habitat areas would be useful.

9.2 Future Research

The following list provides suggested research to aid in conducting future EIA assessments:

- As one of the three operators in northeast Baffin Bay, ConocoPhillips will be supporting a passive acoustic monitoring program involving fixed (bottom-moored) sensors or listening systems that will be done by DCE and GINR during multiple seismic surveys in summer and fall of 2012. This program will involve validation of underwater sound levels predicted by acoustic modeling on the seismic survey that ConocoPhillips would like to carry out in Qamut Block, as well as on multiple seismic surveys that take place at the same time in a regional setting. Based on the results of the program, it is possible that ship-based marine mammal safety zones could be revised in the field, or modified during seismic surveys in the future. Acoustic monitoring will be conducted in critical habitat areas (e.g. NPZ-I) on sufficient temporal and spatial scales to adequately capture pre- and post-seismic events.
- ConocoPhillips will also be supporting aerial reconnaissance surveys on narwhal residency and migration patterns before, during and after multiple seismic surveys in northeast Baffin Bay this year. The study will contribute to better understanding of narwhal response to elevated levels of underwater sound, and the behaviour of this species when seismic operations occur in different licence areas. Aircraft-based monitoring of critical habitats will be performed to evaluate potential displacement of narwhal from critical habitat areas and possible disruption of different behaviours in critical habitat areas due to seismic sound.

Finally, ConocoPhillips will be supporting a study on the effects of seismic sound on local subsistence harvest activities. Interviews will be conducted with Greenlandic hunters to determine potential effects of the 2012 seismic program on marine mammal and fish catch rates, changes in hunting locations and effort and marine mammal behavioural observations.

GXT 2011 Environmental Impact Assessment

This is the Environmental Impact Assessment (EIA) component of GX Technology Corporation's (GXT) 2011 Application to the Greenland Bureau of Minerals and Petroleum (BMP) for its proposed Northeast Greenland offshore survey program. As described below additional technical information is contained in the Application Appendix Volume, and other sections of the Application documents describe (Volume 1) and contain (Volume 2) the detailed safety, emergency response (including spill response), waste management and pollution prevention plans that will be applied during the survey.

1 Relevant Project Components and Method

As described in detail in Section 4.1 – 4.8 of GXT's 2011 Application, GX Technology Corporation is proposing to conduct a marine 2-D (single streamer) seismic, gravity and magnetic program located offshore of Northeast Greenland. Data acquisition is expected between July and October 2011. GXT is requesting to permit approximately 12,610 km of seismic lines in Greenland waters. However, it is expected that approximately half this amount will actually be acquired in 2011, if ice conditions are favourable. The additional permitted lines will allow options / alternatives in case some areas have ice that is too heavy for acquisition, or cannot be surveyed for other environmental / environmental protection reasons.

This program is similar to, and overlaps the area of GXT's previous two Greenland marine programs conducted successfully and without environmental incidents in 2009 and 2010. As in 2009 and 2010, two vessels will be used for the survey - a seismic source vessel with hull modifications for deploying seismic equipment to work in ice (the *Polar Explorer*) and an icebreaker, which will go ahead to open leads and channels (the *Vladimir Ignatyuk*). The *Polar Explorer* (then named the *Geo Explorer*) was also used in 2009 and 2010, and the *Vladimir Ignatyuk* was used for GXT's 2009 survey. As in 2009 and 2010, the seismic source ship will tow a compressed air sound source array (28 airguns, 4330 in^3 array) and a single submerged solid-core passive hydrophone receiver cable, which will extend up to 8.5 km behind the vessel. (A very similar and successful program was also conducted in the Canadian Beaufort Sea in 2010.)

The maps in this EIS show the location of the seismic lines proposed for 2011. Water depths in the Project Area range from less than 50 m to 3,500 m, and lines range from the closest point, ~22 km from the mainland of Greenland (about 12 km from the closest offshore island), to the maximum offshore point of ~365 km, the outer Greenlandic EEZ boundary. The great majority of the survey acquisition (roughly 90%) is more than 50 km from any shoreline.

1.1 Purpose of the Project

The overall purpose of the Project is to conduct a marine 2-D seismic, gravity and magnetic data acquisition program located offshore of Northeast Greenland focused on the areas from North Denmarkshavn Salt Basin to Northeast Greenland Volcanic Province and eastward into Thetis Basin. The survey overlaps portions of both the East Greenland and North Greenland BMP licence Regions, though the great majority is in the North Region.

The aim of the 2011 study is to continue to collect seismic data, supplementing GXT's 2009 and 2010 programs, to reveal the large scale region-wide geological profile. As with the 2009 and 2010 surveys, the 2011 Project is a Basin Span survey. GXT's world-wide Span surveys examine very broad and deep geological formations in and around basin areas using advanced geophysical techniques. They provide information on the geologic evolution, deep basin architecture, and the depositional and structural histories of an entire region. The Northeast Greenland 2009, 2010 and 2011 surveys are part of GXT's Arctic Basin Span programs which have been conducted previously in Arctic waters off Alaska, western Canada and Norway. Surveying these ultra-deep formations allows for a better evaluation of the evolution of the geological basin areas, including identifying source rocks, migration pathways, and play types. These programs are not designed to identify specific potential drilling locations.

1.2 Recent Studies and Assessments

The physical oceanography and biological environment of Northeast Greenland have been reviewed as part of a detailed and comprehensive Preliminary Strategic Environmental Impact Assessment (PSEIA) of expected activities for the KANUMAS East area (Boertmann et al. 2009a). Funded by the Bureau of Minerals and Petroleum, and prepared by the National Environmental Research Institute (NERI / DMU) and the Greenland Institute of Natural Resources (GINR), the PSEIA covers the offshore waters and coastal areas from the eastern Kangerlussuaq Fjord northwards to Amdrup Land (68ºN and 81ºN). All but 5 km of GXT's proposed 2011 survey lines (part of one line north of 81ºN) fall within the KANUMAS East PSEIA assessment area (See Figure 1.)

The environment of the area for this present survey is well described in the KANUMAS East assessment area PSEIA and was also summarized in the GXT EIAs for the 2009 and 2010 2-D surveys in the east and north Greenland Regions (GXT 2009; GXT 2010). The proposed 2011 seismic program occurs entirely within the GXT Study Area applied in the 2010 EIA (shown in Figure 1). For both the 2009 and 2010 survey Applications, comprehensive project-specific environmental assessments were prepared, and reviewed and approved by BMP/NERI.

In the following Section, the physical and biological environments are summarized and largely referenced to the KANUMAS East PSEIA. Section 3 then provides the assessment of potential Project impacts. The section following (Section 4) contains a summary of the environmental protection plan and mitigations, which follow the current BMP/NERI's Seismic Guidelines (Boertmann et al. 2010).

Source references for the EIA citations are included at the end of this EIA in Section 5.

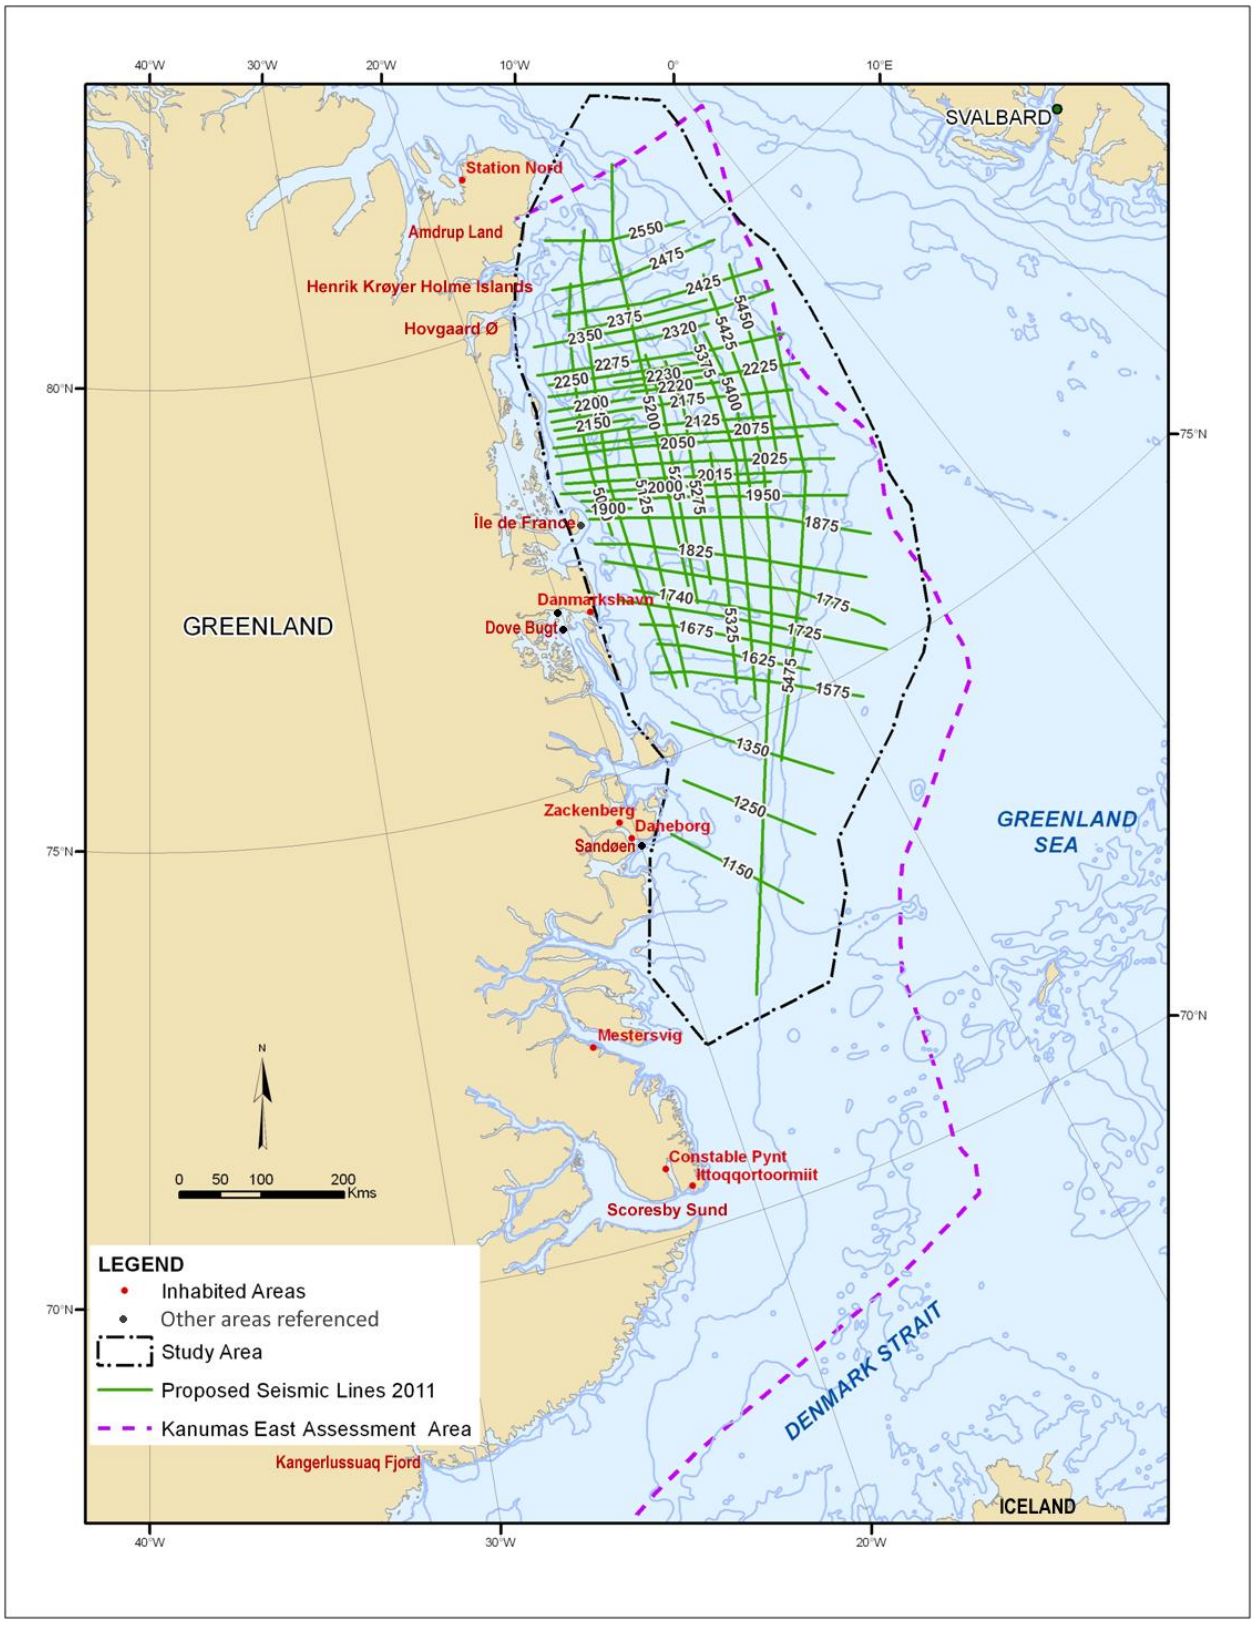

Figure 1. GXT NE Greenland 2011 Seismic Program and Study Areas
(including areas referenced in the text)

2 Project Area Environment (Physical, Biological and Human Use)

Because the Project Area environment is well described in several available studies, such as Mosbech et al. (2000), Jensen and Christiansen (2003), Hvidegaard et al. (2008), Boertmann et al. (2009a; 2009b), key features only are presented here. However, a more detailed technical description is also included in Appendix 4 of GXT's 2011 Application.

2.1 Physical Oceanography

2.1.1 Currents

The dominant current of east Greenland is the cold East Greenland Current which transports massive amounts of cold Arctic water and pack ice southward from the Arctic Ocean. As the current flows south, it encounters the warmer, more saline Irminger Current, a branch of the Gulf Stream, between Iceland and Greenland. Mixing of the two currents causes the East Greenland Current to lose its characteristic polar current traits along the southernmost part of the west coast. The distribution of marine species in Greenland is greatly influenced by the mixing of the currents. The current system of Greenland is also important in the transportation and distribution of sea ice. The East Greenland Current leads the so-called East Greenland Drift Ice (multi-year drift ice of polar origin) from the Arctic Ocean southward.

2.1.2 Ice

Sea ice is very important to Greenland ecosystems because of several factors including the distribution and migration of animals, particularly those that need open water to forage or, in the case of marine mammals, breathe. The ice also provides a platform for seals, Atlantic walrus, polar bear and marine birds.

The sea ice around Greenland is dynamic and varies annually and locally in distribution and shape depending on localized wind and current conditions. The ice conditions on the east coast can be severe with dense ice cover during most of the summer period. The temporary or permanent open areas, such as leads and polynyas (open water areas that form within pack ice in almost the same place and time each year), found within sea ice are important productive areas for a variety of marine life. Leads open and close due to changing water levels and are found in coastal areas and around grounded icebergs. Polynyas are important wintering areas for several Arctic marine mammals and birds. The Northeast Water Polynya, which occurs in the northeast waters by Norøstrundingen, is one of the largest polynyas in Greenland waters (Jensen and Christensen 2003).

2.2 Biological Environment

2.2.1 Primary Production, Zooplankton and Marine Invertebrates

Primary production off Northeast Greenland (phytoplankton, ice algae embedded in fast or pack ice, and benthic algae) varies geographically with water depth and extent of ice cover. Overall, primary productivity is low in Northeast Greenland because large areas are dominated by heavy ice conditions throughout most summers. Areas near the sea ice edge are biologically more important because they become very productive in terms of nutrient concentrations for other species during the spring thaw. The situation for zooplankton is similar, and are likely most concentrated within polynyas.

Crustaceans compose the largest group of marine invertebrates in Greenland with ~800 species including ecologically important ones, such as copepods and krill, and commercial species, such as pink shrimp (northern shrimp; *Pandalus borealis*) and snow crab (*Chionoecetes opilio*). Molluscs and polychaetes are the next largest groups with 282 and 252 species, respectively.

2.2.2 Ice Fauna and Flora

The drifting ice in Northeast Greenland provides habitat for a specialized ecosystem for organisms collectively referred to as "ice fauna and flora". These organisms can form communities that consist of algae living in or on the ice, of small crustaceans (e.g., copepods and amphipods), and of two fish species, namely polar cod (*Boregadus saida*) and Arctic cod (*Arctogadus glacialis*), though little is known about these communities in the Northeast Greenland area.

2.2.3 Fish

Available data suggests that fish diversity in Northeast Greenland waters is lower than in subarctic or boreal regions. The species identified are largely belong benthic-dwelling families, such as Cottidae (sculpins), Zoarcidae (eelpouts), and Liparidae (snailfishes), of low economic value, but high ecological value as food for many Arctic seabirds and marine mammals. Important fish species are described in detail in Section 4.5 of Boertmann et al. (2009a). For species of commercial interest, no major spawning grounds have been identified in east Greenland waters, and sand lance is noted as the only important fish species that spawns in offshore areas during the summer in these waters. Research to date suggests that localized spawning areas with high concentrations of eggs and larvae near the surface are not likely to occur in the area.

2.2.4 Marine-Associated Birds

More than 230 occur in Greenland, with about 75 species occurring regularly, including 58 breeding and 17 non-breeding species. West Greenland's bird life is much better known than other regions of the country. This is largely because most of Greenland's human population live here. Appendix 1 and 2 of this EIA and Appendix 4 of GXT's 2011 Application has more information about the bird species that regularly occur in Northeast Greenland and summarizes their abundance and general distribution. Boertmann et al. (2009a) provided descriptions of important and critical marine habitats for marine-associated birds in the

KANUMAS East assessment area. The areas summarized include breeding colonies, polynyas, other open water (e.g., river outlets, straits, etc), undisturbed areas (for moulting ducks), and the Greenland Sea marginal ice zone.

There are currently 14 Important Bird Areas (IBAs), as designated by the international bird protection organization BirdLife International, in the KANUMAS East assessment area (Boertmann et al. 2009a; see Figure 2). Of these 14 IBAs, one occurs in the GXT 2011 Study Area and seven others occur within 35 to 113 km of the Study Area. Two of these have also been designated as Ramsar sites. A number of regulations, largely concerning mineral exploration, are currently in place for Greenland's Ramsar sites, which include:

- A prohibition of travel within 5 km of a murre site during the breeding season;
- A restriction on helicopters and fixed wing aircraft;
- A ban on hunting or travel within the Ramsar sites additionally designated entirely or partially as nesting bird reserves; and,
- A ban on travel within 500 m of a Ramsar site that is also, in its entirety, designated a nesting bird reserve.

The Ivory Gull is currently listed as *Vulnerable* on Greenland's Red List. Greenland is an international stronghold for the species but the full extent of the breeding population is poorly known. In 2007 and 2008, aerial surveys for seabirds and marine mammals off east and Northeast Greenland, in addition to land surveys and satellite tracking, resulted in locating 35 Ivory Gull breeding sites, including 20 new sites (Gilg et al. 2009). Most of these sites are located in northeasternmost Greenland, including the northern part of the Study Area. See Appendix 1 for a status listing of relevant birds.

2.2.5 Marine Mammals

Boertmann et al. (2009a) provide a detailed review of marine mammals which occur in the KANUMAS East assessment area. The authors noted that 19 marine mammal species occur in the assessment area including the polar bear, walrus, four species of seal, and possibly 13 species of cetaceans. Boertmann et al. (2009a) provide descriptions of periods of occurrence, main habitat, distribution, protection and exploitation, Greenland Red List status, and importance of the assessment area to the marine mammal species (see Section 4.7 *in* Boertmann et al. 2009a). No specific areas have been afforded special status but important ecological areas (as identified by Boertmann et al. 2009a and 2010) are discussed below.

While six species of toothed whales (odontocetes) may occur in the Study Area, only the narwhal is listed as being common in the KANUMAS East assessment area. A significant portion of the global population occurs in the assessment area and the species is a resource for east Greenland communities. This species is also considered a VEC in this EIA. Narwhals usually occur in groups ranging in size from a few individuals to more than 100 and generally occupy relatively shallow summer grounds in fjords and coastal areas (Dietz et al. 1994). Narwhals occur in the wide drift ice belt offshore during the winter. Prior to entering fjords in summer, narwhals tend to congregate along the fast ice edges in spring, waiting for the fjords to open up. Prior to freeze-up of coastal areas in autumn, narwhals migrate to wintering and feeding grounds in deep and densely ice covered waters (Boertmann et al. 2009a).

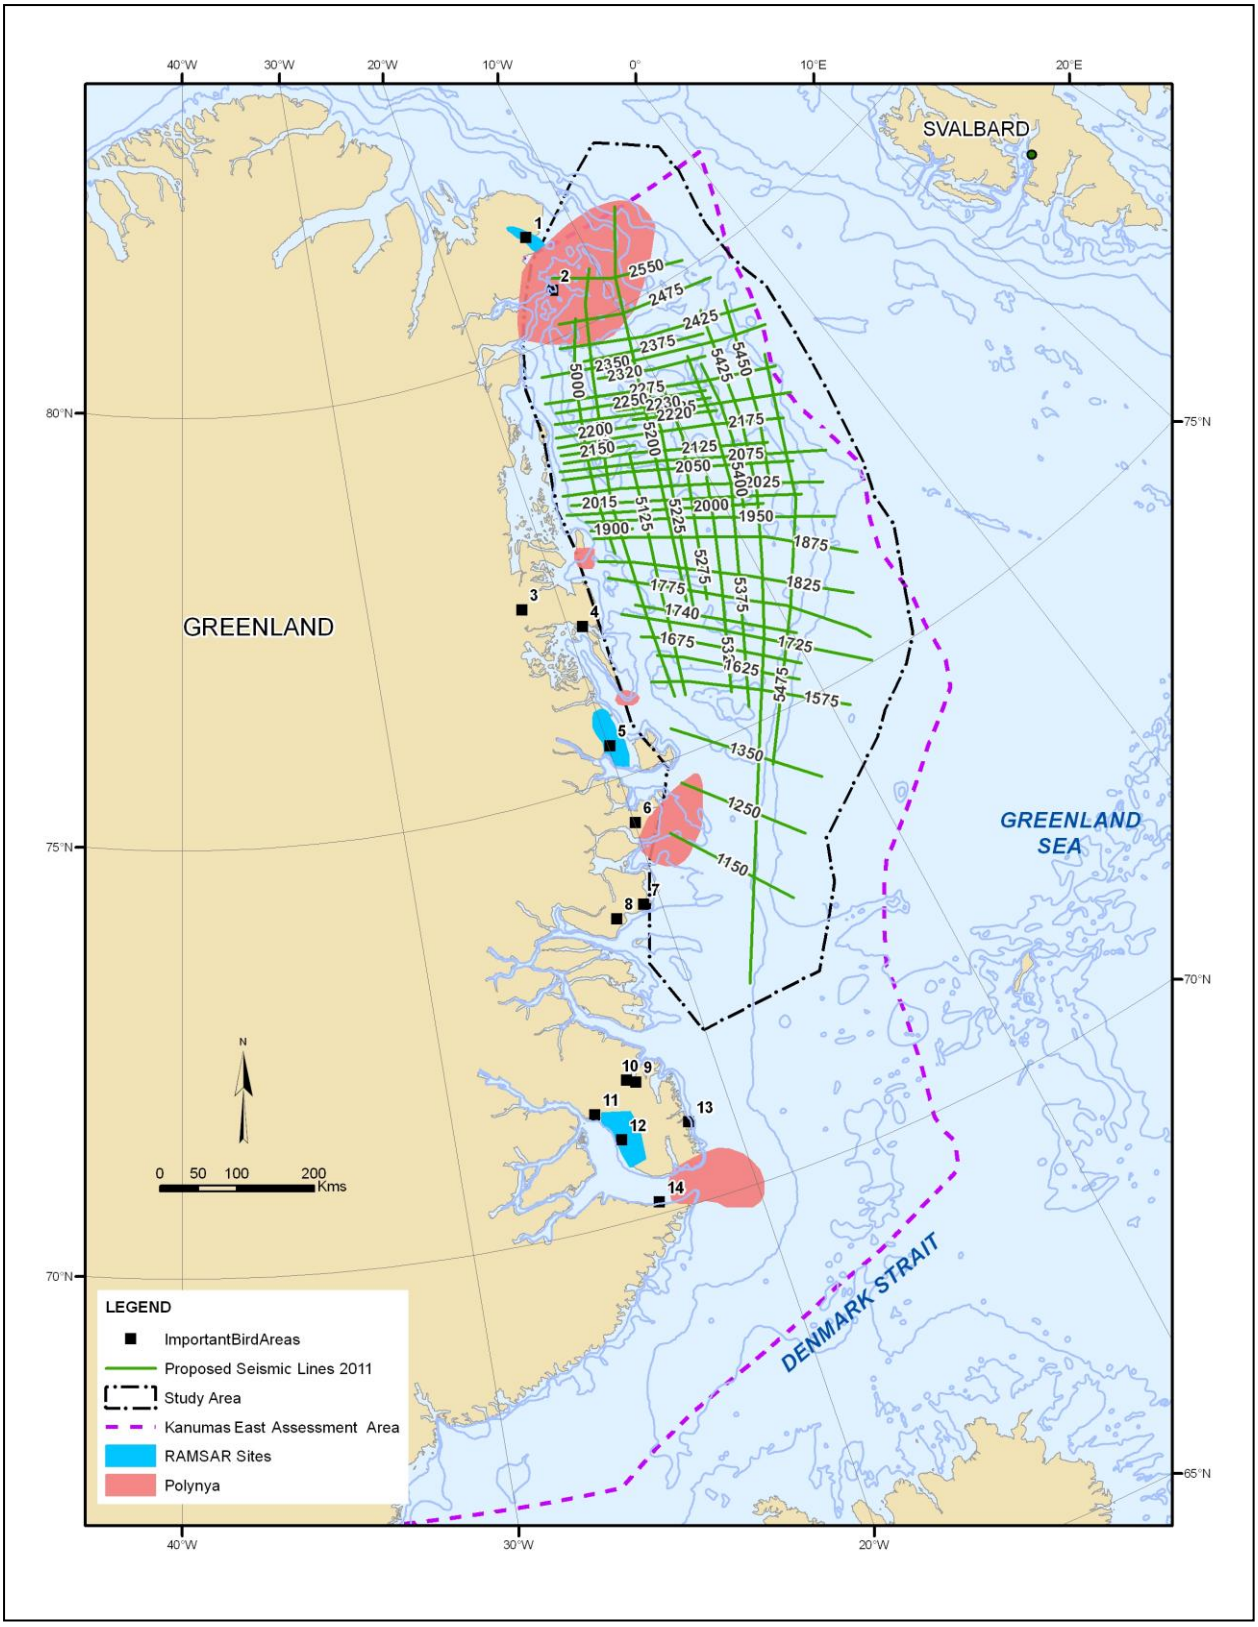

Figure 2. The Locations of Important Bird Areas (IBAs) and Ramsar sites within the KANUMAS East Assessment Area. Numbers in the figure correspond to the IBAs listed in Appendix 2 to this EIA.

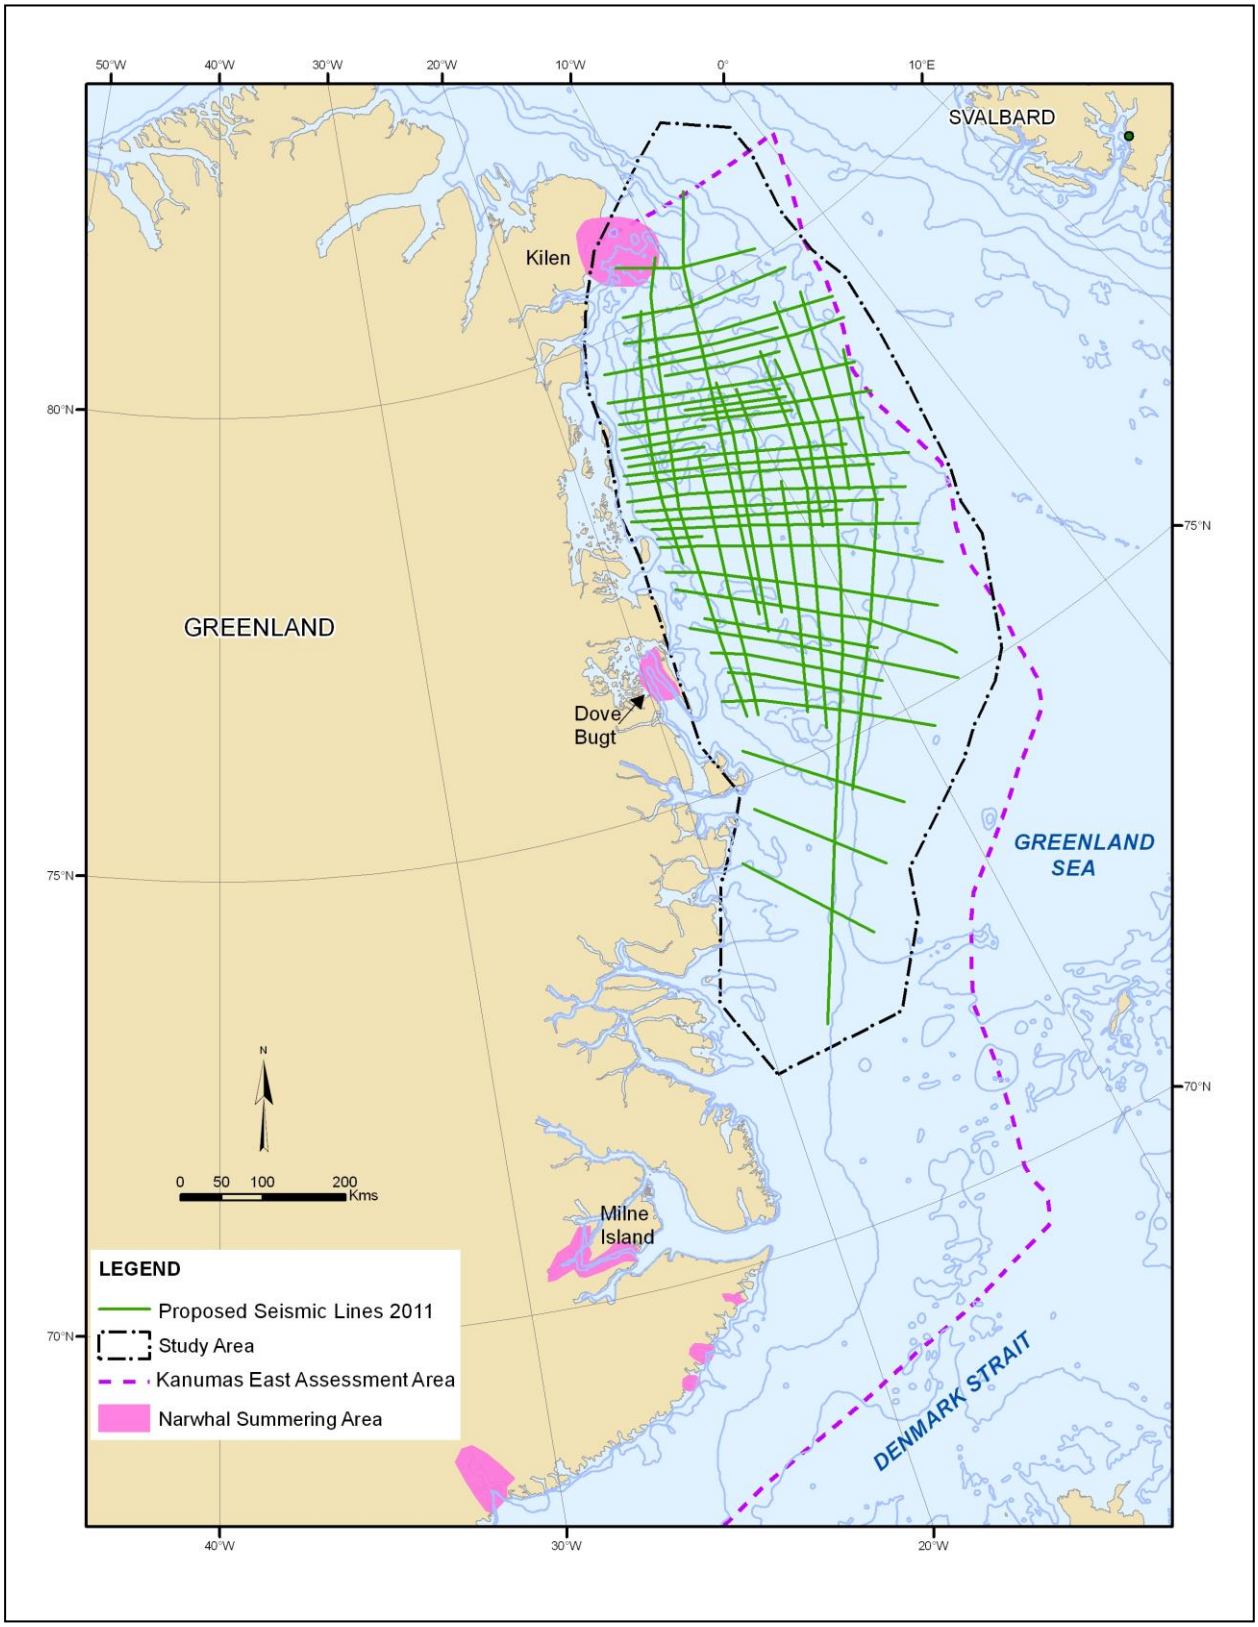

Figure 3. Narwhal Summering Areas in and near the Study Area.

Narwhal protection zones in east Greenland have been designated for the period of 1 July to 30 September, though based on limited information regarding narwhal distribution (Figure 3 shows narwhal summering areas, based on Boertmann et al. 2009a, 2009b and NERI unpublished data; Figure 4 shows the protection zones based on Boertmann et al. 2010). No narwhals were observed during the 2009 or 2010 GXT seismic surveys off Northeast Greenland (Jones et al. 2009, Mactavish and Lang 2011).

Six species of baleen whales (mysticetes) may occur in the Study Area but little is known about the distribution and abundance of these species in the waters off Northeast Greenland. Bowhead whales were considered a VEC in the PSEIA (Boertmann et al. 2009a) because the species is considered *Critically Endangered* and it likely occurs regularly (possibly year-round) in the KANUMAS East assessment area, albeit in low numbers (perhaps a few tens). The remaining five species of baleen whales, all rorquals, are present in the Study Area only during summer. Rorquals migrate north to the North Atlantic in the spring and return south to wintering areas in the fall. Very little information is available regarding these species in the Study Area, but sightings have been most common in drift ice clearings or at the edge of fast ice.

Critical bowhead areas, including potential feeding areas, in Northeast Greenland have not been identified because sightings have been few and very dispersed (Boertmann et al. 2009a); however, precautionary protection zones in east Greenland have been designated (see Figure 4, based on Boertmann et al. 2010).

Bowhead whales were not observed during the 2009 GXT seismic survey off Northeast Greenland (Jones et al. 2009). One cetacean sighting observed within the ice fields was categorized as a single unidentified whale during the 2010 GXT seismic survey off Northeast Greenland, but it is suspected that this cetacean was a bowhead whale based on the habitat (pack ice) and on the features observed during the sighting (Mactavish and Lang 2011).

Pinnipeds. Four species of *seals* (or phocids) are expected to occur in the Study Area including ringed, bearded, harp and hooded seals. Harp seals are most common, followed by hooded seals, ringed seals and bearded seals. Harp and hooded seals are highly migratory species that breed on pack ice off Greenland's west and east coasts. Large aggregations of the two species generally whelp and moult in the same areas on the ice off east and Northeast Greenland. Harp seals typically whelp from March to April and moult in late April. Whelping for hooded seals occurs from late March to early April while moulting occurs from June to early July. After whelping and moulting are completed, individuals of both species disperse into open waters. Ringed and bearded seals occur along all of Greenland's coasts and are commonly associated with sea ice. Unlike harp and hooded seals, these species do not form large whelping and moulting aggregations. The main breeding habitat for ringed seals is considered to be coastal fast ice and consolidated drift ice. From late March to April, the pups are born in lairs made in snowdrifts.

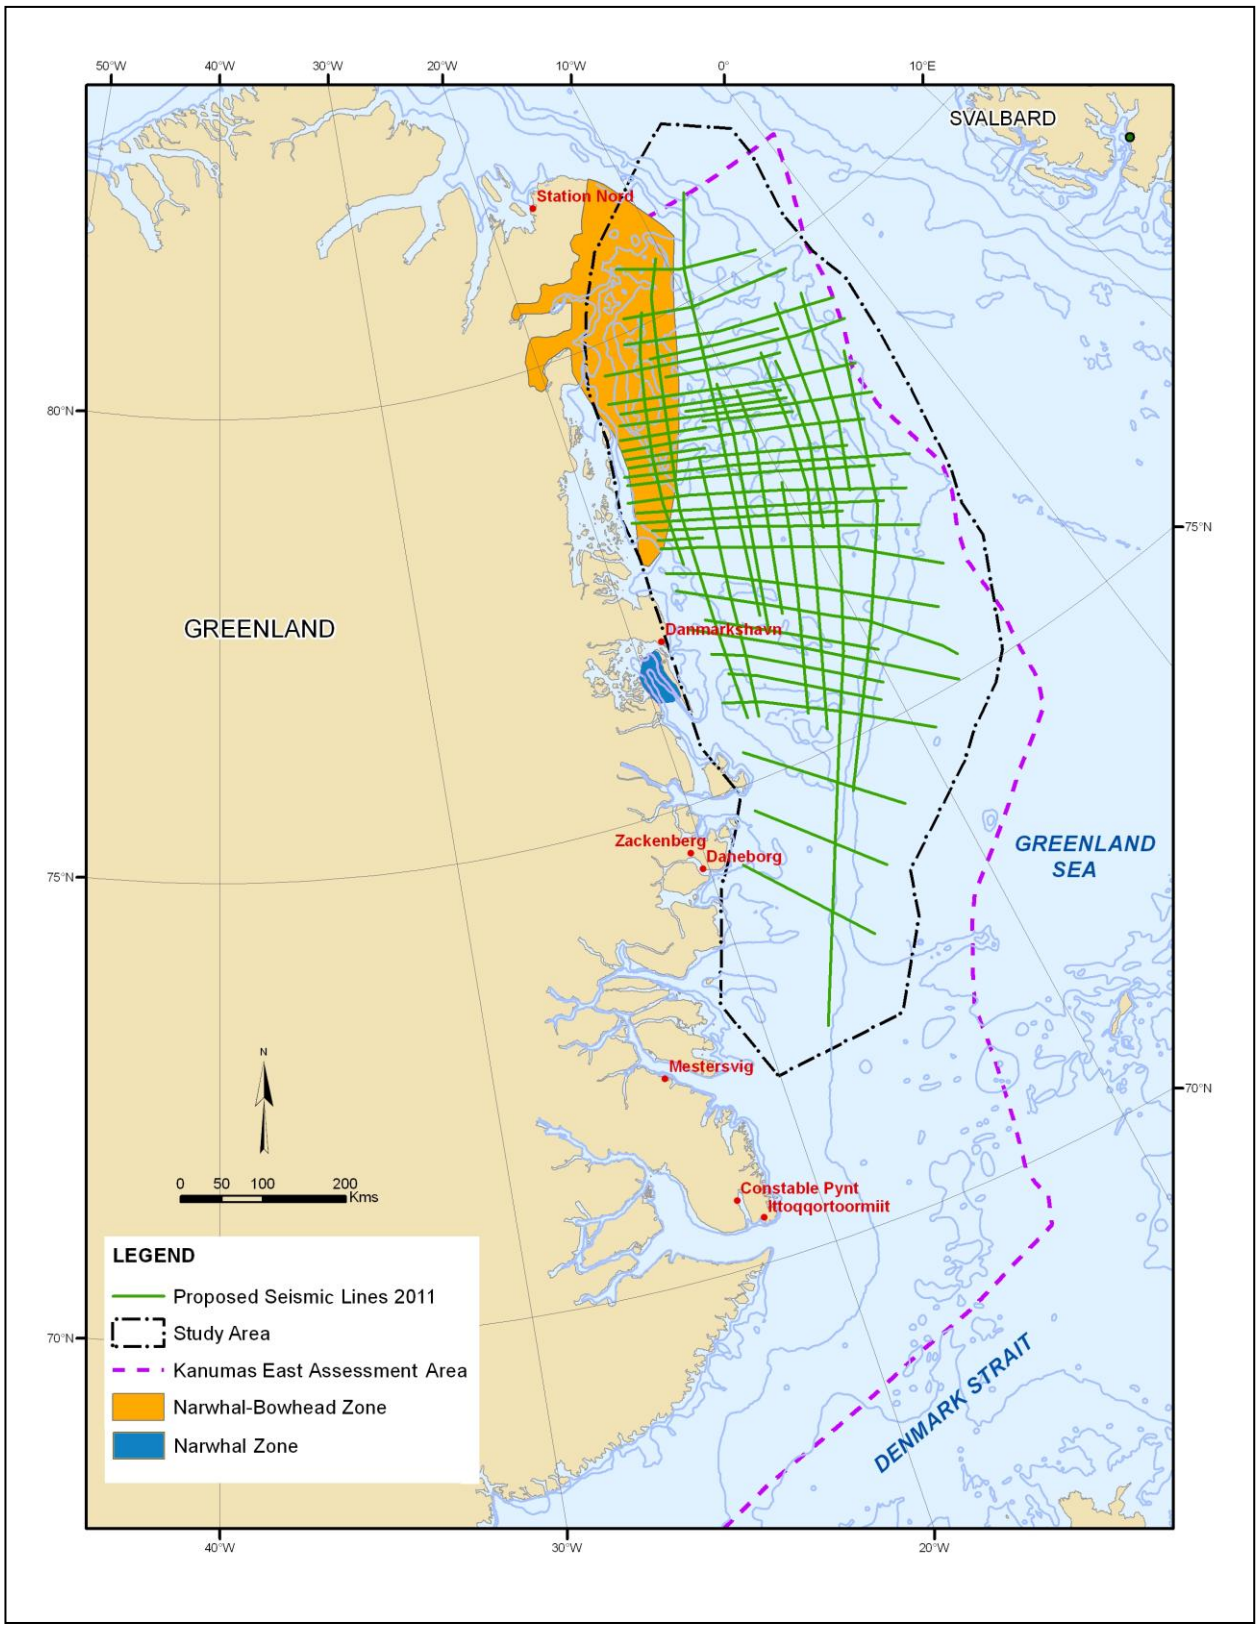

Figure 4. Bowhead and Narwhal Protection Zones in and near the Study Area.

During the 2009 GXT seismic survey off of Northeast Greenland from August through September, there were 16 sightings (18 individuals) of hooded seals, two sightings (two individuals) of ringed seals, and one sighting each of a harp seal and a bearded seal. During the 2010 GXT seismic survey off of Northeast Greenland from July through September, there were 64 sightings (91 individuals) of hooded seals, 15 sightings (15 individuals) of ringed seals, five sightings (six individuals) of harp seals, and three sightings (three individuals) of bearded seals (Mactavish and Lang 2011). The majority of observed seals during the 2009 and 2010 seismic programs could not be identified to the species level (58 sightings of 65 individuals in 2009 and 99 sightings of 145 individuals in 2010; Jones et al. 2009, Mactavish and Lang 2011).

The biology and ecology of the Atlantic walrus in Northeast Greenland is reviewed for the KANUMAS East assessment area in Section 4.7 of Boertmann et al. 2009a). Boertmann et al. (2009a) suggest that close to 1,000 walrus comprise the east Greenland subpopulation; it is listed as *Near Threatened* (Boertmann 2008). The Atlantic walrus generally occurs north of ~63ºN, but principally north of ~73ºN. As described by Boertmann et al. (2009a), the most important areas in Northeast Greenland are (1) the haul-out areas and their surrounding waters, (2) the coastal summer concentration areas, and (3) the winter concentration areas. Walruses can also occur several hundred kilometres offshore from April to August. Mating occurs in winter with an apparent peak in January to April.

No walruses were observed during GXT's 2009 seismic survey offshore of Northeast Greenland (Jones et al. 2009), but four sightings of single walruses were observed during the 2010 GXT seismic survey (Mactavish and Lang 2011). Several protection zones for walruses exist off east Greenland during 1 June to 30 September, although the Northeast Water Polynya is considered a year-round protection zone (see Figure 5, based on Boertmann et al. 2010).

Polar Bears. The polar bear occurs regularly along the entire east coast of Greenland, but the size of this population is unknown (Boertmann et al. 2009a). During summer, polar bears can be found widely distributed in offshore pack ice and prefer areas with dense ice and ice edges. Some bears may also be found associated with the remnants of landfast ice or on land during the minimal ice conditions in summer and early fall (Born and Wiig 1995 *in* Boertmann et al. 2009a). In autumn female bears move to coastal areas where they dig a burrow in snow. This maternity den is where the cubs are born in later winter (Boertmann et al. 2009a).

Polar bear sightings were widespread off of Northeast Greenland during NERI aerial surveys in 2008 (Boertmann et al. 2009b). There were also four sightings (of four individuals) and 21 sightings (24 individuals) during the 2009 and 2010 GXT seismic surveys, respectively, off of Northeast Greenland (Jones et al. 2009, Mactavish and Lang 2011). The biology and ecology of polar bears in Northeast Greenland is extensively reviewed for the KANUMAS East assessment area (see Section 4.7 *in* Boertmann et al. 2009a).

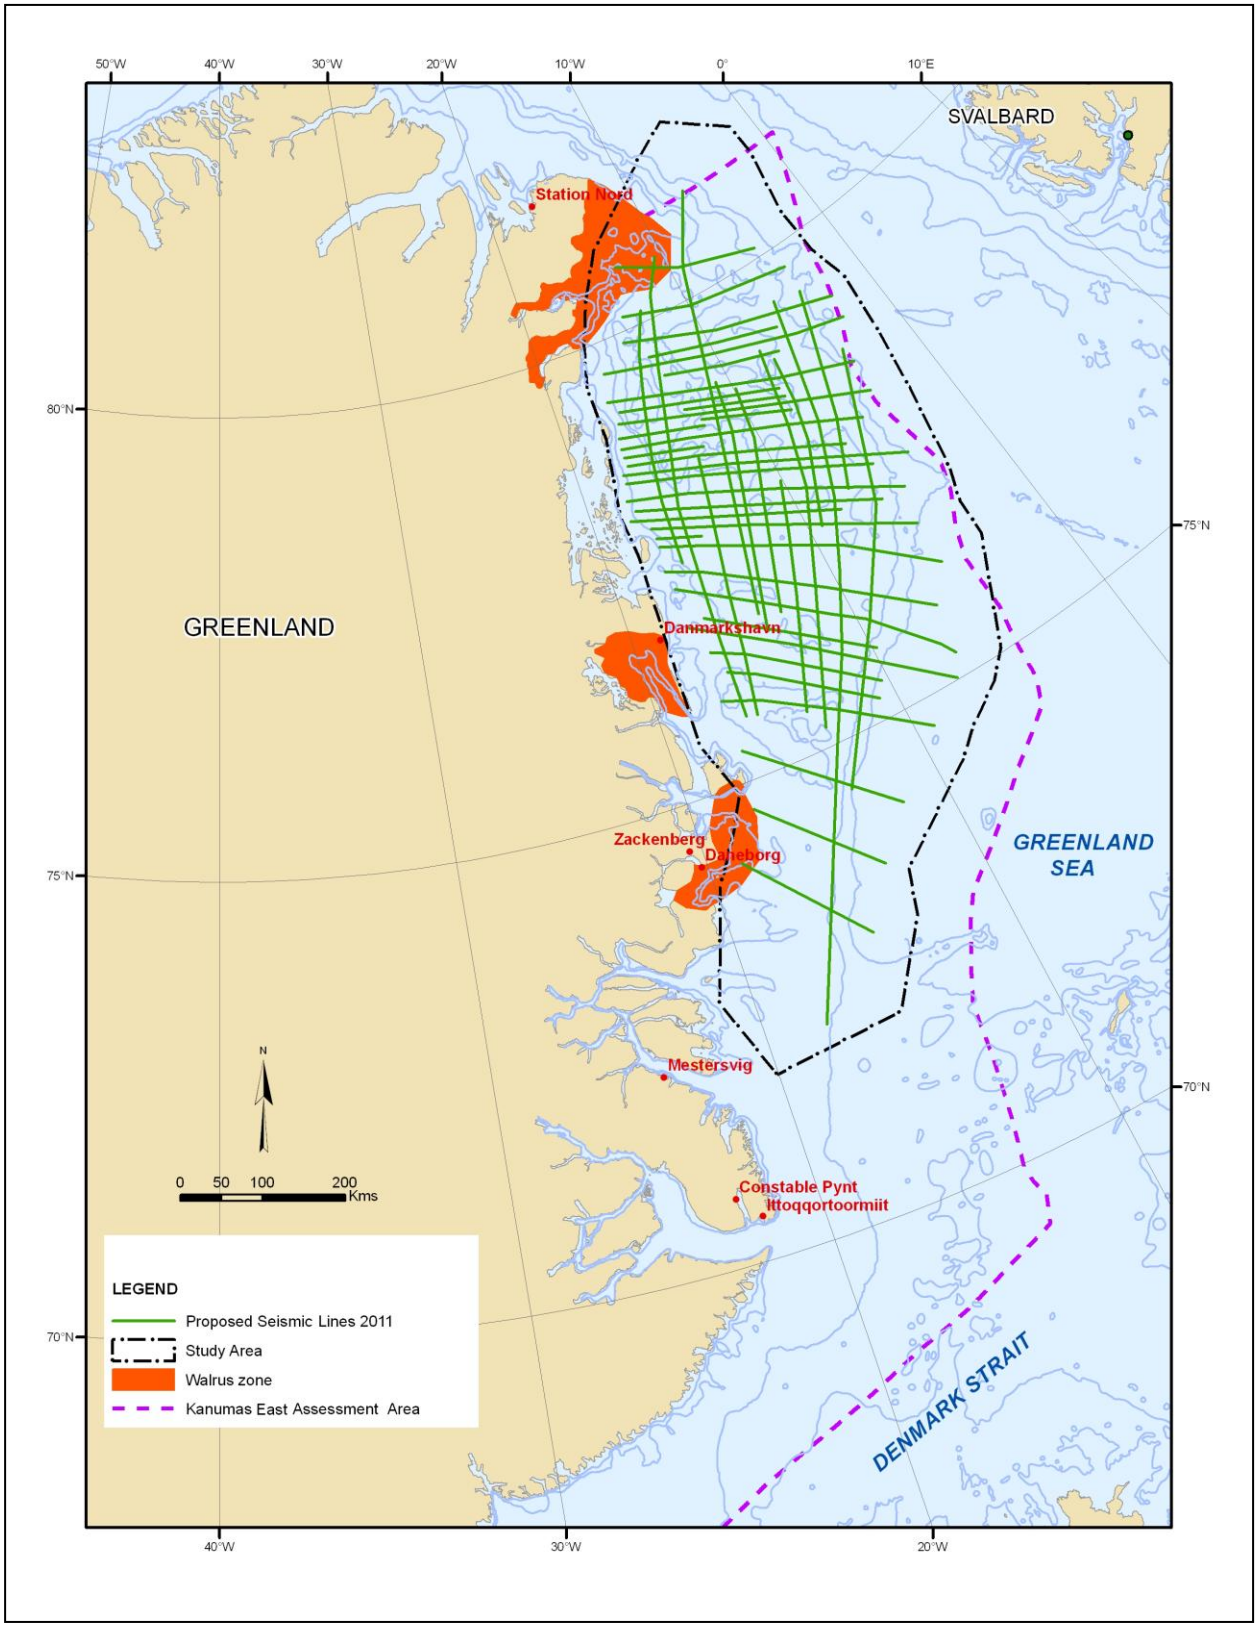

Figure 5. Walrus Protection Zones in and near the Study Area

2.2.6 Threatened Species

Three species of marine mammals and nine species of marine-associated bird species that occur in the KANUMAS East assessment area are listed on the Greenland red list (Boertmann 2008; Boertmann et al. 2009a). In addition, there are seven marine mammals that are currently categorized as *Data Deficient* or *Not Applicable*, but may become red-listed when additional information is available. The *Data Deficient* or *Not Applicable* species include bearded seal, blue whale, killer whale, white-beaked dolphin, narwhal (east Greenland population), sperm whale, and northern bottlenose whale. Appendix 3 to GXT's EIA provides details on relevant species.

Table 1. Greenland Red-listed Marine-associated Species Occurring in the KANUMAS East Assessment Area

Species/Subspecies/Population	Critically Endangered (CR)	Endangered (EN)	Vulnerable (VU)	Near Threatened (NT)
Polar Bear			X	
Walrus				X
Bowhead Whale	X			
Great Northern Diver				X
Light Bellied Brent				X
Sabines Gull				X
Ross's Gull				X
Black-legged Kittiwake			X[1]	
Ivory Gull			X	
Arctic Tern				X[1]
Brünnich's Guillemot			X	
Atlantic Puffin				X

Note: [1]Applies to the entire Greenland population and red-listed because the west Greenland population is decreasing, a trend not apparent in east Greenland.
Source: Boertmann (2008) and Boertmann et al. (2009a). The red list was prepared using regional guidelines issued by the International Union for Conservation of Nature (IUCN) in 2001 and 2003. The Greenland red list did not assess marine fish or invertebrates.

In addition to red-listed species, there are marine-associated species with more than 20% of the global population occurring in Greenland. These species include polar bear, Pink-footed Goose, Light Bellied Brent, Barnacle Goose, Red Knot, Black Guillemot, and Little Auk.

Twenty-three species of marine fish occurring in Greenland waters have been assessed by IUCN with 13 species considered *Data Deficient* or *Least Concern*. With the exception of Atlantic cod, the globally threatened fish species are unlikely to occur in the Study Area. No invertebrate species occurring in Greenland marine waters were listed as globally threatened by IUCN.

Within the KANUMAS East assessment area, there are several hotspots for threatened species, particularly at the mouth of Scoresby Sund, the entrance to Dove Bugt, and the islands of Henrik Krøyer Holme. Polynyas occur at these hotspots (see Figure 45 *in* Boertmann et al. 2009a). Dove Bugt and the islands of Henrik Krøyer Holme occur within or near the Study Area.

2.2.7 Protected Areas and Areas of Interest

National Park. The world's largest national park, encompassing an area of 956,000 km^2, is located in Northeast Greenland. The Northeast Greenland National Park includes the entire northeastern coastline and adjacent interior sections of Greenland. The area is sparsely populated and is composed largely of the Greenland Ice Cap though large ice-free areas occur along the coast and in the north. In addition to a variety of terrestrial mammals, including 40% of the world population of muskox, the park is inhabited by polar bear, walrus, ringed seal, bearded seal, harp seal, hooded seal, narwhal, and beluga. Several species of birds, including Common Loon, Barnacle Goose, Pink-footed Goose, Common Eider, and King Eider, breed in the park (Jensen and Christiansen 2003; WWF 2008). Other protected areas in Northeast Greenland include Important Bird Areas and Ramsar sites, discussed above.

It should also be noted that given the nature of 2-D seismic surveys, the seismic vessel will only occur in a given area for a limited period, and in the case of GXT's 2011 project, will only occur there during August to October, thereby, minimizing the potential for affecting marine mammals in such sensitive areas and during the winter.

2.2.8 Subsistence Hunting and Fisheries

Compared to other regions in Greenland, very little hunting and fishing occurs in and near the Study Area. This is largely attributed to the low number of human inhabitants on the east Greenland coast. In 2006, the human population residing in the KANUMAS East assessment area numbered 529 persons with all living in the town of Scoresbysund (Ittoqqortoormiit) and the surrounding settlements (see Figure 1). There are also several military and research outposts located north of Scoresby Sound though the number of year-round permanent resident is generally low (typically 2 to 12 inhabitants).

In 2004, there were registered 23 occupational hunters and 125 leisure hunters (Aastrup et al. 2005 *in* Boertmann et al. 2009a; Statistics of Greenland 2008). Some hunters from southeast Greenland may venture in the southernmost portion of the KANUMAS East assessment area; however, it is unlikely these hunters travel north of 73ºN and as such, are not expected to occur in or near the survey area. Besides low human population numbers, hunting is likely uncommon in Northeast Greenland because certain species, such as walrus and narwhal, are protected within the boundaries of the Northeast Greenland National Park. Also, all seabird colonies and their immediate surroundings are protected from disturbance. Hunters have historically travelled far north into the National Park to hunt polar bears in early spring; however, this activity has apparently ceased in recent years (Aastrup et al. 2005 *in* Boertmann et al. 2009a).

While fishing is very important in other areas of Greenland, the waters off east Greenland have only been fished commercially since the Second World War (Vihjálmsson et al. 2010). The main reason for this is the rough bottom topography as well as the speed and irregularity of the ocean currents, especially near the edge of the continental shelf. These conditions make fishing in east Greenland waters difficult for most harvesters, except for those using large vessels with robust fishing gear. The major commercial fisheries of east Greenland waters target Greenland halibut, Atlantic cod, redfish (*Sebastes* spp.), Atlantic salmon (*Salmo salar*), Arctic char (*Salvelinus alpinus*), and pink shrimp (Boertmann et al. 2009a; Vihjálmsson et al. 2010). With the exception of pink shrimp since the 1980s, the fisheries off

east Greenland have almost exclusively been conducted by foreign fleets (Vihjálmsson et al. 2010). Boertmann et al. (2009a) noted that the only species of commercial interest off Northeast Greenland is the Greenland halibut. This fishery occurs on the east Greenland coast occurs almost exclusively in open water from Denmark Strait southward. In Northeast Greenland, catches are generally small and largely confined to the southernmost part of the KANUMAS East assessment area near Scoresby Sund. Arctic char is largely fished near inhabited areas in Greenland, typically between June and September.

Other species that may be caught occasionally, mainly for domestic use, include spotted wolffish (*Anarchichas minor*), Greenland shark (*Microcephalus somniosus*), Greenland halibut, shorthorn sculpin (*Myxocephalus scorpius*), and polar cod (Sandell and Sandell 1991 *in* Boertmann et al. 2009a; Petersen 1993 *in* Boertmann et al. 2009a). The fisheries for these species within the 2011 survey area are likely to be minor to none.

3 Impact Assessment

3.1 Impact Assessment Methods

This Environmental Impact Assessment uses the methods presented in the Preliminary Strategic Environmental Impact Assessment (PSEIA) for the KANUMAS East area of Greenland (Boertmann et al. 2009a) and also incorporates relevant guidance from the Application Guidelines (BMP 2011), the Seismic Guidelines (Boertmann et al. 2010), Guidelines for Environmental Impact Assessment in the Arctic: Arctic Environmental Protection Strategy (FMOTE 1997), and the *Canadian Environmental Assessment Act (CEAA) Responsible Authorities Guide* (CEAA 1994). It applies the same approach and methodologies used in GXT's 2009 and 2010 Northeast Greenland survey environmental assessments.

The assessment process includes:

- a description of the proposed project (Section 1, above);
- identification of spatial and temporal boundaries;
- identification of Valued Ecosystem Components (VECs);
- overview of the project environment, with emphasis on key VECs;
- assessment of impacts;
- preparation of an interaction matrix
- assessment of interactions
- identification of impacts
- development of mitigation measures
- impact summary;
- assessment of cumulative impacts; and
- development of environmental protection plan / mitigations (presented in Section 3 and summarized in Section 4).

3.2 Spatial and Temporal Boundaries

For the purposes of this EIA, the following spatial and temporal boundaries are defined. These are the same defined for GXT's 2009 and 2010 survey assessments since the relevant parameters have not changed.

Temporal—the temporal boundaries of the Project are July to October 2011.

Project Area—the 'Project Area' is defined as the area of the "footprint" of the seismic lines plus an additional area (~5 km) around the outer perimeter of these lines to accommodate the ships' lead in requirements and turning radii .

Affected Area—the 'Affected Area' varies according to the specific vertical and horizontal distributions and sensitivities of the VECs of interest and is defined as that area within which effects (physical or important behavioural ones) have been reported to occur. It is likely that most potential effects will be confined within the Project Area because the actual effects on animals are caused by the operating array at a particular time. At each point in time, the array

ensonifies a particular area around the array and potentially affects animals in that area. The array then moves along the seismic line and affects new areas while the previously affected areas returns to normal and any effects may be reversed. In the assessment that follows, we have used an area referred to as '*spatial extent*'. This is the area where impacts on VECs may occur at any point in time. As noted, this area is dynamic because it "moves along" with the seismic source vessel within the Project Area.

Study Area—an area around the Project Area large enough to encompass effects reported in the literature. Because belugas in the Canadian Beaufort have been shown to avoid seismic operations by 10-20 km (Miller et al. 2005), this EIA considers an area ~ 20 km around the outer perimeter of the proposed survey lines (see Figure 1). (Though the overall 2011 survey "footprint" is smaller, the same Study Area used in 2010 is used here for consistency of the assessment.)

KANUMAS East Assessment Area—when considering cumulative effects, we have considered a broader or regional area whose boundaries were defined as the "assessment area" for the larger KANUMAS East PSEIA (Boertmann et al. 2009a) (see Figure 1). Cumulative effects assessment would also include the GXT Study Area which extends northward of the KANUMAS East assessment area.

3.3 Identification of Potential Impacts

This EIA focuses on the potential impacts that result from the interactions between project activities and Valued Ecosystem Components (VECs). As defined in the PSEIA, VECs can be "a species, a population, biological events or other environmental features that are important to the human population (not only economically), have a national or international profile, can act as indicators of environmental change or can be the focus of management or other administrative efforts." The VECs selected here are species and faunal groups which potentially can be impacted by seismic exploration activities in the Study Area.

An interaction matrix was prepared that identified all possible Project activities that could interact with any of the VECs. This matrix is used only to identify potential interactions; they make no assumptions about the actual or potential effects of the interactions.

Interactions were then evaluated for their potential to cause effects. In instances where the potential for an effect of an interaction was deemed impossible or extremely remote, these interactions were not considered further. In this way, the assessment focused on key issues and the more substantive potential environmental effects. Although the likelihood of a significant fuel spill is remote, information pertaining to potential effects of accidents and malfunction (primarily the release of hydrocarbons) has been provided.

An interaction was considered to be a potential effect if it could change the abundance or distribution of VECs, or change the prey species or habitats used by VECs. The potential for an effect was assessed by considering:

- the location and timing of the interaction;
- the literature on similar interactions and associated effects;
- when necessary, consultation with other experts; and
- results of similar effects assessments and especially, monitoring studies done in the Arctic, notably the Beaufort Sea.

A Level 1 Interaction Matrix (Table 2) is provided below.

Table 2. Potential Interactions (Level 1 Matrix) between the Project and VECs

VEC	Project Activity				
	Airgun Array	**Vessel/Icebreaker: Noise / Disturbance**	**Vessel Lights**	**Sanitary/ Domestic Wastes**	**Accidental Spills**
Bowhead Whale	X	X	X	X	X
Narwhal	X	X	X	X	X
Walrus	X	X	X	X	X
Seals [1]	X	X	X	X	X
Polar Bear	X	X	X	X	X
Sea-associated Birds	X	X	X	X	X
Fish	X	X	X	X	X
Zooplankton	X		X	X	X
Invertebrates	X		X	X	X

Note: Accidental spills refers to the release of fuel (or other hydrocarbons); see Section 3.12.
[1] Combines ringed, bearded, hooded, and harp seals.

The selection of VECs closely follows those selected for assessment under seismic programs in the PSEIA (Boertmann et al. 2009a). An important factor considered in the assignment of impact significance is the official status of the VEC. For example, particular attention is paid to species considered to be 'at risk' under the Greenland Red List (Boertmann 2008) which are likely to occur in the Study Area, and VECs that have identified protected areas within the Study Area. There is little hunting or commercial harvesting activity in the Study Area and as such, this is not considered further in the EIA.

3.4 Impact Definitions and Evaluation of Impact Significance

It is important that the terminology used to describe potential impacts be clear and easily understood. Words such as minor, moderate, and significant or insignificant are subjective and their meaning differs depending on the context in which they are used and the experience of the reader. Therefore, precise definitions for the ranking of potential impacts have been provided and used in this EIA. The impact definitions used in this EIA are based on those outlined in CEAA (1994) and subsequent CEAA-compliant EAs prepared by LGL Limited[1]. More specifically the terminology of *magnitude*, *spatial (or geographic) extent*, *and duration*, has been used.

Where possible, the assessment technique and terminology provided in the PSEIA (Boertmann et al. 2009a) are considered in the assessment. The PSEIA specifically includes consideration of the risk of impact on critical habitat, the level of impact (individual vs. population), and the risk of long-term population impacts. The assessment of significance of

[1] The following criteria have not been specifically included in this assessment are *frequency of occurrence*, *ecological, socio-cultural and economic context*, *reversibility,* and *likelihood of occurrence*.

the potential effects of the proposed project on environmental components is made considering the application of mitigation measures (see Environmental Protection Plan). The assessment of residual impacts, including mitigation measures, is summarized in Table 3.

3.4.1 Magnitude of Impacts

Magnitude describes the nature and extent of the environmental effects for each activity. It is a challenge to define magnitude since it is unclear which "biological" (and in some cases, "socio-economic") measures should be included in the definition. After careful consideration, we have decided to use definitions similar to those used in the Devon seismic EA for the Canadian Beaufort (IEG 2001) and in recent EAs conducted for seismic programs in Atlantic Canada (e.g., Moulton et al. 2003). The magnitude of impacts can be rated as:

Major: An impact on a VEC is rated major if it is judged to result in a 10%, or greater, change in the size or health of a population, or the carrying capacity of its habitat. A change in a population can result from an absolute reduction in population size or from displacement of animals to areas outside the area of consideration.
Moderate: An impact on a VEC is rated moderate if it is judged to result in a 1% to 10% change in the size or health of a population, or the carrying capacity of its habitat.
Minor: An impact on a VEC is rated minor if it is judged to result in a less than 1% change in the size or health of the population or the carrying capacity of its habitat.
Negligible Impact: Negligible impacts would result in no to very minimal effects to a VEC.

It should be noted that changes as low as 1%, or even 10%, cannot be measured in practice. However, these levels are used so that the reader has a clear indication of the expected magnitude of potential impacts.

Table 3. Summary of Potential Impacts, Proposed Mitigation, and Predicted Residual Impacts for the Project Area VECs

VEC / Interaction	Potential Impact	Mitigation Measure(s)	Impact Definition Ratings			Predicted Residual Impact	Level of Confidence in Prediction
			Spatial Extent	Magnitude	Duration		
Bowhead Whales x Seismic Noise	[1]Hearing damage. Masked communication. [2]Disturbance including avoidance of seismic ship and alteration of migration route.	Ramp-up of airgun array following detailed BMP/NERI advice. Delayed start of airguns if whale sighted in safety zone. Array shutdown (500 m in Protected Zones; 200 m elsewhere). Widely spaced lines in sensitive areas. Additional marine mammal watch from icebreaker.	[1] < 1 km^2 to 1-10 km^2; [2] 11-100 km^2 to 101-1,000 km^2	[1] Minor; [2] Minor to Moderate	Short-term	Not significant	[1] High; [2] Medium
Bowhead Whale x Vessel Noise	Disturbance including avoidance.	Boats will maintain constant course & speed when possible. Widely spaced lines in sensitive areas. Additional marine mammal watch from icebreaker.	11-100 km^2	Negligible to minor	Short-term	Not significant	High
Narwhal x Seismic Noise	[1]Hearing damage. [2]Disturbance including localized avoidance of seismic ship.	Ramp-up of airgun array following detailed BMP/NERI advice. Delayed start of airguns if whale sighted in safety zone. Array shutdown (500 m in Protected Zones; 200 m elsewhere). Widely spaced lines in sensitive areas. Additional marine mammal watch from icebreaker.	[1] na, [2]11-100 km^2 to 101-1,000 km^2	[1]Negligible, [2] Minor to Moderate	[1] na, [2] short-term	Not significant	[1] High; [2] Medium
Narwhal x Boat Noise	Temporary disturbance.	Boats will maintain constant course & speed when possible. Widely spaced lines in sensitive areas. Additional marine mammal watch from icebreaker.	11-100 km^2	Minor to Moderate	short-term	Not significant	Medium

VEC / Interaction	Potential Impact	Mitigation Measure(s)	Impact Definition Ratings			Predicted Residual Impact	Level of Confidence in Prediction
			Spatial Extent	Magnitude	Duration		
Walrus x Seismic Noise	[1]Hearing damage (seismic). [2]Disturbance including localized avoidance (of seismic ship).	Ramp-up of airgun array following detailed BMP/NERI advice. Delayed start of airguns if whale sighted in safety zone. Array shutdown (500 m in Protected Zones; 200 m elsewhere). Widely spaced lines in sensitive areas. Additional marine mammal watch from icebreaker.	[1] na, [2] <1 km^2 to 11-100 km^2	[1]Negligible, [2] Minor to Moderate	[1] na, [2] short-term	Not significant	[1] High; [2] Medium
Walrus x Boat Noise	Temporary disturbance.	Boats will maintain constant course & speed when possible. Minimize time spent near summering areas. Additional marine mammal watch from icebreaker.	[1] < 1 km^2; [2] 101-1,000 km^2	Minor to Moderate	short-term	Not significant	High
Seals x Seismic Noise	[1]Hearing damage. [2]Disturbance including localized avoidance of seismic ship.	Ramp-up of airgun array. Additional marine mammal watch from icebreaker.	[1] na, [2] <1 km^2 to 11-100 km^2	[1]Negligible, [2] Minor to Moderate	[1] na, [2] short-term	Not significant	High
Seals x Boat Noise	Temporary disturbance.	Boats will maintain constant course & speed when possible. Additional marine mammal watch from icebreaker.	na	Negligible	na	Not significant	High
Polar Bear x Seismic Noise	[1]Hearing damage (seismic). [2]Disturbance including localized avoidance (of seismic ship).	Ramp-up of airgun array. Additional marine mammal watch from icebreaker.	[1] na, [2] 1-10 km^2	[1]Negligible, [2] Negligible to Minor	[1] na, [2] short-term	Not significant	High

VEC / Interaction	Potential Impact	Mitigation Measure(s)	Impact Definition Ratings			Predicted Residual Impact	Level of Confidence in Prediction
			Spatial Extent	Magnitude	Duration		
Polar Bear x Boat Noise	Temporary disturbance.	Boats will maintain constant course & speed when possible. Additional marine mammal watch from icebreaker.	na	Negligible	na	Not significant	High
Sea-associated Birds x Seismic and Boat Noise	[1] Hearing damage (seismic). [2] Disturbance including localized avoidance (of seismic vessel)	Ramp-up of airgun array. Boats will maintain constant course and speed. Not near IBA, etc. Aircraft (if used) will avoid important bird areas.	na	Negligible	Short-term	Not significant	High
Zooplankton x Seismic Noise	Physical damage.	None	< 1 km^2	Minor	Short-term	Not significant	High
Macroinvertebrates x Seismic Noise	Physical damage, behavioural disturbance	Ramp-up of airgun array.	<1 km^2 to 11-100 km^2	Minor	Short-term	Not significant	High
Fish x Seismic Noise	[1] Hearing damage. Masked communication. [2] Disturbance including avoidance of seismic ship	Ramp-up of airgun array.	[1] < 1 km^2; [2] 101-1,000 km^2	Minor	Short-term	Not significant	High
Fish x Boat Noise	Localized avoidance	None (not likely in survey area)	<1 km^2 to 101-1,000 km^2	Minor	Short-term	Not significant	Medium

Notes: na = not applicable

3.4.2 Spatial Extent

The spatial or geographic extent of impacts refers to the specific area (km^2) affected by the project activity, which may vary depending on the activity and the relevant VEC. Spatial extent can be categorized as:

- < 1 km^2
- 1-10 km^2
- 11-100 km^2
- 101-1,000 km^2
- 1,001-10,000 km^2
- >10,000 km^2

It should be noted that an area of 100 km² is a circle with a radius of 5.6 km around the airgun array. A circular area of 1,000 km² would have a radius of about 17.8 km and an area of 10,000 km² would have a radius of about 56 km around the array. The PSEIA (Boertmann et al. 2009a) uses "local" to describe a spatial extent of <100 km², "regional" for larger areas, including the entire KANUMAS East Assessment Area, and national and global spatial extents.

3.4.3 Duration of Impacts

Duration refers to the time period impacts are expected to persist. Duration categories include:

- **Immediate:** Impact duration is limited to less than two days.
- **Short-term:** Impact duration is longer than two days but less than one year.
- **Medium-term:** Impact duration is one year or longer but less than ten years.
- **Long-term:** Impact duration extends ten years or longer.

The PSEIA (Boertmann et al. 2009a) uses "immediate", "short term", and "long term", as indicators of duration; specific definitions are not provided.

3.4.4 Significance of Impacts

Significant environmental effects are those that are considered to be of sufficient magnitude, duration, and spatial extent to cause a change in the VEC that will alter its status or integrity beyond an acceptable level, even after mitigation measures are applied. Establishment of the criteria is based on professional judgment, but should be transparent and repeatable. In this EIA, a *significant* effect is defined as:

Having a major magnitude; or a moderate magnitude for a duration of greater than one year and over a spatial extent greater than 100 km^2.

An effect can be considered ***significant*** *(negative by definition)*, ***not significant***, or ***positive***. For this assessment, impacts are judged assuming the implementation of project mitigation measures, i.e., an assessment of residual impacts.

3.4.5 Level of Confidence

An assessment of scientific certainty (low, medium, and high levels of confidence) will be provided based on our confidence in the scientific information available when we have judged an impact as having a particular adverse impact on a VEC.

- **Low:** Based on incomplete understanding of cause-effect relationships and/or incomplete data specific to project area.
- **Medium:** Based on good understanding of cause-effect relationships using data from elsewhere or incompletely understood cause-effect relationships using data specific to project area.
- **High:** Based on good understanding of cause-effect relationships and data specific to project area.

The PSEIA (Boertmann et al. 2009a) use terms such as "most likely" and "most probably" to reflect the level of certainty in the assessment.

3.5 Potential Impact of Project Activities

This assessment of the potential impacts of project activities on VECs is based on recent field studies of similar seismic operations in Northeast Greenland, the Alaskan and Canadian Beaufort Sea (including GXT's 2006, 2007, 2008 and 2010 programs in the Canadian Beaufort Sea) and on an extensive review of the available literature on the subject. Residual impacts (those impacts that result after implementation of mitigation) resulting from the proposed project are identified in terms of their scope and significance for each VEC.

It should be noted that, in terms of whales, seismic operations in ice appear to be less likely to encounter them, particularly when the survey is operating deeper into ice covered areas. This is suggested by the lack of observation in such areas during GXT's two previous Northeast Greenland surveys and GXT's 2010 in-ice survey in the Canadian Beaufort Sea, all of which were conducted with marine mammal observers on board the ships.

To further ensure the accuracy of the assessment predictions that no effects will be significant with mitigations in place, GXT will apply enhanced mitigation measures for the 2011 program, over those applied in previous years, particularly within the Protection Zones (for walrus, narwhal and bowhead). For example, as described in Section 3.6 below, as a further cautionary approach, GXT will increase the shutdown zone implemented during its 2009 and 2010 seismic programs from 200 m to 500 m around the seismic source for bowhead whale, northern right whale, beluga, narwhal, or walrus in all protection areas/zones. Further, in all areas, GXT will maintain an increased marine mammal watch from the icebreaker. This should extend the ability to detect whales / walruses in the approaching waters a further 1000 m or more and to alert the seismic ship MMSOs. These are in addition to previously stated / implemented measures, such as avoidance of the ice edge by 10 km in the Hovgaard - Île de France region.

3.5.1 Underwater Sound

Most treatments of the effects of underwater sound are based on the Source:Path:Receiver concept. In the present case, the sound source is an airgun array that generates short pulses

that contain large amounts of underwater sound. A seismic pulse is created by a burst of compressed air released from each airgun that makes up the array. Sound from the array radiates outward and travels through the water as pressure waves. Approximately 90% of the sound energy is focused downward with some travelling radially in the horizontal plane. Water is an efficient medium through which sounds can travel long distances. The receiver of these sounds is a marine animal of interest (*i.e.* VECs). The sounds received depend upon how much propagation loss occurs between the source and the receiver. Propagation loss is much higher in shallow water due to attenuation.

The ability of the receiver to detect these signals depends upon the hearing capabilities of the species in question and on the amount of natural ambient or background noise in the sea around the receiver. The sea is a naturally noisy environment and this noise can "drown out" or mask weak signals from distant sources.

Pressure waves from airguns used in seismic exploration have slower rise times than traditional explosives and therefore cause much less injury to animals in water. Single airguns produce downward-directed pulses that last only 10-20 ms, with only one strong positive and one strong negative peak pressure (Caldwell and Dragoset 2000).

Current seismic data acquisition practices utilize arrays of airguns to achieve the penetration requirements needed to illuminate the geologic subsurface. The distribution of the airgun elements within the array forms a geometry that increases the efficiency of the total energy source by directing its output downward into the subsurface by means of constructive interference of the signals from the individual guns. This happens at the expense of the amount of energy that propagates laterally due to geometric destructive interference. Approximately 90% of the useful energy is focused downward; the predominant energy is at low frequencies.

3.5.2 Effects of Sound on Marine Animals

Appendix 4 of GXT's Application (Volume 2) contains more detailed information about sound fundamentals, sound exposure measurement, and the effects of underwater sounds on marine animals.

Sounds produced by airgun arrays are lower in frequency than those at which toothed whales (such as narwhals), seals and walrus have optimal hearing, but are probably within the best hearing range of baleen whales (such as bowheads). Data on the specific hearing capabilities of polar bears are limited. However, polar bears' usual behaviour (e.g., remaining on the ice, at the water surface, or on land) reduces or avoids their exposure to underwater sounds.

Recent reviews of the effects of sound from seismic surveys, and sources of man-made noise in general, on marine mammals can be found in several recent sources. There are four types of potential effects of seismic sounds on marine mammals considered in the following sections. These include:

1. temporary reduction in hearing sensitivity, evident as Temporary Threshold Shift (TTS);
2. permanent hearing impairment, evident as Permanent Threshold Shift (PTS);
3. masked communication, and

4. changes in behaviour and distribution of the animals that are of sufficient magnitude to be "biologically significant".

Temporary Threshold Shift (TTS) is the mildest form of hearing impairment that occurs when exposure to a strong sound results in a non-permanent elevation of the hearing threshold. TTS is common in humans. While experiencing TTS, a sound must be louder in order to be heard. TTS is not considered an injury (Southall et al. 2007). Recent preliminary simulation modeling suggested that some baleen whales whose closest point of approach to a seismic vessel is 1 km or more could experience TTS or even PTS (Gedamke et al. 2008). In practice during seismic surveys, few if any cases of TTS are expected in baleen whales given the strong likelihood that baleen whales would avoid the approaching airguns (or vessel) before being exposed to levels high enough for there to be a possibility of TTS. For odontocetes, it is expected that—for impulse sound—the onset of TTS would occur at a lower cumulative sound exposure levels given the assumed greater auditory effect of broadband impulses with rapid rise times.

There are no available data on TTS in polar bears. However, TTS is unlikely to occur if they are swimming at the water surface or on ice, given the pressure release and Lloyd's mirror effects at the water's surface. In pinnipeds, TTS thresholds associated with exposure to brief pulses (single or multiple) of underwater sound have not been measured. Initial evidence from more prolonged (non-pulse) exposures suggested that some pinnipeds (harbour seals in particular) incur TTS at somewhat lower received levels than do small odontocetes exposed for similar durations (Kastak et al. 1999, 2005; Ketten et al. 2001).

The U.S National Marine Fisheries Service (NMFS 1995, 2000) has concluded that whales should not be exposed to impulse noise at received levels exceeding 180 dB re 1 μPa (rms). The corresponding limit for seals has been set at 190 dB. These exposure criteria used by NMFS were intended as a precautionary estimate below which physical injury would not occur from airgun pulses. There was no empirical evidence about whether higher levels of pulsed sound would cause hearing or other injuries.

Permanent Threshold Shift is the result of physical damage to a marine mammal's hearing apparatus can occur if it is exposed to sound impulses that have high peak pressures, especially if they have very short rise times, or if the animal is exposed to long periods of high noise levels. Such damage can result in a permanent decrease in functional sensitivity of the hearing system at some or all frequencies. When PTS occurs, there is physical damage to the sound receptors in the ear. In some cases, there can be total or partial deafness, while in other cases, the animal is unable to hear sounds at specific frequency ranges.

Single or occasional occurrences of mild TTS do not cause permanent auditory damage in terrestrial mammals, and presumably do not do so in marine mammals. However, very prolonged exposure to noise strong enough to elicit TTS, or shorter-term exposure to noise levels well above the TTS threshold, can cause PTS. Some factors that contribute to onset of PTS are

- exposure to single very loud noises,
- repetitive exposure to loud sounds that individually do not cause PTS, and
- health of the receiver's ear (e.g., recurrent ear infections).

Sound impulse duration, peak amplitude, and rise time are the main factors thought to determine the onset and extent of PTS. Based on existing data, Ketten (1995) has noted that

the criteria for differentiating the sound pressure levels that result in PTS (or TTS) are location and species-specific.

On an SEL (Sound Exposure Level, a standard means of quantifying received sound) basis, Southall et al. (2007:441-4) estimated that received levels would need to exceed the TTS threshold by at least 15 dB for there to be risk of PTS. Thus, for cetaceans (like bowhead whales) they estimate that the PTS threshold might be a cumulative SEL (for the sequence of received pulses) of ~198 dB re 1 $\mu Pa^2 \cdot s$.[2] Southall et al. (2007) also note that, regardless of the cumulative received energy (SEL), there is concern about the possibility of PTS if a cetacean or pinniped received one or more pulses with a very high peak pressure. Based on data from terrestrial mammals, a precautionary assumption is that impulse sounds might cause immediate PTS if the received peak pressure were 6 dB (or more) above than the TTS threshold as measured on a peak-pressure basis (Southall et al. 2007). They conclude that PTS might occur if cetaceans (as exemplified by belugas and bottlenose dolphins) and pinnipeds (as exemplified by the harbour seal) were exposed to peak pressures exceeding 230 or 218 dB re 1 µPa (peak), respectively. A peak pressure of 230 dB re 1 µPa (3.2 bar · m, 0-pk) would only be found within a few meters of the largest airguns used in most airgun arrays (Caldwell and Dragoset 2000). A peak pressure of 218 dB re 1 µPa could be received somewhat farther away.

Masking. Masking effects by pulsed sounds on marine mammal calls and other natural sounds are expected to be limited, although there are few specific data on this. Because of the intermittent nature and low duty cycle of seismic pulses, animals can emit and receive sounds in the relatively quiet intervals between pulses. Most studies that have examined the potential adverse effects of masking caused by anthropogenic underwater sounds have involved exposure of marine mammals to sounds that are often continuous or nearly continuous, and are not airgun pulses. Such sounds will mask (*i.e.*, reduce) the effective communication or echolocation distance of a marine mammal only if the anthropogenic sound source overlaps the sound signal in time and frequency. If little or no overlap occurs between the sound and the frequencies used, communication and echolocation are not expected to be disrupted or masked. As previously discussed, most energy in sound pulses emitted by seismic airgun arrays is at low frequencies, with strongest spectrum levels below 200 Hz, considerably lower spectrum levels above 1,000 Hz, and smaller amounts of energy emitted up to ~150 kHz. These low frequencies are mainly used by mysticetes, but generally not by odontocetes and pinnipeds. Strong anthropogenic sounds are presumed not to interfere with signalling of marine mammals that are using frequencies outside the range of the anthropogenic sounds. Furthermore, the discontinuous nature of seismic pulses makes significant masking effects unlikely even for mysticetes.[3]

Masking effects of seismic pulses are expected to be negligible in the case of the smaller odontocetes, given the intermittent nature of seismic pulses plus the fact that sounds important to them are predominantly at much higher frequencies than are airgun sounds. This

---

[2] This is based on the evidence from Finneran et al. (2002) that the TTS threshold in a beluga exposed to a watergun pulse is about 186 dB re 1 $\mu Pa^2 \cdot s$ (flat weighted), or 183 dB re 1 $\mu Pa^2 \cdot s$ after discounting the low-frequency components that are not heard well by odontocetes; and on evidence that the PTS threshold, on an SEL basis, would be at least 15 dB higher than the TTS threshold (Southall et al. 2007).

[3] Near the source, the predominant part of a seismic pulse is about 10–20 ms in duration and the interpulse interval for GXT's 2011 program will be ~18 s, which is a longer quiet interval than for most surveys. Other sounds are audible in the gaps except perhaps in the unusual situation where there is strong reverberation of sound that persists for much of the gap between received pulses.

is particularly likely in the case of GXT's proposed seismic program, where seismic pulses would occur ~ every 18 seconds.

***Changes in Behaviour and Distribution*.** There have been studies of the behavioural responses of several types of marine mammals to airgun pulses. However, information is lacking for many species. Detailed studies of short-term responses (or lack thereof) have been done on humpback, gray, bowhead and sperm whales, and on ringed seals. Less detailed data are available for some other species of baleen whales and small toothed whales. The proposed monitoring program will provide additional data on marine mammal response to seismic activities. As suggested in the PSEIA (Boertmann et al. 2009a) and Boertmann et al. (2010), the marine mammal species most vulnerable to seismic survey noise in the KANUMAS East assessment area are narwhals, bowhead whales, and walruses. The authors indicate that there is some risk that these species could be displaced from critical habitat. Particular concern was also suggested for walrus which haul out in coastal areas. Following the guidance in Boertmann et al. (2009a and 2010), the assessment of seismic noise on marine mammals focuses on bowhead whales, narwhals, and walruses.

Behavioural reactions of marine mammals to a sound are difficult to predict. Reactions to sound, if any, depend on species, state of maturity, experience, current activity, reproductive state, time of day, weather, and many other factors.

If a marine mammal does react to an underwater sound by changing its behaviour or moving a small distance, the impacts of the change may not be significant to the individual, the stock, or the species as a whole. On the other hand, if a sound source displaces marine mammals from an important feeding or breeding area for a prolonged period, impacts on the animals could be significant.

3.6 Effects on Marine Mammals (Seismic Array)

3.6.1 Narwhals

During summer, narwhals generally occupy relatively shallow waters in fjords and coastal areas. Two summering areas (and protection zones) have been identified in or near the Study Area; one is in the northern portion of the Project Area (Northeast Water Polynya) where ~ 60 km of a seismic line is planned and the other identified summering area occurs shoreward of Store Koldewey Island in Dove Bugt (see Figure 3 below, and Boertmann et al. 2009a). Narwhals could be encountered during the seismic program, particularly in shallower waters and along ice edges, though none were seen by GXT MMSOs in 2010 or 2009. The species is gregarious, usually occurring in groups from a few individuals to more than 100 so it is possible that large groups may be seen from the seismic vessel.

To the best of our knowledge there are no published data on the responses of narwhals to seismic surveys. Despite the relatively poor low-frequency hearing thresholds of small- and medium-sized odontocetes (like narwhals), they should often be able to hear pulses from airgun arrays operating many tens of kilometres away (Richardson et al. 1995; Richardson and Würsig 1997). Few studies similar to the more extensive baleen whale/seismic pulse work have been reported for odontocetes, and none similar in size and scope to the studies of humpback, bowhead, and gray whales. However, there are recent systematic studies on sperm whales (e.g., Gordon et al. 2006; Madsen et al. 2006; Winsor and Mate 2006; Jochens et al.

2008; Miller et al. 2009), and there is an increasing amount of information about responses of various odontocetes to seismic surveys based on monitoring studies (e.g., Smultea et al. 2004; Moulton and Miller 2005; Bain and Williams 2006; Holst et al. 2006; Stone and Tasker 2006; Potter et al. 2007; Hauser et al. 2008; Holst and Smultea 2008; Weir 2008; Barkaszi et al. 2009; Richardson et al. 2009).

Seismic operators and MMOs regularly see dolphins and other small odontocetes near operating airgun arrays, but in general there seems to be a tendency for most delphinids to show some limited avoidance of operating seismic vessels, on the order of 1 km or less (e.g., Moulton and Miller 2005; Holst et al. 2006; Weir 2008; Richardson et al. 2009; see also Barkaszi et al. 2009). Some dolphins (and Dall's porpoises) seem to be attracted to the seismic vessel and floats, and some ride the bow wave of the seismic vessel even when large arrays of airguns are active (e.g., MacLean and Koski 2005; Moulton and Miller 2005). Nonetheless, small toothed whales often tend to head away, or to maintain a somewhat greater distance from the vessel, when a large array of airguns is operating than when it is silent (see Stone and Tasker 2006; Weir 2008).

The beluga, the closest odontocete relative of narwhals, may be a species that (at least at times) shows long-distance avoidance of seismic source vessels (see Miller et al. 2005). Aerial surveys conducted in the southeast Beaufort Sea in summer found that sighting rates of belugas were significantly lower at distances 10–20 km compared with 20–30 km from an operating airgun array (Miller et al. 2005). The low number of beluga sightings by marine mammal observers on the vessel seemed to confirm there was a strong avoidance response to the 2,250 in^3 airgun array. More recent seismic monitoring studies in the same area have confirmed that the apparent displacement effect on belugas extended farther than has been shown for other small odontocetes exposed to airgun pulses (e.g., Harris et al. 2007). It is uncertain how narwhals will react to seismic surveys. For the purposes of this assessment, we have (conservatively) assumed that they will react on a similar scale as did belugas in the Canadian Beaufort Sea.

Assessment of Impacts. The Seismic Guidelines (Boertmann et al. 2010, Section 6.1.2, Figure 3) maps important narwhal (and other species) protection areas in Northeastern Greenland waters (reproduced in Figure 4, below). These Guidelines state: "Narwhals occur in these areas throughout the open water season, and in the Northeast Water probably throughout the year. … Seismic activities in the narwhal protection zones of East Greenland should be avoided or of limited extend (a few widely spaced (>10 km) lines). If such limited seismic surveys are planned in the protection zones a detailed shooting program is subject to approval by BMP, and if approved, impact studies on the narwhals shall be considered."

GXT's survey area overlaps a small portion of the narwhal summering area in the Northeast Water Polynya, and the western ends of several of GXT's pre-plot lines are within the northern narwhal/bowhead protection zone (Figure 4). Nearly all are more than 10 km apart (several are much more than this), though portions of 2 or 3 of these lines are between 8 km and 10 km distant from each other in the area. However, given the realities of surveying in these northern areas, it is unlikely that GXT will be able to do all of these lines, and specific ice conditions in the area at the time will determine the actual limitations. (For instance, in previous years GXT has permitted lines in the new narwhal/bowhead protection zone between Hovgaard Island and Île de France but has never been able to do acquisition there because of ice/weather. Project-wide it is estimated that – in a good ice year – only about 50% of the pre-plots would be acquired.) Given that the GXT survey is a large regional 2-D

survey with very long acquisition lines (most in this are generally east-west in orientation, and 200 – 300 km long) unlike a locally focused 3-D survey, the actual time spent in the area with an active array will be relatively short on any one occasion, and there may be many hours to several days between the acquisition of these segments. There is a potential for encountering narwhal within the Project Area. However, narwhals are known to avoid the area around vessels, particularly icebreakers (Richardson et al. 1995). This avoidance greatly reduces the potential for hearing impacts on these whales.

In any case, as advised by NERI and the BMP in 2010, when working in this area the survey ships will avoid the seaward edge of the landfast (permanent / persistent) ice between Hovgaard Ø and Île de France by a distance of at least 10 km.

As specified in Boertmann et al. 2010, the airgun array will be "ramped up" gradually to full power whenever airgun operations start. Hence, any narwhals (or other species) near the array when it starts can move away before being exposed to full power airgun pulses. Also, ramp-up will not begin if any narwhal is detected within a 500 m radius zone of the array 30 minutes prior to ramp-up (or 60 minutes in deeper waters).

Although no shutdown for marine mammals is required, GXT will implement a shutdown if a bowhead whale, northern right whale, beluga, narwhal, or walrus is observed within or about to enter within a 500m radius of the seismic source when operating in any designated Protection Zone or within a 200 m radius in all other areas. Also, in addition to the MMSOs on the seismic ship, GXT will utilize on-watch personnel on the icebreaker bridge to sight and record marine mammals, and to relay this information immediately to the MMSOs on the seismic ship.

Further, if recommended by BMP/NERI, GXT will reduce its overall acquisition in the Narwhal/ Bowhead Protection zone by line 240 km compared to the amount proposed. This is equivalent to reducing every second line by 25 km within the area, though the actual location of the line reductions would likely be dictated by ice conditions at the time.

Given these enhanced mitigations, and that narwhals will likely avoid the icebreaker vessel, GXT's seismic program is predicted to cause *negligible* impacts on narwhal hearing (see Table 3).

As noted in the PSEIA (Boertmann et al. 2009a), there is a risk that narwhal may be displaced from areas where they concentrate during summer. In particular, displacement from the Northeast Water Polynya summering area may occur. It is expected that this displacement, should it occur, would be temporary. GXT is expected to operate the airgun array only ~6 - 8 hours in the summering area as shown in Figure 3.

Given narwhal reactions to icebreakers (see below), it is likely that whales will avoid the seismic operations particularly when the airgun array is operational. Although there are no specific data available on narwhal reactions to seismic survey sound, beluga whales in the Canadian Beaufort Sea have been shown to avoid an area 10-20 km from an operating offshore seismic ship where received sound levels from airgun pulses were estimated to be ~150 to 130 dB re 1 μPa (rms). It is uncertain at what received sound level narwhals in the Study Area may react to seismic surveys. Narwhals are generally believed to be sensitive to noise from seismic surveys (Boertmann et al. 2009a). Marine mammal response to sound is

highly variable and can depend on the activity an animal is engaged in at the time of exposure.

It is likely that narwhals will avoid the immediate area around the active airgun array. Behavioural impacts (i.e., disturbance and displacement) should be *minor to moderate, short-term,* and may occur over a spatial extent ranging from *11-100 km^2* to *101-1,000 km^2*. Therefore, *no significant* behavioural impacts are expected and there is no risk of long-term population impacts given the temporary nature of the seismic program (Boertmann et al. 2009a, 2010). The level of confidence associated with this prediction is judged as medium.

3.6.2 Bowhead Whales

Bowhead whales are expected to occur in the Study Area during GXT's seismic program, although only small numbers occur off Northeast Greenland. These whales seem to occur most often along ice edges or the marginal ice zone, though few have been seen during GXT's Northeast Greenland surveys. It is possible that bowheads which occur in the Study Area during summer engage in foraging but this is not known with certainty.

In the Canadian Beaufort Sea, bowhead whales on their summering grounds showed no obvious reactions to pulses from seismic vessels at distances of 6 to 99 km and received sound levels of 107–158 dB on an approximate *rms* basis (Richardson et al. 1986); their general activities were indistinguishable from those of a control group. Bowheads usually did show strong avoidance responses when seismic vessels approached within a few kilometres (~3–7 km) and when received levels of airgun sounds were 152–178 dB (Richardson et al. 1986, 1995; Ljungblad et al. 1988; Miller et al. 2005). They also moved away when a single airgun fired nearby. In one case, bowheads engaged in near-bottom feeding began to turn away from a 30-airgun array with a source level of 248 dB at a distance of 7.5 km, and swam away when it came within about 2 km. Some whales continued feeding until the vessel was 3 km away. Recently, drawing on data collected by DFO during GXT's western Canadian seismic surveys, Harwood et al. (2010) have found that "While limited in scope, existing research results obtained while seismic or drilling operations were underway have shown no marked or measurable effects on either the behaviour or distribution of these species [bowhead whales, beluga whales and ringed seals] by offshore industrial operations in the [Canadian Beaufort Sea] to date. Differences in behaviour and distribution have been recorded, but were localized and temporary."

The results of a seismic monitoring program conducted in the nearshore waters of the Canadian Beaufort Sea in the summers of 2001 and 2002 (Miller and Davis 2002; Miller and Moulton 2003; Miller et al. 2005) partially supports the findings of the aforementioned study. Lower sighting rates and greater sighting distances during periods of seismic operations vs. periods when no airguns were operating suggested that bowheads did usually avoid close approach to the area of seismic operations. However, the still substantial number of sightings during seismic periods and the relatively small (600 m), but significant difference, in sighting distances suggest that the avoidance was localized and relatively small in nature. Bowheads at the average vessel-based sighting distance (1,957 m) during line seismic would have been exposed to sound levels of about 170 dB re 1 μPa (rms). Similarly, preliminary analyses of recent data from the Alaskan Beaufort Sea indicate that bowheads feeding during late summer and autumn also did not display large-scale distributional changes in relation to seismic operations (Christie et al. 2009; Koski et al. 2009).

Sighting distances during non-seismic (average 2,873 m) and seismic (average 2,903 m) periods were very similar for bowhead whales during GXT's 2006 seismic monitoring program in the Canadian Beaufort Sea (Harris et al. 2007). During GXT's 2007 seismic monitoring program in the Canadian Beaufort Sea, bowheads were sighted closer to the vessel during non-seismic periods (average 1,527 m) than during seismic periods (average 1,976 m). Average sighting distance was greatest when the full array was active (average 2,109 m) (Harris et al. 2008). These results support the monitoring results from 2001 and 2002 and suggest that bowheads avoid airgun noise, at least in a localized area.

Migrating bowhead whales seem more responsive to noise pulses from a distant seismic vessel than are summering bowheads. In 1996–98, a partially-controlled study of the effect of Ocean Bottom Cable (OBC) seismic surveys on migrating bowheads was conducted in late summer and autumn in the Alaskan Beaufort Sea (Miller et al. 1999; Richardson et al. 1999). Aerial surveys showed that some westward-migrating whales avoided an active seismic survey boat by 20-30 km, and that few bowheads approached within 20 km. Received sound levels at those distances were only 116–135 dB re 1 μPa (*rms*). Some whales apparently began to deflect their migration path when still as much as 35 km away from the airguns. At times when the airguns were not active, many bowheads moved into the area close to the inactive seismic vessel. Avoidance of the area of seismic operations did not persist beyond 12–24-h after seismic shooting stopped. These and other data suggest that migrating bowhead whales are more responsive to seismic pulses than were summering bowheads. Analysis of recent data on traveling bowheads in the Alaskan Beaufort Sea also showed a stronger tendency to avoid operating airguns than was evident for feeding bowheads (Christie et al. 2009; Koski et al. 2009). During GXT's 2010 Beaufort Sea in ice survey (similar to the 2011 Greenland survey), very few bowheads were seen compared to the ice-free areas in the southern Beaufort.

Assessment of Impacts. The Seismic Guidelines (Boertmann et al. 2010, Section 6.2.1) states "The Northeast Water Polynya and the waters off the ice edge between Île de France and Amdrup Land are important habitats for bowhead whales in summer and early autumn. The protection zone for this species is similar to the protection zone for narwhals and so are the regulations: Seismic activities shall be avoided or of limited extend (a few widely spaced (>10 km) lines). If limited seismic surveys are planned within the protection zone a detailed shooting program is subject to approval by BMP, and if approved, impact studies on the whales shall be considered."

As noted above for narwhal, parts of several of GXT's pre-plot lines are within the northern narwhal/bowhead zone (Figure 4) but are generally widely spaced. Also, as advised by NERI and the BMP in 2010, when working in this area the survey ships will avoid the seaward edge of the landfast (permanent / persistent) ice between Hovgaard Ø and Île de France by a distance of at least 10 km. Also, as noted for narwhals, if requested by BMP/NERI, GXT will reduce its overall acquisition in the Narwhal/ Bowhead Protection zone.

Further, bowhead whales are expected to move away as the operating airgun array approaches, and to remain outside the zone where received sound levels are 180 dB re 1 μPa (rms) or higher. Pre-watch and ramp-up procedures will be used, as will shutdowns for bowheads and other species, as described above for narwhal (a 500 m shutdown safety zone will be applied in the Protection Areas, and additional watch from the icebreaker.)

Given these enhanced mitigation measures and that bowheads will likely avoid at least the immediate area around the seismic array, GXT's seismic program is predicted to cause *minor* and *short-term* impacts on bowhead hearing over a spatial extent ranging from *<1 km^2 to 1-10 km^2* (see Table 3). Therefore, *no significant* hearing impairment or other physiological effects on bowheads are expected. The level of confidence associated with this prediction is judged as high.

Bowheads may migrate through the Study Area and/or spend time foraging in the area. Based on monitoring studies in the Beaufort Sea, the degree of avoidance seems to be dependent upon the activity the whales are engaged in. Bowheads in feeding areas typically exhibit localized avoidance whereas migrating bowheads exhibit larger scale avoidance. GXT's 2-D SPAN seismic program has widely spaced survey lines which extend over a large area, therefore, the seismic vessel will operate in a given area for only a short period. This should minimize potential impacts of bowheads that may be concentrated in a localized area.

It is predicted that behavioural impacts of airgun sounds on bowheads would be *minor to moderate, short-term,* and may occur over a spatial extent ranging from *11-100 km^2 to 101-1,000 km^2* (Table 3). Therefore, *no significant* behavioural impacts are expected and there is no risk of long-term population impacts given the temporary nature of the seismic program (Boertmann et al. 2009a, 2010). The level of confidence associated with this prediction is judged as medium.

3.6.3 Walruses

Boertmann et al. (2009a) note that the walrus is considered a sensitive species because the population is dependent on relatively few and localized benthic feeding areas. Within GXT's Project Area, walrus (likely females and young) are expected to occur primarily in coastal waters (typically <100 m) near Kilen, Hovgaard Ø, and Amdrup Land where they likely forage on bivalves. Two primary male walrus haul-out sites are located at Sandøen and Lille Snenæs which are located about 40 km - 50 km from the Project Area. Walruses using these haul-out sites may occur at summering and feeding areas associated with sites that border the GXT survey area, although the Northeast Water Polynya may be used year-round. Areas associated with feeding and haul-outs have also been designated as protection zones for walruses from 1 June to 30 September, although the Northeast Water Polynya remains a year-round protection zone (see Figure 5; Boertmann et al. 2010).

There are few data available on walrus responses to seismic surveys. Monitoring data collected during seismic programs in the Alaskan Chukchi Sea during 2006-2008 suggest that Pacific walrus exhibit localized avoidance of active airguns (Haley et al. 2009). Walrus sighting rates decreased as sound levels from the seismic source vessel increased. The authors warn that these results may be biased by a large group (169 of 571 sightings) of walruses which were seen during a 24-hour period when no airguns were operating. Most walruses observed from the seismic source vessel showed no obvious reaction to airgun operations and closest points of approach did not differ significantly relative to sound levels (Haley et al. 2009).

Assessment of Impacts. The Seismic Guidelines (Section 6.3.2) state, "Specific walrus protection zones are designated on Figure 3, and the protection period is from 1 June to 30 Sept., when open water is present at the coasts. However the Northeast Water is a year round habitat and here the protection period is the entire year. … Seismic activities in these walrus

protection zones shall be avoided or of limited extend (a few widely spaced (>10 km) lines). If such limited seismic surveys are planned in the protection zones a detailed shooting program is subject to approval by BMP, and if approved, impact studies on the walruses shall be considered.

Figure 5 indicates GXT's proposed 2011 lines in relation to the identified walrus protection zones. Relatively small portions of three of GXT's pre-plot lines enter any of these areas (a total 15 km in the southernmost zone and ~100 km in the north). Except where the two lines intersect in the north, these lines are not within 10 km of each other, or any other nearby lines. In the south, the one line (1150) that extends into the southern Walrus Protection Zone (15 km) is lines is approximately 68 km from the next nearest line to the north, and is thus within NERI's precaution that any lines in the area should be "of limited extend (a few widely spaced (>10 km) lines)". The same is the case or the two northern nines.

Given this, and since walruses will likely avoid at least the immediate area around the seismic array (and vessels), and that ramp-up will be used, GXT's seismic program is predicted to cause *negligible* impacts on walrus hearing (see Table 3).

Some walruses will likely avoid the operating airgun array by distances of up to several hundred metres. However, some walruses may remain in close proximity to the seismic source vessel; in the Chukchi Sea many walruses were observed within 500 m of the source vessel when the airgun array was active and received sound levels exceeded 160 dB re 1uPa rms (Haley et al. 2009). It is possible that there would be short-term behavioural responses such as interruption of foraging dives. In the Chukchi Sea, there was no indication that Pacific walrus behaviour was affected by seismic surveying; however, effects on foraging were not specifically examined (Haley et al. 2009). Given the design of the GXT SPAN seismic program, as noted, the seismic vessel is expected to operate in the vicinity of a given walrus areas for short time periods only and they will be of limited extent and greater than 10 km apart (see Boertmann et al. 2010). The behavioural impacts of seismic and related underwater sounds on walruses could be *minor to moderate*, *short-term*, and may occur over a spatial extent ranging from *<1 km^2 to 11-100 km^2*. Therefore, *no significant* behavioural impacts are expected and there is no risk of long-term population impacts given the temporary nature of the seismic program (Boertmann et al. 2009a, 2010). The level of confidence associated with this prediction is judged as medium.

3.6.4 Seals

Harp, hooded, ringed and bearded seals are expected to occur in coastal and offshore waters of GXT's Project Area. Concentration areas for seals have not been identified in the Project Area for these species during the period when seismic operations are expected to occur (July to October). Available data indicate that ringed seals show less reaction to seismic sounds than do bowhead and beluga whales. There are few data available for bearded and harp seal response to seismic survey sound but both species have been observed from seismic vessels. Monitoring work in the Alaskan Beaufort Sea during 1996-2001 (Harris et al. 1997, 1998, 2001; Lawson and Moulton 1999; Moulton and Lawson 2000a,b, 2002) as well as the Canadian Beaufort Sea and Alaskan Chukchi Sea in 2006-2009 (e.g., Miller and Davis 2002; Miller et al. 2005; Reiser et al. 2009) has provided considerable information regarding the behaviour of seals exposed to seismic pulses.

In these studies, the numbers of seals sighted from the source vessel were sometimes lower when the airguns were operating than when the vessel was moving without airguns operating.

Seals sighted from the source vessel were located at significantly greater distances when an airgun array was firing than during periods with no guns operating. Overall, avoidance reactions were apparently limited to a radius of no more than a few hundred metres, and many of the seals well inside that distance showed no evidence of either avoidance or behavioural reactions. However, recent vessel-based monitoring suggested that phocid seals were seen less frequently while airguns were operating than when airguns were silent, and observers on seismic vessels saw seals less frequently than did observers on nearby vessels without airguns (Reiser et al. 2009). These results are indicative of a tendency for phocid seals to exhibit localized avoidance of the seismic source vessel when airguns are firing.

Preliminary results of a radio telemetry study by Thompson et al. (1998) suggested that more pronounced (but short-term) behavioural changes can occur in harbour seals and gray seals exposed to airgun pulses. They stated that normal foraging dives were interrupted and that avoidance reactions usually occurred. The seals returned to their previous foraging areas after airgun operations ceased. These preliminary results suggest that seal reactions to airgun pulses may be more pronounced than can be documented by visual observations at the surface.

Assessment of Impacts. Most seals are expected to avoid close approach to the airgun array. If seals are exposed to close approach to the airgun array, any effects would most likely be limited to mild TTS, from which seals would recover. Also, seals that are hauled out on ice floes would be unaffected by underwater sound unless they dove in response to the oncoming vessels. Given this, plus the small proportion of the population that would occur close enough to the airgun array to incur hearing impairment, impacts of seismic sound sources on seal hearing would be *negligible*.

Some seals likely will avoid the operating airgun arrays by distances of up to a few hundred metres. However, some seals are expected to remain in close proximity to the seismic source vessel. It is possible that there would be short-term behavioural responses such as interruption of foraging dives. The behavioural impacts of seismic and related underwater sounds on seals could be *minor to moderate, short-term,* and may occur over a spatial extent ranging from *<1 km^2 to 11-100 km^2*. Therefore, *no significant* behavioural impacts are expected and there is no risk of long-term population impacts given the temporary nature of the seismic program (Boertmann et al. 2009a, 2010). The level of confidence associated with this prediction is judged as high.

3.6.5 Polar Bears

Airgun effects on polar bears have not been studied. However, polar bears on the ice would be unaffected by underwater sound. Sound levels received by polar bears in the water would be attenuated because polar bears generally swim with their heads out of the water or at the surface and polar bears do not dive much below several metres. Received levels of airgun sounds are reduced near the surface because of the pressure release effect at the water's surface (Greene and Richardson 1988; Richardson et al. 1995). Recent measurements of the in-air hearing of polar bears suggest bears have best hearing sensitivity for sounds with frequencies between 11.2-22.5 kHz (Nachtigall et al. 2007). Their hearing is presumably adapted for in-air hearing, and—even when submerged—they may not be very sensitive to underwater sound. There are few published data available for polar bear responses to seismic surveys. Polar bears may occur in the offshore pack ice in the GXT Study Area, particularly in areas with dense ice and ice edges.

Assessment of Impacts. Given the small proportion of the polar bear population involved, and that bears generally swim with their head out of water, impacts of seismic sound sources on polar bear hearing are predicted to be *negligible*. Similarly, impacts of airgun array sound on polar bear behaviour are predicted to be *negligible to minor, short-term, and 1-10 km^2* (see Table 3). Therefore, no significant behavioural impacts are expected and there is no risk of long-term population impacts given the temporary nature of the seismic program (Boertmann et al. 2009a, 2010). The level of confidence associated with this prediction is judged as high.

3.7 Effects on Marine Mammals (Vessel and Ice Breaker Traffic)

Reactions of whales to vessels often include changes in general activity (e.g., from resting or feeding to active avoidance), changes in surfacing-respiration-dive cycles, and changes in speed and direction of movement. Responses to vessel approaches tend to be reduced if the animals are actively involved in a specific activity such as feeding or socializing (reviewed in Richardson et al. 1995). Past experiences of the animals with vessels are important in determining the degree and type of response elicited from a whale-vessel encounter. Whales react most noticeably to erratically moving vessels with varying engine speeds and gear changes, and to vessels in active pursuit, none of which apply to the seismic program.

Icebreakers pushing ice radiate noise ~10-15 dB stronger than when they are underway in open water, mostly due to strong propeller cavitation (Richardson et al. 1995). In quiet ambient conditions in fast ice areas, peak noise levels from icebreakers may exceed the ambient noise level up to 300 km from the icebreaker (Davis et al. 1990). Off NE Greenland, the ambient noise in areas of moving pack ice will be higher and the energy required by an icebreaker to move ice pans will be lower. Therefore, peak noise levels from icebreakers may not exceed ambient levels at distances up to 300 km. Narwhals (and particularly beluga) are known to exhibit long distance avoidance of ships.

3.7.1 Narwhal

As previously discussed, narwhals are expected to occur in the Project Area, particularly in the Northeast Water Polynya. It is uncertain how narwhals will react to the seismic and icebreaker vessels. Some narwhals have moved long distances away (many km) from icebreakers (see Richardson et al. 1995, p. 257). After initially being displaced in response to relatively low levels of noise from the ship (94-105 dB), narwhals sometimes returned 1-2 days later when icebreaker noise levels where still 120 dB.

In the Canadian High Arctic, Finley et al. (1990) studied the reactions of closely related beluga whales at ice edges to the sound of approaching ships. The whales were waiting for the ice edge to break up so they could continue their migration to summering areas. The whales made possible alarm vocalizations when the ships were 80 km distant, and showed strong avoidance reactions when the ships were 35-50 km away. Similar observations have been reported independently by Cosens and Dueck (1988). However, belugas in the Beaufort Sea have not been observed to react to ships or ship sounds at such long distances. Harwood et al. (2005) suggested that belugas likely avoided ice breakers in deep-water regions of the Canadian Beaufort when belugas were expected to be in that area.

Assessment of Impacts. As noted in the PSEIA (Boertmann et al. 2009a), there is a risk that narwhal may be displaced from areas where they concentrate during summer. In particular, displacement from the Northeast Water Polynya summering area may occur. It is expected that this displacement, should it occur, would be temporary. The seismic vessel and icebreaker are expected to occur in the area of the Northeast Water Polynya for only a few days, if acquisition proceeds according to GXT's planned schedule, and lines in important areas to the south are widely spaced.

It is likely that narwhals will avoid the immediate area around the seismic vessel and icebreaker. Behavioural impacts (i.e., disturbance and displacement) should be *minor to moderate, short-term,* and may occur over a spatial extent ranging from *11-100 km^2* to *101-1,000 km^2*. Therefore, *no significant* behavioural impacts are expected and there is no risk of long-term population impacts given the temporary nature of the seismic program (Boertmann et al. 2009a, 2010). The level of confidence associated with this prediction is judged as medium.

3.7.2 Bowhead Whales

Bowheads may swim away from approaching vessels when they come within 2-4 km. If a vessel approaches within several hundred metres, the response usually is conspicuous. The whales typically swim at a higher speed than they normally travel, either attempting to "outrun" the vessel or changing direction to swim perpendicularly away from the vessel's path (Richardson et al. 1985a,b, 1995; Richardson and Malme 1993). In contrast, if the vessel travels slowly, bowhead whales often are more tolerant of the approaching vessel, and may show little or no reaction even when the vessel is within several hundred metres. This is especially so when the vessel is not directed toward the whale and when there are no sudden changes in direction or engine speed (Wartzok et al. 1989; Richardson et al. 1995). Bowhead response to icebreakers is uncertain. During GXT's seismic program, both vessels will be operating at a consistently slow speed.

Assessment of Impacts. Bowhead whales are expected to avoid vessels that are underway, including the icebreaker and the seismic vessel when it is not operating an airgun array. The effects of vessel traffic on bowheads are expected to be *negligible to minor, short-term,* and may occur over a spatial extent of *11-100 km^2* (see Table 3). Impacts on whales can be reduced if the vessels steer a straight course and maintain a constant speed whenever possible, both of which will be normal operating conditions for the seismic source vessel and icebreaker involved with the Project. Therefore, *no significant* behavioural impacts are expected and there is no risk of long-term population impacts given the temporary nature of the seismic program (Boertmann et al. 2009a, 2010). The level of confidence associated with this prediction is judged as high.

3.7.3 Walrus

As previously noted, Boertmann et al. (2009a) suggested that the walrus is a sensitive species because the population is dependent on relatively few and localized benthic feeding areas. Some of these feeding and summering areas occur within and near GXT's Project Area.

The reactions of walruses to icebreaking tend to occur at longer distances than their reactions to ships in open water. Fay et al. (1984) reported that female and young walruses which were on the ice entered the water and swam away when the icebreaker was 0.5-1 km away and

males did so when the ship was 0.1-0.3 km away. The authors noted that some walruses scrambled onto the ice when a ship breaking ice moved towards them. Brueggeman et al. (1992) found that based on aerial survey results, walruses hauled out on ice, tended to avoid the area within ~10-15 km of the icebreaker.

Assessment of Impacts. Given the design of the GXT SPAN seismic program (see Figure 5), the seismic vessel and ice breaker are expected to operate in the vicinity of important walrus areas for short time periods only, on widely spaced lines. Most operations will occur in deeper offshore waters. The behavioural impacts of vessel traffic and related underwater sounds on walrus could be *minor to moderate*, *short-term*, and may occur over a spatial extent ranging from *<1 km^2 to 101-1,000 km^2*. Therefore, *no significant* behavioural impacts are expected and there is no risk of long-term population impacts given the temporary nature of the seismic program (Boertmann et al. 2009a, 2010). The level of confidence associated with this prediction is judged as high.

3.7.4 Seals

Few authors have described the responses of pinnipeds to boats, and most of the available information concerns pinnipeds hauled out on land or ice. Ringed and bearded seals hauled out on pack ice often dove into the water when an icebreaker breaking ice approached within 0.9 km (Brueggeman et al. 1992). Similarly, ringed and harp seals within 1 km of an icebreaker often dove into the water but seals 1-2 km away mostly stayed on the ice (Kanik et al. 1980). During the 2009 GXT seismic program off Northeast Greenland, 59 sightings were of seals initially observed on ice; 25% (15 sightings) of those subsequently dove into the water as the vessels approached (Jones et al. 2009). In areas of open water ringed and bearded seals are commonly observed close to vessels (*e.g.*, Harris et al. 1997, 1998, 2001, 2007, 2008). Inuvialuit hunters in the Canadian Beaufort Sea have indicated that during seal hunting, they often create underwater noise, to attract ringed seals to their boat, noting that seals are "curious" (LGL 2008). Ringed seals have also been seen feeding among overturned ice floes in the wake of icebreakers (Brewer et al. 1993).

Assessment of Impacts. Some seals are likely to avoid the icebreaker when it is breaking ice by ~ 1 km whereas seals may occur within a few tens of metres of the seismic and icebreaker vessel when these vessels are not engaged with activating the airgun array or breaking ice. Some "curious" seals are likely to swim toward vessels. Given that seals are expected to be widely dispersed in the Project Area and that any displacement will be temporary and in a small area, the impact of vessel traffic on seals is expected to be *negligible* (see Table 3).

3.7.5 Polar Bears

Like seals, polar bears exhibit variable responses to boats. Some seem to approach vessels while others exhibit avoidance (e.g., Harwood et al. 2005). Polar bears show either no or very limited reactions to icebreakers (Richardson et al. 1995). The impact of vessel traffic on polar bears is expected to be *negligible* (see Table 3).

3.8 Effects on Marine-associated Birds

3.8.1 Potential Effects of Seismic Survey Sounds

There are few data on the effects of underwater sound on birds. Stemp (1985) made observations on the reactions of birds to seismic exploration programs in southern Davis Strait over three summer periods. No mortality or effects on distribution were detected in 1982, the only year when an airgun-based program was conducted. Evans et al. (1993:8) made observations from operating seismic vessels in the Irish Sea. They noted that when seabirds were near the seismic boats, "there was no observable difference in their behaviour, birds neither being attracted nor repelled by seismic testing".

A study on the effects of underwater seismic surveys on moulting Long-tailed Ducks in the Beaufort Sea showed little effect on their movement or diving behaviour (Lacroix et al. 2003). However, the study did not monitor the physical effects on the ducks. The authors suggested caution in interpretation of the data because they were limited in their ability to detect subtle disturbance effects and recommended studies on other species to fully understand the potential effects of seismic testing. This lack of overt response may be at least partly related to the fact that received levels of underwater sound from airguns are greatly reduced at and immediately below the surface as compared with levels deeper in the water (Greene and Richardson 1988).

Boertmann et al. (2009a) indicate that seabirds are generally not considered to be sensitive to seismic surveys, because they are readily able to avoid the seismic sound source. The authors suggest caution is warranted in coastal waters where the presence of vessels may disturb breeding and moulting concentrations of birds.

Assessment of Impacts. The presence of the survey vessel and icebreaker and perhaps the ramp-up period for the airguns will displace birds from the immediate program area. Thus, any effects of seismic survey sound on birds in the Project Area are expected to be *negligible*.

3.8.2 Potential Effects of Vessel and Icebreaker Traffic

Waterbirds may be affected by vessel traffic in various ways. In extreme responses, some studies have shown that individuals displaced from habitat by vessel activity do not return (Green Heron *Butorides virescens*: Kaiser and Fritzell 1984; waterfowl: Knapton et al. 2000; Kenow et al. 2003). However, limited vessel traffic resulted in only short-term displacement of a seabird (Kittlitz's Murrelet, *Brachyramphus brevirostris*) in southeast Alaska (Agness et al. 2008).

Assessment of Impacts. The closest 2011 survey line is roughly 8 – 10 km from the closest coastal islands, more than 40 km from the closest IBA, and more than 60 km from the nearest Ramsar site (Figure 2). Sea-associated birds encountered during the seismic program are expected to be temporarily displaced by vessels that are underway, including the seismic vessel when it is not operating the airgun array. Because the vessels will be making way at a constant, low speed, the affected area will be limited to the immediate vicinity of each vessel and the effects on birds within that area will be localized and temporary. Because the vessels will be unlikely to return along the same survey-lines on the same day, affected birds in a given area will be unlikely to be disturbed more than once. In addition, it is unlikely that birds will be attracted to vessel lights (particularly given the extended periods of daylight). Bird strandings on ships have not been an issue in recent seismic programs in the Beaufort Sea (LGL Ltd., unpubl. data). The effects of vessel traffic on sea-associated birds are expected to be *negligible*.

3.9 Effects on Zooplankton

In the following sections, zooplankton refers to the small invertebrates generally less than 1 mm in body size that float freely throughout the water column. The potential impacts of ichthyoplankton (i.e., eggs and larvae) of macroinvertebrates and fish are addressed in Sections 3.10 and 3.11, respectively.

Few studies examining the effects of seismic sound on zooplankton have been conducted to date (DFO 2004; Payne 2004). Of the studies that have been completed, the data provided are generally insufficient to evaluate the potential effects on planktonic organisms that might be caused by exposure to seismic sound under field operating conditions (DFO 2004). It is generally accepted that zooplankton cannot actively move away from the airgun source used during seismic surveys. Zooplankton may sustain lethal injuries within 2 m of the sound source while sub-lethal injuries may occur within 5 m (Østby et al. 2003 *in* Boertmann et al. 2009a). No studies examining the effects of seismic sound on zooplankton located further from the sound source were found. Boertmann et al. (2009a) noted that only limited data concerning zooplankton densities in the KANUMAS East assessment area exist and assumed that densities were not higher than in other areas of Greenland where seismic surveying has occurred. Based on this assumption, the authors suggested that the impacts of seismic activity on zooplankton would likely be negligible in the KANUMAS East assessment area.

Assessment of Impacts. The proposed seismic program for 2011 is predicted to have *minor* impacts on the zooplankton VEC over a *short-term* duration in an area *< 1 km*^{2}. Therefore, the impacts of the proposed program on the zooplankton VEC are predicted to be *not significant* (Table 3). There is no risk of long-term population impacts given the temporary

nature of the seismic program (Boertmann et al. 2009a). The level of confidence associated with this prediction is judged as high.

3.10 Effects on Macroinvertebrates

3.10.1 Sound Detection

Because they lack air filled cavities and are often the same density as seawater, marine macroinvertebrates detect underwater acoustics differently than some fish. Rather than being pressure sensitive as some fish appear to be, marine macroinvertebrates appear to be sensitive to particle displacement. However, their sensitivity to particle displacement and hydrodynamic stimulation seem poor compared to fish. Crustaceans appear to be most sensitive to sounds of low frequency (i.e., <1,000 Hz) (Budelmann 1992; Popper et al. 2001).

Lovell et al. (2005) found, via the auditory brainstem response (ABR) technique, that the prawn, *Palaemon serratus*, responds to sounds ranging in frequency from 100 to 3,000 Hz. They also showed that the statocyst of *P. serratus* is sensitive to the motion of water particles displaced by low frequency sounds with a hearing acuity similar to that of a generalist fish. Measured threshold rms SPLs ranged from 106 dB re 1 µPa @ 100 Hz to 131 dB re 1 µPa @ 3,000 Hz.

As with fishes, there are three categories of potential effect of exposure to seismic on aquatic macroinvertebrates. They include (1) physical, (2) physiological, and (3) behavioural. The three categories should not be considered as independent of each other. They are certainly interrelated in complex ways. For example, it is possible that certain physiological and behavioural changes could potentially lead to the ultimate pathological effect on individual animals (i.e., mortality). A wide range of macroinvertebrates occur in Greenland waters and possibly the Study Area. Some examples of macroinvertebrates include crustaceans, molluscs, polychaetes, bryozoans, sponges, cnidarians, echinoderms, tunicates, sea spiders, sea anemones, corals, and many others.

3.10.2 Potential Effects of Seismic Survey Sound

Physical Effects. To date, there have not been any well-documented cases of acute aquatic macroinvertebrate mortality as a result of exposure to seismic sound under normal seismic operating conditions. Sub-lethal injury or damage has been observed but generally as a result of exposure to very high received levels of sound, higher than would be expected in the field under normal seismic operating conditions (Pearson et al. 1994). Possible effects on eggs and larvae have been demonstrated in experimental exposures but only when the eggs and larvae were exposed very close to the seismic sources and the received pressure levels were very high (Pearson et al. 1994; Christian et al. 2003, 2004). Limited information has not indicated any chronic mortality as a direct result of exposure to seismic (LaBella et al. 1996; McCauley et al. 2000a,b; Christian et al. 2003, 2004; DFO 2004).

Physiological Effects. Primary and secondary stress responses of aquatic macroinvertebrates after exposure to seismic energy all appear to be temporary in any studies done to date (McCauley et al. 2000a,b ; Christian et al. 2003, 2004; Payne et al. 2007). The times necessary for these biochemical changes to return to normal are variable depending on

numerous aspects of the biology of the species and of the sound stimulus (Lagardère 1982).

Behavioural Effects. The full determination of behavioural effects of exposure to seismic is difficult. There have been well-documented observations of aquatic macroinvertebrates exhibiting behaviour that appeared to be in response to exposure to seismic (i.e., startle response, change in swimming direction and speed, change in vertical distribution), but the ultimate importance of these behaviours is unclear (McCauley et al. 2000a,b). Some studies indicate that such behavioural changes are temporary while others imply that marine animals might not resume pre-seismic behaviours / distributions for a number of days (Christian et al. 2003). There have been anecdotal reports of decreased snow crab and northern shrimp catches in waters off Newfoundland shortly after exposure to seismic but there is no evidence to support those reports. Other studies have concluded that exposure to seismic did not alter catch rates (Andriguetto-Filho et al. 2005). As is the case with physical and physiological effects of seismic on aquatic macroinvertebrates, available information is relatively scant and often contradictory.

Assessment of Impacts. There is little evidence to suggest that exposure to typical seismic surveying activity has any acute physical and physiological impact on macroinvertebrate animals. Effects have been noted after exposure to very high levels of seismic under conditions that would not occur naturally. These effects under extreme conditions have been noted mostly with egg and larval stages of macroinvertebrates. It appears that some macroinvertebrates will alter behaviour to avoid a seismic source by moving away in either or both the horizontal and vertical planes (e.g., squid, shrimp). These distributional shifts are temporary.

The proposed seismic program for 2011 is predicted to have *minor* impacts on the macroinvertebrate VEC, including eggs and larvae, over a *short-term* duration over a spatial extent ranging between *< 1 km^2 to 11-100 km^2*. Therefore, the impacts of the proposed program on the macroinvertebrate VEC would be *not significant* (Table 3). There is no risk of long-term population impacts given the temporary nature of the seismic program (Boertmann et al. 2009a). The level of confidence associated with this prediction is judged as high.

3.11 Effects on Fish

Exposure to seismic pulses sometimes elicits behavioural reactions by fish, but there is limited information on the effect of noise-induced behavioural changes on fish. Most of the available information indicates that effects of underwater sounds on fish are transitory. Thus, obvious changes in behaviour may have inconsequential biological effects on the fish. Current research indicates that effects on fish behaviour should translate into negligible impacts on individuals and populations.

3.11.1 Hearing in Fish

Fish species are generally divided into two groups – hearing specialists and hearing generalists (see reviews by Popper et al. 2003; Ladich and Popper 2004; Hastings and Popper 2005; Popper 2009; Popper and Hastings 2009a,b). Hearing specialists have special adaptations that enhance their hearing bandwidth and sensitivity (i.e., lower their hearing threshold). Hearing specialists can typically detect signals up to 3,000 to 4,000 Hz with thresholds that are 20 dB lower than the fishes without specializations for sound detection

(i.e, generalists). There have been suggestions that certain fishes, including many clupeiforms (i.e., herring, shads, anchovies, etc.) may be capable of detecting ultrasonic signals with frequencies as high as 180 kHz (Dunning et al. 1992; Nestler et al. 1992; Mann et al. 2001). Studies on Atlantic cod, a non-clupeiform fish, suggested that this species could detect ultrasound at almost 40 kHz (Astrup and Møhl 1993). The majority of fishes are hearing generalists and have a hearing bandwidth range from below 100 Hz to ~2 kHz.

The hearing bandwidth range for many fish species within the Study Area is not currently known. A summary of available information pertaining to fish audiograms was published by Nedwell et al. (2004). Included in this summary paper were audiograms for Atlantic salmon (*Salmo salar*). While this anadromous fish does not occur in the Study Area, the salmonid Arctic char does occur in southern portions of the Project Area, typically within 25 km of shore when summer marine feeding areas are occupied (Jensen and Christiansen 2003). Nedwell et al. (2004) reported a minimum threshold SPL of 95 dB re 1 µPa (unknown metric) at 100-200Hz for Atlantic salmon. Thresholds were measured over a frequency range of 30 to 350 Hz. Knudsen et al. (1992, 1994) reported that juvenile Atlantic salmon exhibited avoidance responses to non-seismic sound at 10 Hz but not at 150 Hz.

It is important to note that data on hearing capabilities exist for approximately 100 of the 27,000 or more extant species of fish; therefore, extrapolation of hearing capabilities between different species must be done with extreme caution (Hastings and Popper 2005). Though hearing capabilities are known for relatively few fish, particularly those that occur in the Project Area, the majority of fish species with known hearing abilities are capable of detecting a range of sounds, including those produced during seismic surveys.

3.11.2 Potential Effects of Seismic Survey Sound

It has been shown that exposure to seismic sound sometimes elicits behavioural reactions by fish, but information on the effect of sound-induced behavioural changes on fish remains limited. Most of the available information suggests that effects of underwater sounds on fish are transitory, and, therefore, obvious changes in behaviour may have inconsequential biological effects on the fish. Current research suggests that effects on fish behaviour likely translate into negligible impacts on individuals and populations.

There are three categories of potential effects of exposure to seismic on fishes. They include (1) physical, (2) physiological, and (3) behavioural. Physical effects include lethal and sub-lethal damage, physiological effects include temporary primary and secondary stress responses, and behavioural effects refer to changes in exhibited behaviours. The three categories should not be considered as independent of each other. They are certainly interrelated in complex ways. For example, it is possible that certain physiological and behavioural changes could potentially lead to the ultimate physical effect on individual animals (i.e., mortality).

Physical Effects. To date, there have not been any well-documented cases of acute post-larval fish mortality as a result of exposure to seismic sound under normal seismic operating conditions. Sub-lethal injury or damage has been observed but generally as a result of exposure to very high received levels of sound, higher than would be expected in the field under normal seismic operating conditions (Enger 1981; McCauley et al. 2000a,b, 2003; Amoser and Ladich 2003; Smith et al. 2004; Popper et al. 2005). Fish that had exhibited temporary threshold shift as a result of exposure to seismic sound (Popper et al. 2005) were

also examined for evidence of physical damage to the ear region (Song et al. 2008). No evidence of physical damage was found. Acute mortality of eggs and larvae have been demonstrated in experimental exposures but only when the eggs and larvae were exposed very close (1-3 m) to the seismic sources and the received pressure levels were presumably very high (Kostyuchenko 1973; Dalen and Knudsen 1987; Holliday et al. 1987; Matishov 1992; Booman et al. 1996; Dalen et al. 1996). A recent study by Payne et al. (2009) exposed fertilized capelin (*Mallotus villosus*) eggs and monkfish (*Lophius americanus*) larvae to seismic sound from a single airgun and subsequently examined and monitored for possible effects of the exposure. Approximate received SPLs measured in the capelin egg and monkfish larvae exposures were 199 to 205 dB re 1 μPa_{p-p} and 205 dB re 1 μPa_{p-p}, respectively. The capelin eggs were exposed to either 10 or 20 airgun discharges, and the monkfish larvae were exposed to either 10 or 30 discharges. No statistical differences in mortality/morbidity between control and exposed subjects were found at 1 to 4 days post-exposure in any of the exposure trials for either the capelin eggs or the monkfish larvae.

Limited information has not indicated any chronic mortality as a direct result of exposure to seismic.

Physiological Effects. Primary and secondary stress responses of fish after exposure to seismic energy all appear to be temporary in studies done to date. The times necessary for these biochemical changes to return to normal are variable depending on numerous aspects of the biology of the species and of the sound stimulus (Sverdrup et al. 1994; McCauley et al. 2000a,b).

Behavioural Effects. The full determination of behavioural effects of exposure to seismic is difficult. There have been well-documented observations of fish exhibiting behaviour that appeared to be in response to exposure to seismic (i.e., startle response, change in swimming direction and speed, change in vertical distribution) (Blaxter et al. 1981; Schwarz and Greer 1984; Løkkeborg 1991; Pearson et al. 1992; Skalski et al. 1992; Engås et al. 1996; McCauley et al. 2000a,b; Wardle et al. 2001; Hassel et al. 2003; Slotte et al. 2004; Broeger et al. 2006; Payne et al. 2008; Popper and Hastings 2009a,b) but the ultimate importance of these behaviours is unclear. Some studies indicate that such behavioural changes are very temporary while others imply that fish might not resume pre-seismic behaviour/distributions for a number of days. As is the case with physical and physiological effects of seismic on fish, available information is relatively scant and often contradictory. There is also evidence that certain clupeids show a graded series of responses to exposure to ultrasound. The strongest responses involve rapid movement away from the sound source.

Assessment of Impacts. As previously mentioned, there is little evidence to suggest that exposure to typical seismic surveying activity has any acute physical and physiological impact on fish. Effects have been noted after exposure to very high levels of seismic under conditions that would not occur naturally. It appears that some fish will alter behaviour to avoid a seismic source by moving away in either or both the horizontal and vertical planes. These distributional shifts appear to be temporary.

The proposed seismic program for 2011 is predicted to have *minor* impacts on the fish VEC, including eggs and larvae, over a *short-term* duration in area spatial extent ranging between < *1 km^2 to 101-1,000 km^2*. Therefore, the predicted impacts of the proposed program on the fish VEC would be *not significant* (Table 3). There is no risk of long-term population impacts

given the temporary nature of the seismic program (Boertmann et al. 2009a). The level of confidence associated with this prediction is judged as high.

3.11.3 Potential Effects of Vessel and Icebreaker Sound on Fish

Underwater sound generated by marine vessels is continuous but of somewhat lower level than other anthropogenic sound sources. Sound generated by marine vessels within the Project Area could potentially have behavioural effects on fish but such effects would be temporary and similar to the effects of sound generated by other marine vessels not associated with the Project (e.g., research vessels, fishing vessels). The loudest sound levels from marine vessels may result from large icebreakers, particularly when they operate in ramming mode (Boertmann et al. 2009a). The peak sound levels of icebreaking may then exceed the ambient sound level up to 300 km from the sound source (Davis et al. 1990). No studies were found that examine the effects of icebreaking sound on fish.

Assessment of Impacts. Vessel noise, including icebreaker noise, is predicted to have *minor* impacts on the fish VEC over a *short-term* duration in an area *<1 km^2 to 101-1,000 km^2*. Therefore, the impacts of underwater sound generated by Project marine vessels on the fish VEC are *not significant* (Table 3). There is no risk of long-term population impacts given the temporary nature of the seismic program (Boertmann et al. 2009a). The level of confidence associated with this prediction is judged as high.

3.12 Accidental Events

For the purposes of this EIA, a worst case scenario approach was used as the basis for assessing the impacts of an accidental event (i.e. a fuel spill) during GXT's proposed seismic program. The fuel capacity of the *Polar Explorer* is 650,000 litres and the fuel capacity of the *Vladimir Ignatyuk* is 1,918,560 litres, though typically less is carried. A worst-case scenario spill would result in a spill of 1,918,560 litres of fuel during a vessel collision at sea. (Response considerations and procedures for other types of accidental events are included in the Project Safety Plan in Application Volume 2, Appendix 3.)

3.12.1 Probability of Occurrence

Fuel spills have occurred in the seismic industry but not to GXT. Such a spill is considered to be highly unlikely. For example, no such spills occurred in the Canadian Beaufort Sea during the 1970s and 1980s or 2000s when some 100,000 km of seismic surveys were conducted.

3.12.2 Mitigation

Fuel is contained in 16 separate tanks onboard the *Vladimir Ignatyuk*. The maximum single tank size is 264,880 litres. Numerous preventative measures and plans will be in place to avoid any fuel spillage or any other accidental events during the GXT seismic program. Plans and measures include: spill prevention plans and ship-board oil pollution prevention plans, crew training, adherence to the safety management procedures including proper bunkering procedures, oil pollution drills and other safety plans to prevent or respond to accidents. (See

Section 5.1 of the GXT Application and Appendix 3, Safety Plan.)

Also, most of the survey will occur in an offshore area away from the Greenland coast and as such will avoid sensitive areas outlined in Boertmann et al. (2009a; see Figure 7.6, below).

If a fuel spill did occur, oil spill kits (kits built for Arctic operations) are aboard both ships and both can be applied. These measures will further reduce the likelihood of an event and/or assist in mitigation if a spill should occur. For a spill, personnel would also follow the *Field Guide for Oil Spill Response in Arctic Waters* (Emergency Prevention, Preparedness and Response 1998) prepared for the Arctic Council, as well as each vessels' Shipboard Oil Pollution Emergency Plan (SOPEP). See Application Volume 2, Appendix 3 (Safety Plan) and Appendix 3-17 to 3-22.

3.12.3 Residual Risk

A major spill of fuel is very unlikely but if one did occur, depending upon location, at least some cleanup is possible. However, Boertmann et al. (2009a) note that "Adding to the severity of an oil spill in the assessment area is the general lack of response methods to recover oil from icy waters. Another important factor in this respect is the remoteness, inaccessibility and lack of infrastructure in the region."

3.12.4 Potential Environmental Effects

In the worst case scenario up to 1,918,560 L of fuel could be lost if all fuel compartments on the *Vladimir Ignatyuk* ruptured. Such a spill would likely form a diminishing surface slick. It is such a slick that has the most potential to harm wildlife. The oil that disperse in the water column would be diluted to low levels that would not be harmful to fish and invertebrates although there could be some very limited mortality of animals near the surface at the spill site just after the spill occurred. Such mortality would be small and would have no effect on the viability of the populations in that area. This topic was reviewed by Sprague et al. (1982) and Thomson et al. (1981). Boertmann et al. (2009a) noted that adult fish occupying coastal habitats, where oil may become trapped within bays and inlets, may be more sensitive to oil spills than those in the open ocean. The authors suggested that Arctic char, a common and important species in the KANUMAS East assessment area, would be vulnerable under such conditions. Refuelling is planned to occur in port, but if any at-sea fuel transfers do occur during GXT's program, it will be in offshore areas away from the Greenland coast. Effects of a spill during fuel transfer on fish, zooplankton, and macroinvertebrate VECs are judged to be not significant. There is no risk of long-term population impacts (Boertmann et al. 2009a).

The known effects of oil on marine mammals have been reviewed by Engelhardt (1983, 1985), Geraci and St. Aubin (1990) and Richardson et al. (1989). In general, the main effect of oil on marine mammals is to destroy the insulating capability of the fur of mammals that rely on fur for insulation. In the Arctic, all whales and seals rely on a layer of blubber, rather than fur, for insulation. During GXT's seismic program, the only species that would be vulnerable to effects on insulation is the polar bear which suffer reduced insulation capabilities if oiled. Also, bears ingest oil when trying to clean their fur and the ingested oil can make them very sick and cause mortality (Engelhardt 1981; Øritsland et al. 1981). Thus, the only effect of the spill examined here would occur if a polar bear happened to be in the

area and happened to become oiled. Mortality might occur. Given that polar bears will be widely dispersed in the Project Area and that GXT will not refuel in or near the Northeast Water Polynya, such mortality is within the annual levels of natural and hunting mortality for this stock of polar bears. It is also possible that marine mammals may be susceptible to the effects of inhaling fuel or its vapours (Matkin et al. 2008). Boertmann et al. (2009a) note that "It is difficult to assess the impacts of an oil spill on seals and whales in the [KANUMAS east] assessment area. There is at least a risk for major impacts on individuals if oil is trapped in a polynya or along an ice edge, where also marine mammals assemble." Given that GXT will not refuel in polynyas, the risk of impacting large numbers of marine mammals is minimized, and the effects of an accidental release of fuel are judged to be not significant.

The main concern about an oil spill is the resulting surface slick that could contaminate birds that landed on it or swam through it. Even very small amounts of oil are enough to breakdown the insulation capability of the feathers and cause the bird to die in cold waters. Spills can cause large bird mortalities if they occur near large concentrations of birds or near large nesting colonies (Joensen 1972; Campbell et al. 1978). Boertmann et al. (2009a, see Section 11.2.6) review the effects of oiling on seabirds and present times and areas where seabirds may be most sensitive to a spill in Northeast Greenland. During summer seabirds will be assembled near the breeding colonies and large numbers of birds, most notably eiders are known to moult in coastal waters. In late summer, large Svalbard populations of Little Auks and Thick-billed Murres migrate through the KANUMAS East assessment area, along with a significant part of the breeding population of the threatened Ivory Gull (from north Greenland, Svalbard and Arctic Russia). If these birds land in spilled fuel near the time of an accidental release, large numbers of birds could experience mortality. GXT will not refuel near the sensitive areas outlined in Figure 6. Given this mitigation measure, the magnitude of potential impacts is reduced. However, much is not known about the offshore distribution of some bird species. Significant impacts on certain seabird species could occur if a spill coincided in time and space with large groups of seabirds in offshore waters.

Figure 6 shows areas as identified in Boertmann et al. (2009a); designations should be considered preliminary (taken from Figure 51 in Boertmann et al. 2009a).

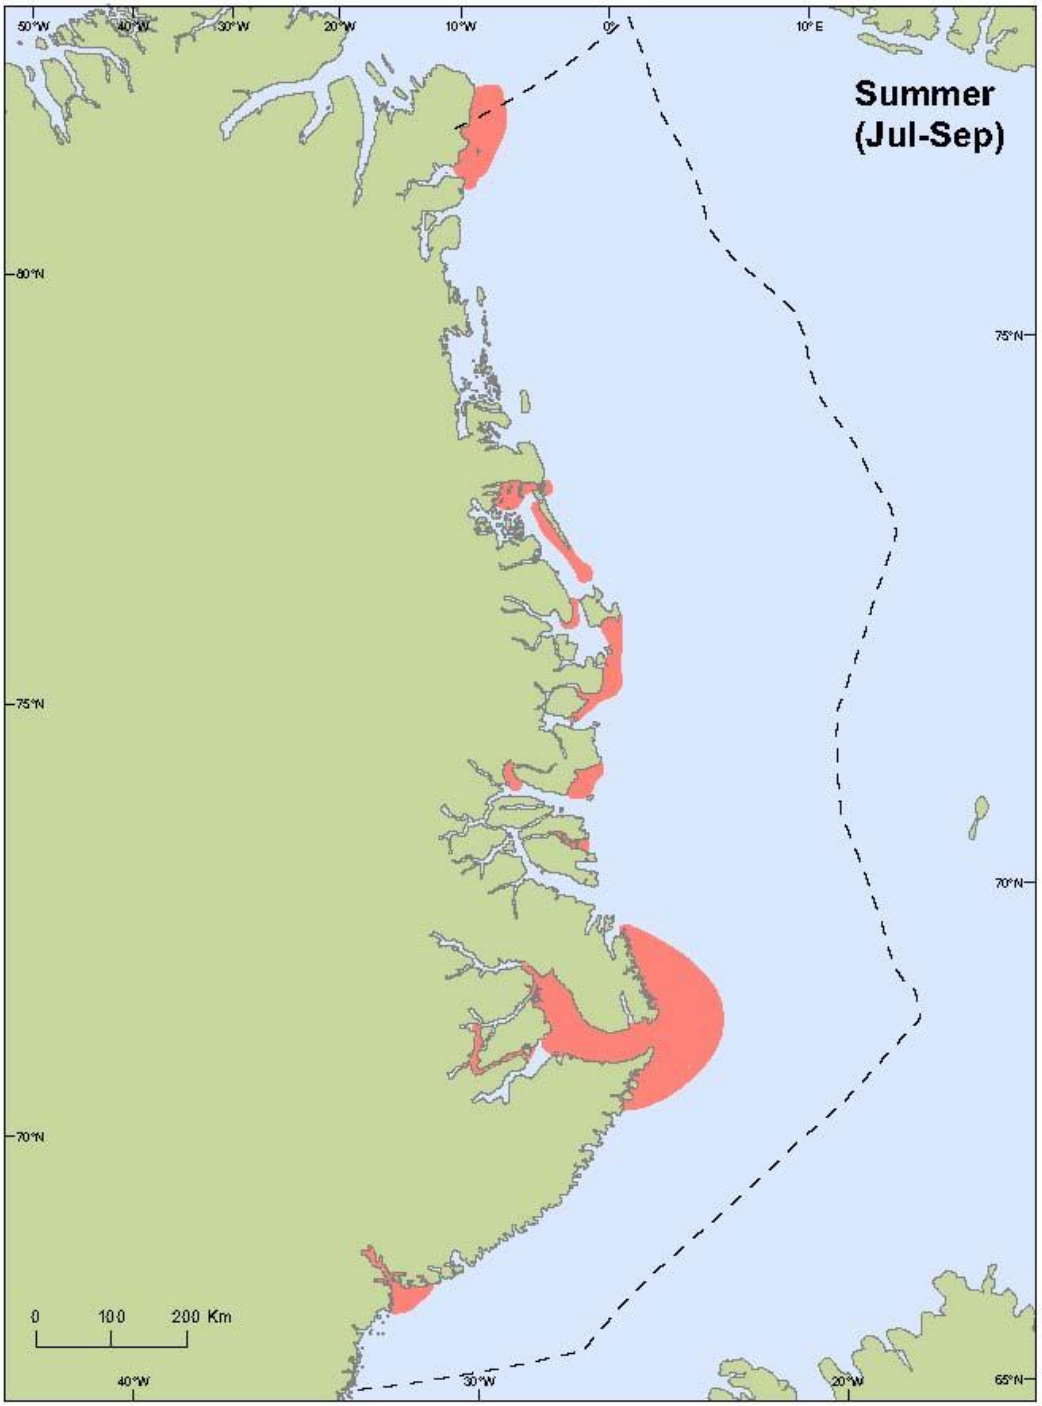

Figure 6. Oil Spill Sensitive Areas for July to September

3.13 Cumulative Effects

Cumulative effects refer to the impacts on the environment that result from combined activities of GXT's proposed seismic program as well as other activities that may occur in Northeast Greenland. Relative to other areas of the Arctic where seismic survey programs occur, there are few other activities which can contribute to cumulative effects on VECs. In 2011, some cruise ships and fishing activity are expected, and the Danish Continental Shelf Project is planned to occur north of GXT's Project Area.

3.13.1 Tourism

Tourism is a growing industry in Greenland, particularly in the KANUMAS East assessment area (Boertmann et al. 2009a). Included in the tourism industry are cruise ships visits that may occur in any ice free waters during the summer (Boertmann et al. 2009a). In Greenland, the cruise ships largely frequent coastal areas where major attractions include wildlife sightings (e.g., marine mammals, birds), scenic views, and visits to inhabited areas. On the east coast, the cruise ships that arrive from Svalbard move southwards along the outer coast and in the fjord lands while those from the south, namely Tasiilaq or Iceland, mainly visit the town of Scoresbysund (Ittoqqortoormiit) and the adjacent fjord land. The number of cruise ship visits to the Scoresbysund area has increased from three in 2002 to 14 in both 2006 and 2007. Over that time period, the number of passengers has increased from <100 to ~1,000. Some cruise ships frequent the waters of the National Park but most areas are only accessible for a short time period because of sea ice. The number of cruise ship visits to the Project Area in 2011 is unknown but expected to be much lower than the number of visits to the Scoresbysund area.

3.13.2 Fishing Activity

As described above, very little fishing activity occurs in the waters off Northeast Greenland. A limited Greenland halibut commercial fishery occurs in the southern portion of the KANUMAS East assessment area and outside of the Project Area. Some Arctic char fishing may occur in coastal areas. This limited fishing activity suggests that very few, if any, fishing vessels will occur within or adjacent the Project Area during the seismic survey.

3.13.3 Research Cruises

TUNU-MAFIG Program. In recent years, fish surveys have been conducted in Northeast Greenland waters during the TUNU-MAFIG Program (2002 to 2012) which is headed by the University of Tromsø in Norway. The program is part of the International Polar Year initiative and involves eight nations and roughly 35 scientists and research students. The program is largely addressing questions related to the diversity of genes, species, and communities in Arctic marine ecosystems, in particular the little studied marine fishes of Northeast Greenland between 69°N to 79°N (the National Park). A minor part of the research is allocated for studies of benthos and plankton communities and seal physiology. Fish surveys are typically conducted in September and October and involve sampling stations distributed from the innermost part of Northeast Greenland fjords to the continental slope (Christiansen 2003, 2005; Christiansen et al. 2008; J. Christiansen, pers. comm. 2010). Four research cruises (TUNU-MAFIG I-IV in 2003, 2005, 2007, and 2010, respectively) have been completed to date (Christiansen et al. 2008). No research cruises are planned for 2011. A fifth and final research cruise (TUNU-V) is planned for 2012 (J. Christiansen, pers. comm. 2010).

Danish Continental Shelf Project. The Danish Continental Shelf Project (DCSP) (see www.A76.dk) has been conducting research cruises in recent years to acquire data to document possible claims for an extended continental shelf (beyond 200 n.mi.) in areas north, northeast, and south of Greenland. The area of interest off Northeast Greenland is bordered by the exclusive economic zones (EEZ) of Svalbard (Norway) to the north, Jan Mayen (Norway) to the south, and Greenland to the west. Refraction and reflection seismic data was collected in the area in 2002 while multibeam bathymetric and seismic data were collected at the end of the LOMROG cruise in 2007 (http://a76.dk/greenland_uk/east_uk/index.html). For 2011, the Continental Shelf Project has planned a cruise using the icebreaker *Oden* in an area off Northeast Greenland. The cruise will acquire seismic refraction and reflection data using an array of ~ 2000 cu. in. along three seismic lines, as well as multibeam bathymetric data along the East Greenland Ridge and the continental slope along the shelf south of the Ridge. Its focus will be generally eastward from the EEZ boundary, between ~74° and 78° N though some acquisition will be inside the EEZ in some areas. The *Oden* will leave Longyearbyen on Svalbard on 17 August 2011 and will be back in Longyearbyen by about 9 September (pers. comm. Christian Marcussen, GEUS, May 2011).

Although GXT's acquisition is within the EEZ and primarily away from this area, there is a potential for sound overlap if the two projects are in the same general area at the same time. It will therefore be necessary to communicate and coordinate with the Continental Shelf Project. GXT has met with relevant GEUS personnel (February 2011) to present information about its survey and GXT will continue to coordinate with them.

3.13.4 Assessment of Cumulative Impacts

With the avoidance of overlap between GXT's survey and the DCSP work, and in the absence of other activities, the impacts of the proposed GXT seismic project (relating to underwater sound and presence of vessels) are expected to be, at most, short-term and minor to moderate based on an assessment of VECs (Table 3). The cumulative effects on VECs of all of the expected activities are expected to be negligible to minor for most parts of Northeast Greenland. There is a possibility that seismic surveys, as part of the Danish Continental Shelf Project, will be conducted off Northeast Greenland. If two concurrent seismic surveys do occur off Northeast Greenland, it is expected that the two seismic vessels will not operate close enough concurrently to affect VECs particularly since they would have to stay apart far enough not to cause mutual acoustic signal interference. Therefore, there will be no synergistic cumulative effects on VECs. Cumulative impacts are judged to be not significant.

3.14 Data Gaps and Potential Research

Section 8 of the Seismic Guidelines (Boertmann et al. 2010) notes several areas for possible future research, including the potential for non-standard sound transmission conditions resulting from the more strongly stratified water columns that might be expected in Arctic areas. They note, "It is therefore difficult to base impact assessments on simple transmission loss models (spherical or cylindrical spreading) and to apply assessment results from southern latitudes …. For example, the sound pressure may be very strong in convergence zones far (> 50 km) from the sound source, and this is particularly evident in stratified Arctic waters." The same section also notes, "Direct measurements around an operating airgun array in the arctic

are missing and future research should focus on this issue."

During the Canadian regulatory process for GXT's 2010 in-ice seismic program in the Arctic waters of the Canadian Beaufort Sea (modeled on GXT's Northeast Greenland surveys), GXT commissioned JASCO Research Ltd. (www.jasco.com) to model its planned seismic array, a somewhat larger sound source (4450 cu. in. *vs* the 4330 array used off Greenland). The work also involved direct measurement of the array in the Beaufort Sea during the 2010 survey (Sound Source Verification).

JASCO's modeling, analysis and report preparation are still under way (as of May 2011), but GXT is prepared to share results from that research with NERI when it is completed.

In terms of discussions and information from JASCO to date, their modeling has not noted instances of convergence zones resulting from the array at great distances (e.g. > 50 km) from the source. They have indicated that water depths and bottom type (including the presence of permafrost) appear to have the greatest influence on propagation loss.

It is also of note that many of the studies used as background information in this EIA were conducted in the U.S. and Canadian Arctic were sound transmission has been shown to be enhanced by such features as subsea permafrost and possibly water column stratification. GXT recognizes that underwater sound propagation can vary widely from region to region. However, the effects predictions are based on the best available scientific information and are considered valid, applying enhanced mitigations described above.

4 Environmental Management and Mitigations Summary

This section summarizes GXT's plan for mitigating, monitoring and otherwise managing potential environmental effects that might result from the Project (detailed above) with particular reference to the Seismic Guideline requirements (Boertmann et al. 2010). Other aspects of GXT's overall environmental management and protection plans, including those for accidental events, are described in GXT 2011 Application Section 5.1 (Safety and Emergency Response) and Appendices under the headings Waste Management and Sewage Pollution Prevention, Air Pollution Prevention, Oil Pollution Prevention and Spill Response, Other Emergency Response, and Safety and Emergency Training (see Section 4.6, below, for waste management and pollution prevention).

GXT's mitigation and monitoring are designed to conform to the requirements and advice set out in Boertmann et al. (2010) and in the Application Guidelines (Section 7.1 – 7.7) with respect to protection of the natural environment and environmental monitoring. As described above in Section 3, no significant residual effects were identified during the preliminary environmental impact assessment for this Project with planned mitigations in place.

To make sure that all personnel are aware of the environmental issues and mitigations that will be applied for the 2011 survey, GXT environmental and Project management personnel had meetings with the seismic survey vessel crew and managers in Munkebo, Denmark, in early July 2011 to ensure full compliance.

4.1 Best Technology and Best Practices

The Project has been planned to use the technology best suited to the requirements of the data to be collected, the working environment and the protection of safety, while minimizing the potential for environmental risks from its use. For instance, the sound source is a compressed air array (no explosives will be used); the array power is the lowest practicable to achieve the data results required; the seismic streamer is solid core which minimizes the potential for cable leaks; there is strict control of waste and emissions; and onboard fuel is separated into multiple compartments. Descriptions of other technology used and practices applied to ensure Project safety (and thus to prevent accidents which could have environmental consequences) are contained in Section 5 of GXT's 2011 Application.

The Project Safety Plan (Appendix 3 of the Application) also contains ION/GXT's QHSE Policy and ISS Marine Environmental Guidelines with which all project vessels and contractors must comply. The following sections describe other environmental best practices GXT will employ during the 2011 Northeast Greenland Project.

4.2 Marine Mammals and Seismic Array Operations

The mitigations / precautions related to the operation of the seismic sound source array (airguns) during the survey follows the guidance provided in the most recent BMP/NERI Seismic Guidelines (Boertmann et al. 2010). GXT will follow the Best Practices as described in Boertmann et al 2010. These are also consistent with "JNCC guidelines for minimising the risk of injury and disturbance to marine mammals from seismic surveys" (Joint Nature

Conservation Committee, August 2010). Specifically, GXT will adhere to the following practices:

- The airgun array will not be larger than needed for the survey.
- A safety zone of 500 m from the airgun array will be applied.
- GXT's MMSOs will conduct a pre-shooting search before commencement of any use of the airguns. If waters are less than 200 m deep, this search will be 30 min. If waters are more that 200 m deep, it will be conducted for 60 min. If marine mammals are spotted within the safety zone, the ramp-up procedure will be delayed 20 minutes, from the time when the animal has left the safety zone (or the ship has moved so far that the animal is outside). The pre-shooting search can be initiated before the end of a survey line, while the airguns are still firing.
- The array will not be started at full power. Individual airguns will be added one by one or else, output of each airgun slowly increased by manipulation of pressure (ramp-up procedure).
- The ramp-up procedure will occur over a period of about 20 min and can occur while the survey ship is en route to the starting point of the transect line.
- Ramp-up will not be initiated if marine mammals are inside the array or within the safety zone (500 m) of the array. If marine mammals are discovered within this safety zone during the ramp-up procedure, the airguns shall be turned off, and a new ramp-up procedure initiated when the mammal has left the safety zone - i.e. at least 20 min. after the last sighting. If proper ramp-up cannot be performed for technical or other reasons, other measures should be taken to assure that no animals are within the safety zone at start up.
- If the array is shut down for any reason while on the transect line it can be re-initiated at full power given that the silent break is not longer than 5 min. Otherwise a full ramp-up procedure should be followed.
- The array will be shut down completely between lines, if the transit time is longer than the time it takes to conduct a ramp-up and a full ramp-up will be initiated prior to arrival at the next line. If transit time is less than 20 min the array can be operated during transit, preferably at reduced power output.
- Two MMSO will be posted on the *Polar Explorer* and at least one will be continuously on the look out particularly for whales during the preshooting search and when airguns are operated.
- Observation of marine mammals during shooting and inside the safety may not lead to shutdown.
- A log of marine mammal observations will be kept on the ship and reported as part of the cruise report.
- Airguns will not be used outside the transect lines, except in the cases mentioned above (ramp-up prior to arrival and on short transit lines) and for strictly necessary testing purposes. Testing the array at full power will be initiated with a ramp-up procedure as above.
- GXT will implement a shutdown if a bowhead whale, northern right whale, beluga, narwhal, or walrus is observed within or about to enter within a 500 m radius of the seismic source within any of the designated Protection Zones and within a 200 m radius in all other areas.

Although BMP/NERI does not require shutdowns for marine mammals entering the safety zone after the array is at full power, a 200 m shutdown was required during the 2009 NE

Greenland survey, and continued to be implemented (voluntarily) for the 2010 survey (see Section 3.6).

GXT's MMSOs who will be implementing these procedures during the 2011 survey are highly qualified and have extensive experience implementing similar procedures in many jurisdictions. In addition, as described earlier, GXT environmental and Project management personnel had meetings with the seismic survey vessel crew and managers in Munkebo, Denmark, in early July 2011 to ensure full understanding of these requirements and the need for full compliance.

4.3 Fishing Activities

Fishing (or other activities) will not be prevented or unnecessarily impeded by GXT's survey (see Section 3.13) Fishing activities will be given priority if encountered. As stated in Section 4.1 of GXT's 2011 Application, acquisition will be coordinated with any other activities in the area to avoid disruption. However, given the very low level of fishing activity (and other marine activity) expected in the seismic survey area it is not expected that any potential for interference will occur.

4.4 Important Wildlife Areas and Protection Zones

The important wildlife areas and sensitive zones (Boertmann et al. 2010, Chapter 6) in the vicinity of the 2011 survey lines are discussed and mapped in Section 3, above, as are the mitigations to be put in place related to them. These are areas for seabirds, narwhals, bowhead whales and walruses, and sensitive areas in relation to fuel spills.

4.5 Monitoring

4.5.1 Fisheries

The 2011 Application Guidelines state (Section 7.5) that "The licensee shall, upon BMP request, include one or more Fishery Liaison Officers (FLO) in the operation. The FLO must be approved by the BMP and shall serve as an advisory observer and communicator in matters related to fishery. BMP may impose specific requirements on the FLO's qualifications, including, for example that he must be speaking Greenlandic in order to communicate with local fishery actors." However, it is not anticipated that a Fisheries Observer will be required considering the location of GXT's 2011 Northeast Greenland survey. Nevertheless, it is understood that GXT will place a FLO onboard if so requested and will bear all associated costs. If a FLO is required, a logbook of observations will be kept using the template in Appendix H of the Application Guidelines, and will be submitted to the BMP (with a copy to GXT) within 2 weeks of the termination of the exploration activity.

4.5.2 Marine Mammals

GXT will have two MMSOs (Biological Observers) aboard the *Polar Explorer* at all times during the seismic program a (as per Section 5.3 of Boertmann et al. 2010). Details about the MMSOs' qualifications have been provided to NERI (same MMSOs as in 2010). The seismic guidelines state:

> At least two Marine mammal and seabird observers (MMSOs) shall be on board the seismic vessels operating in Greenland waters in order to observe continuously when operating the airguns. They shall be especially trained in observation methodology and seismic mitigation.
>
> The MMSOs have two tasks. Firstly, they have to watch systematically for marine mammals before start-up and during seismic survey in order to mitigate and observe safety distances to whales and seals.
>
> Secondly, the MMSOs shall collect data on abundance and distribution of seabirds and marine mammals through systematic surveys. This task shall be carried out both during times when seismic survey is conducted, and when sailing in transit.
>
> The latter task is not secondary to the former, and considerable effort should be spent on the systematic surveys.
>
> The purpose of the second task is to improve the knowledge on temporal and spatial distribution of marine mammals and seabirds in the West [and Eastern] Greenland waters, which generally is low. The collected data will be included in the NERI-databases of background information. The information in these databases will constitute the basis for future EIA-work by NERI and is moreover available to the companies which shall operate in Greenland waters and prepare EIAs of their activities. Data have to be collected according to NERI standards to fit into the databases, and guidelines to observation methodology will be provided when a seismic survey is approved by BMP.

The MMSOs will monitor marine mammals near the seismic source vessel. They will be responsible for monitoring marine mammals and delaying start of the airguns if a cetacean is seen inside the 500 m zone during the 30 minutes prior to ramp-up (60 minutes in deeper waters). GXT monitors will follow specific monitoring and data collection protocols as advised by BMP/NERI (those protocols described in the 2010 Manual for seabird and marine mammal surveys on seismic vessels in Greenland). A log of marine mammal observations will be kept and reported as part of the cruise report.

As noted above, although no shutdown for marine mammals is required, GXT will implement a shutdown if a bowhead whale, northern right whale, beluga, narwhal, or walrus is observed within or about to enter within a 500 m radius of the seismic source in all Protection Zones and within 200 m in all other areas. In addition, further observations for marine mammals will be maintained by bridge personnel on the icebreaker, as described above. GXT will bear all costs associated with the MMSOs' participation in the Project.

Seabirds. GXT's MMSO will place a particular focus on observing and recording seabird sighting data during the 2011 survey, as in 2010. GXT MMSOs will use NERI Field Recording and Data Entry sheets/database forms, and will follow the latest NERI/BMP procedures described in the most recently available manual for seabird and marine mammal surveys on seismic vessels in Greenland.

4.6 Waste Management and Pollution Prevention

The *Polar Explorer* and the *Vladimir Ignatyuk* have Shipboard Garbage Management Plans that are issued in accordance with the requirements of MARPOL Annex V. Both plans include the following components: Garbage Record Book; Incinerator Management; Designated Persons and Duties; Procedures for Collection, Storage and Processing garbage. No non-degradable materials will be disposed of in the area.

Both the *Polar Explorer* and the *Vladimir Ignatyuk* both have sewage treatment plants that comply with MARPOL Annex IV of the International Convention of for the Prevention of Pollution from Ships. Both sewage treatment plants of meet the effluent standards as provided in resolution MEPC.2 (VI).

Both vessels have a MARPOL International Air Pollution Certificate. The *Polar Explorer* certificate was issued under the provisions of the Protocol of 1997 as amended by resolution MEPC.176(58) in 2008. The *Vladimir Ignatyuk* certificate was issued on the Protocol 1997 to amend the International Convention for Prevention of Pollution from Ships, 1973 as modified by the Protocol of 1978 related thereto and as amended by Resolution MEPC.132(53).

Both vessels have MARPOL International Oil Pollutions Prevention Certificates issued under the provisions of the International Convention for the Prevention of Pollution from Ships, 1973, as modified by the Protocol of 1978. Both vessels have a Shipboard Oil Pollution Emergency Plan issued in accordance with the Requirements of Regulation 26 Chapter IV of MARPOL 73/78 International Convention amended in 1999. The Field Guide for Oil Spill in Arctic Waters, a program by the Arctic Council will be used in the event of an oil spill. The vessels will conduct drill using these guidelines.

GXT's vessels will only use diesel and gasoil with a sulphur content less than 1.5 % (weight). Heavy fuel oil and oil with a sulphur content >1.5 % should will not be used.

4.7 Other Environmental Conditions

The BMP's Application Guidelines (Section 7.7) also note requirements related to other environmental conditions and considerations:

- When acquiring seismic data, the operation shall be conducted in accordance with the Best Practices listed in NERI Report No. 785, Chapter 5 concerning acquisition of seismic data.
- All non-degradable materials and structures shall be removed upon termination of the operation, unless BMP approves otherwise (see 4.5.3, above).
- Discharge of waste water and kitchen waste shall be in compliance with the provisions of Annex IV and Annex V of the MARPOL Convention (see 4.5.3, above).
- Hunting and fishing is not permitted in connection with exploration activities, unless specific permission is given by the Greenland Government.
- BMP may when approving specific exploration activities require the licensee to perform further impact studies and / or limit the operation to certain periods or from certain areas.
- Vessels engaged and machinery used in the exploration activities should only use diesel and gasoil with a sulphur content less than 1.5 % (weight). Heavy fuel oil and oil with a sulphur content >1.5 % should not be used (see 4.5.3, above).

.

GXT will comply with each of these requirements (as described above) and has briefed Project personnel about these and all other environmental commitments and requirements during in-person start up meetings before acquisition (during early July 2011). GXT project vessels will also comply with all parts of Landstings-forordning No. 4 of 3 November 1994 on the protection of the marine environment that apply to the GXT project area and vessels.

Appendix 1. Important Bird Areas and Ramsar Sites within the KANUMAS East Assessment Area.
Location includes minimum distance (in parentheses) from the approximate centre of the IBA to the Project Area. Grey shading indicates sites which occur well south of the Study Area.

	Name	Location	Size (ha)	Habitat	Importance
1	Kilen (also Ramsar site)	81º15'N, 13º30'W (35.0 km)	51,300	A flat, gravel plain comprising polar desert and melt-water rivers, surrounded on three sides by glaciers and on the fourth by the polar sea.	*Non-breeding*: 625 Brent Geese (moulting); 2,500 Common Eider and 1,000 King Eider (staging) *Breeding*: 70 pairs Brent Geese, 35 Ivory Gulls 20-30 Sabine's Gulls, 50 Arctic Terns.
2	Henrik Krøyer Holme	80º45'N, 13º45'W (within Proj. Area)	1,000	Three small, low-lying, barren islands located in the north-eastern water polynya.	*Breeding*: 510 Ivory Gulls; possible breeding Ross's Gulls
3	Western part of Germania land	77º15'N, 22º0'W (104.5 km)	100,000	Rolling tundra lowland with lakes and ponds, situated adjacent to the Inland Ice between 76°45'N and 77°35'N. Large expanses of bare ground (moraine) occur close to the ice sheet.	*Non-breeding*: 7,000 Pink-footed Geese, significant moulting site. *Breeding*: Diverse breeding birds that are restricted in Europe to the Arctic/tundra biome (Pink-footed Goose, Barnacle Goose, King Eider, Sanderling, Gray Phalarope and Long-tailed Skua).
4	South coast of Germania Land, and Slaedelandet	76º50'N, 19º20'W (44.4 km)	35,000	A 5-10 km wide expanse of gravel moraines and uplifted former sea floor, separating the large fjord-like Lake Saelsøen from Dove Bay. The area is crossed by several rivers, notably Lakseelven, and there are numerous small lakes and ponds with narrow fringes of vegetation. Arctic tundra grows on the slopes	*Non-breeding*: Moulting area for 1,500 Pink-footed Geese and 350 Barnacle Geese. *Breeding*: Diverse breeding birds that are restricted in Europe the Arctic/tundra biome (Barnacle Goose, Long-tailed Duck, Gyrfalcon, Red Knot, Sanderling, Gray Phalarope, Long-tailed Skua and Snowy Owl.

	Name	Location	Size (ha)	Habitat	Importance
				rising up towards the hinterland.	
5	Hochstetter Forland (also Ramsar site)	75º27'N, 20º0'W (56.5 km)	184,800	An extensive area of coastal tundra with river valleys and wetlands.	*Non-breeding*: Moulting area for 3,000 Pink-footed Geese and 400 Barnacle Geese. *Breeding*: Diverse breeding birds that are restricted in Europe the Arctic/tundra biome (Barnacle Goose, King Eider, Long-tailed Duck, Red Knot, Sanderling, Gray Phalarope and Long-tailed Skua.
6	Albrecht Sletten (Storsletten), Wollaston Forland	74º30'N, 20º0'W (64.3 km)	30,000	An extensive area of tundra with several ponds.	*Non-breeding*: 2,000 Pink-footed Geese moulting. *Breeding*: Long-tailed Duck, waders and Long-tailed Skua.
7	Østersletten and Knudshoved, Hold With Hope	73º34'N, 20º45'W (72.6 km)	55,000	A large, rather dry area of lowland traversed by two rivers. The site includes the mouth of the Tobias Dal valley.	*Non-breeding*: Moulting area for 350 Barnacle Geese
8	Stordal-Moskusoksefjord-Badlanddal-Loch Fyne-Myggbukta	73º30'N, 22º0'W (113.2 km)	90,000	A series of converging, wide glacial valleys in otherwise mountainous terrain, containing fjords, seasonal stream channels and water-bodies, and tundra vegetation overlying thick glacial deposits. Moskusoksefjord and Loch Fyne are long, narrow sea inlets that continue inland as valleys. The site includes Ternholme˜a flat, low-lying island located 2.5 km offshore from Myggbukta.	*Non-breeding*: Moulting area for Pink-footed Geese and 440 Barnacle Geese. *Breeding*: Snowy Owl, waders, Long-tailed Skua and Common Eider
9	Enhjørningens Dal and Pingel	71º37'N, 23º7'W	50,000	Two river valleys situated in eastern Scoresby Land, with marsh	*Non-breeding*: An important moulting and breeding site for Brent Geese (750).

	Name	Location	Size (ha)	Habitat	Importance
	Dal	(269.6 km)		and dwarf-shrub heath vegetation.	
10	Ørsted Dal and Coloradodal	71º40'N, 23º22'W (271.5 km)	40,000	A c.60-km long valley containing marshes, lakes, ponds and gravel plains, bisecting a plateau (700-1,000 m) in Scoresby Land	*Non-breeding*: 1,864 Barnacle Geese *Breeding*: 60 Pink-footed Geese and 200 Barnacle Geese.
11	Liverpool Land coast and mouth of Scoresby Sund	71º0'N, 21º40'W (293.2 km)	150,000	A rocky coastline with cliffs and small offshore islands (Raffles Ø and Rathbone Ø), extending from 70°30'N to 71°30'N. Scoresby Sund is the mouth of a wide fjord between Liverpool Land coast and Kap Brewster (IBA 042), which remains ice-free for much of the year due to strong tidal currents (i.e. a polynya). The nutrient-rich waters provide excellent feeding for seabirds. Subsistence hunting takes place.	*Breeding*: 3.5 million pairs of Little Auks (Internationally significant numbers). Also 2,000 Brünnich's Guillemot.
12	Kjoveland	71º22'N, 24º47'W (330.8 km)	15,000	An area of tundra and dwarf-shrub heath situated in western Jameson Land, containing lakes, rivers and several marshes. Subsistence hunting takes place.	*Non-breeding*: 621 moulting Barnacle Geese
13	Heden (also Ramsar site)	71º0'N, 24º7'W (344.2 km)	252,400	Situated in the western part of Jameson Land, this site comprises flat tundra (mainly dwarf-shrub heath and grassland) and areas of bare ground interspersed with many rivers, lakes and ponds. The	*Non-breeding*: Very important numbers of moulting Pink-footed Geese (5,300) and Barnacle Geese (1,750). Note: In 2010 there is a proposal to add Ørsted Dal to the Ramsar site to compensate for mining activities to take place at Gurreholm located within the Heden

	Name	Location	Size (ha)	Habitat	Importance
				primary habitats for geese are areas of marsh and wet grassland adjacent to lakes and streams, and coastal saltmarshes.	Ramsar site (Glahder et al. 2010). The Ørsted Dal area will include 4,700 moulting Barnacle Geese (an additional 7%) of the breeding population of Greenland Barnacle Geese to the Ramsar site.
14	Kap Brewster and Volquart Boon's coast	70º10'N, 23º22'W (406.5 km)	20,000	Rocky coastline and cliffs located on the south shore of Scoresby Sund (IBA 043), extending from 22°W to 25°W. Subsistence hunting takes place	*Breeding*: Internationally significant numbers of breeding Little Auk (999,999). Brünnich's Guillemot (15,000) and Black-legged Kittiwake also breed.

Appendix 2. List of Marine-Associated Birds and Summary of their Distribution and Abundance in Northeast Greenland

Species	Scientific Name	Occurrence in Northeast Greenland	Greenland Red List Status
Gaviidae			
Red-throated Diver	*Gavia stella*	Widespread, sparse breeder	LC
Great Northern Diver	*Gavia immer*	Sparse breeder	NT
Procellariidae			
Northern Fulmar	*Fulmarus glacialis*	A few colonies, common offshore in summer	LC
Sulidae			
Northern Gannet	*Morus bassanus*	Rare offshore, summer	NL
Anatidae			
Pink-footed Goose	*Anser brachyrhynchus*	Breeder, Common moulting	LC
Snow Goose	*Chen caerulescens*	Breeder, rare	NL
Canada Goose	*Branta Canadensis*	Rare	LC
Barnacle Goose	*Branta leucopsis*	Common breeder.	LC
Brent Goose	*Branta bernicla*	Former breeder, now rare migrant	NT
Common Teal	*Anas crecca*	Rare summer	NL
Mallard	*Anas platyrhynchos*	Rare summer	LC
Common Eider	*Somateria mollissima*	Common breeder. Uncommon winter.	LC
King Eider	*Somateria spectabilis*	Common breeder	LC
Harlequin Duck	*Histrionicus histronicus*	Rare summer	NL
Long-tailed Duck	*Clangula hyemalis*	Common widespread breeder	LC
Red-breasted Merganser	*Mergus serrator*	Rare breeder	NL
Charadriiformes			
Common Ringed Plover	*Charadrius hiaticula*	Common breeder	LC
Red Knot	*Calidris canutus*	Locally common breeder	LC
Sanderling	*Calidris alba*	Common breeder	LC
Purple Sandpiper	*Calidris maritime*	Scarce breeder	NL
Dunlin	*Calidris alpina*	Common breeder	LC
Whimbrel	*Numenius phaeopus*	Rare breeder	NT

Ruddy Turnstone	*Arenaria interpres*	Common breeder	LC
Red-necked Phalarope	*Phalaropus lobatus*	Scarce breeder	LC
Grey Phalarope	*Phalaropus fulicarius*	Uncommon breeder	LC
Laridae			
Pomarine Skua	*Stercorarius pomarinus*	Locally common summer visitor	NL
Arctic Skua	*Stercorarius parasiticus*	Common breeder	LC
Long-tailed Skua	*Stercorarius longicaudus*	Common breeder	NL
Great Skua	*Stercorarius skua*	Uncommon offshore	NL
Lesser black-backed Gull	*Larus fuscus*	Rare breeder, increasing	LC
Herring Gull	*Larus argentatus*	Rare summer vagrant	NL
Iceland Gull	*Larus glaucoides*	Summer and autumn vagrant	LC
Glaucous Gull	*Larus hyperboreus*	Widespread/common to sparse breeder	LC
Great black-backed Gull	*Larus marinus*	Annual summer vagrant	NL
Black-legged Kittiwake	*Rissa tridactyla*	Only a few colonies	VU
Ross's Gull	*Rhodostethia rosea*	Rare visitor	VU
Sabine's Gull	*Xema sabini*	Several breeding colonies; uncommon summer visitor in most coastal areas	NT
Ivory Gull	*Pagophila eburnea*	Locally common migrant and summer visitor; breeds in north.	VU
Arctic Tern	*Sterna paradisaea*	Widespread; sparse and locally common breeder	NT
Alcidae			
Brünnich's Guillemot	*Uria lomvia*	A few large colonies near Scoresby Sund	VU
Razorbill	*Uria aalge*	A few records near Scoresby Sund	LC
Black Guillemot	*Cepphus grylle*	Common breeder	LC
Little Auk	*Alle alle*	Huge colonies near Scoresby Sund	LC
Atlantic Puffin	*Fratercula arctica*	One small breeding colony	NT

Appendix 3: Overview of Marine Mammals Occurring in the KANUMAS East Assessment Area. Modified from Boertmann et al. (2009a).

Common Name	Scientific Name	Period of occurrence	Main habitat	Distribution and occurrence in assessment area	Protection/ exploitation	Greenland Red List status[1]	Assessment area importance to population
Polar bear	*Ursus maritimus*	Whole year	Mainly ice covered waters	Widespread	Hunting regulated	VU	High
Walrus	*Odobenus rosmarus*	Whole year	Coastal waters	Low numbers, very localised	Hunting regulated	NT	High
Hooded seal	*Cystophora cristata*	Mar to Oct	Whelp on drift ice	Numerous	Hunting unregulated	LC	High
Harp seal	*Phoca groenlandica*	Mar to Oct	Whelp on drift ice	Numerous	Hunting unregulated	LC	High
Bearded seal	*Erignathus barbatus*	Whole year	Both in coastal and offshore waters	Widespread in low numbers	Hunting unregulated	DD	High
Ringed seal	*Phoca hispida*	Whole year	Whole area, usually in ice	Common and widespread	Hunting unregulated	LC	High
Bowhead whale	*Balaena mysticetus*	Whole year?	Marginal ice zone	Widespread, few	Protected (1932)	CR	High
Minke whale	*Balaenoptera acutorostrata*	Jun to Oct	Ice free waters	Unknown[2]	Hunting regulated	LC	Potentially medium
Sei whale	*Balaenoptera borealis*	Jun to Oct	Ice free waters	Unknown[2]	Protected	DD	Potentially medium
Blue whale	*Balaenoptera musculus*	Jul to Oct	Ice free waters	Unknown[2]	Protected (1966)	DD	Potentially medium
Fin whale	*Balaenoptera physalus*	Jun to Oct	Ice free waters	Unknown[2]	Hunting regulated	LC	Potentially medium

Common Name	Scientific Name	Period of occurrence	Main habitat	Distribution and occurrence in assessment area	Protection/ exploitation	Greenland Red List status[1]	Assessment area importance to population
Humpback whale	*Megaptera novaeangliae*	Jun to Oct	Ice free waters	Unknown[2]	Protected (1986)	LC	Potentially medium
Pilot whale	*Globicephala melas*	Jun to Oct	Outside the ice covered areas	Unknown[2]	Hunting unregulated	LC	Probably low
White-beaked dolphin	*Lagenorhynchus albirostris*	Jun to Oct	Outside ice covered areas	Unknown[2]	Hunting unregulated	NA	Probably low
Killer whale	*Orcinus orca*	Jun to Aug	Mainly ice free waters, whole area	Unknown[2]	Hunting unregulated	NA	Unknown
Beluga	*Delphinapterus leucas*	Summer	Fjords and shallow waters	Very rare	Hunting unregulated	CR	Low
Narwhal	*Monodon monoceros*	Whole year	Fjords, ice edges	Common	Hunting unregulated	DD	High
Sperm whale	*Physeter macrocephalus*	May to Nov	Deep waters, southern part	Unknown	Protected (1985)	NA	Probably low
Northern bottlenose whale	*Hyperoodon ampullatus*	May to Nov	Deep waters only, mainly in south	Probably rare	Unregulated	NA	Probably low

Modified from Boertmann et al. (2009a)

[1] Red-list status from Boertmann et al (2009a). NA=Not Applicable; DD=Data Deficient; LC=Least Concern; VU=Vulnerable; NT=Near Threatened; CR=Critically Endangered.

[2] No or limited data available for the KANUMAS East assessment area, but species is abundant in neighbouring Norwegian and/or Icelandic waters.

ABSTRACT

Numbers, sighting distances, and behavior of seals were studied during a nearshore seismic program off northern Alaska in July–September 1996. We observed from the seismic vessel for 885.6 h, including all periods (day and night) when airguns operated and many periods without airguns. Of 422 seals seen, 421 were seen in daylight; 91.8% were ringed seals, 7.3% were bearded seals, and 0.9% were spotted seals. About 79% were first seen within 250 m of the seismic boat, and sighting rate declined rapidly at lateral distances >50 m. During daylight, seals were seen at nearly identical rates (0.60–0.63/h) during periods with no airguns firing, one airgun, and a "full-array" of 8–11 120-in^3 airguns. However, seals tended to be farther away ($P < 0.0001$) during full-array seismic. There was partial avoidance of the zone <150 m from the boat during full-array seismic, but seals apparently did not move much beyond 250 m. "Swimming away" was more common during full-array than no-airgun periods, but relative frequencies of five behaviors did not differ significantly among distance categories. Airgun operations were interrupted 112 times when seals were sighted within safety radii (150–250 m). The National Marine Fisheries Service specified these radii in the Incidental Harassment Authorization issued for the project; they are based on a 190 dB re 1 μPa (rms) criterion for broadband received level. Methods for estimating numbers of seals potentially affected by the seismic program are described, and effectiveness of monitoring and mitigation is discussed. There is an urgent need for more data on effects of strong seismic pulses on seals.

Key words: ringed seal, *Phoca hispida,* Beaufort Sea, Alaska, arctic, seismic disturbance, airgun array, underwater noise, behavior, harassment.

[1] Person to whom correspondence should be sent.

In recent years arrays of airguns have been the usual source of the strong pulses of underwater sound used for open-water seismic surveys. Nominal source levels, pertaining to downward propagation, are typically 245–255 dB re 1 μPa-m (instantaneous peak). Several pulses are emitted per minute, usually at uniform intervals. Received levels in the near field are high, but are less than expected from the nominal source level. This occurs because an array of airguns is not a point source, and because less sound propagates horizontally than downward (Caldwell and Dragoset 2000, Dragoset 2000). Nonetheless, in the Beaufort Sea, airgun pulses are often at least faintly detectable 50–100 km away (Greene and Richardson 1988, Richardson *et al.* 1995, Greene 1997). Most emitted sound energy is at frequencies below 125 Hz. However, there is also some energy at higher frequencies. In shallow water it is often the components at 100–500 Hz that are detectable farthest away.

Reactions of pinnipeds to open-water seismic exploration are poorly documented. An airgun caused an initial startle reaction among South African fur seals (*Arctocephalus pusillus*), but was ineffective in scaring them away (Anonymous 1975). Gray seals (*Halichoerus grypus*) exposed to noise from airguns did not react strongly (J. Parsons *in* G. D. Greene *et al.* 1985:283), but no details were given. Seals in the water sometimes tolerate strong noise pulses from scaring devices, especially if attracted to the area for feeding or reproduction (Richardson *et al.* 1995:304, 311; Reeves *et al.* 1996). The relevance of these observations to disturbance by a moving seismic vessel is uncertain. On-ice seismic exploration in winter/spring by the Vibroseis method may cause localized displacement of some ringed seals, *Phoca hispida* (Kelly *et al.* 1988, Richardson *et al.* 1995:291). However, the circumstances and sounds associated with on-ice Vibroseis operations *vs.* open-water airgun operations are very different.

Source levels of pulses from airgun arrays are high enough to raise concern about the possibility that they might cause temporary or even permanent hearing damage to marine mammals exposed at close range (Richardson *et al.* 1995:372, NMFS 1995, HESS 1999). However, there are no specific data on hearing damage from sequences of seismic pulses.

Some recent open-water seismic programs in U.S. waters have been conducted under Incidental Harassment Authorizations (IHAs), as provided for by the 1994 amendments to the Marine Mammal Protection Act (NMFS 1996*a*). An IHA allows disturbance of small numbers of marine mammals if no serious injuries or deaths are expected, impacts on the stocks will be negligible, no unmitigable adverse impacts on subsistence uses are expected, and monitoring is done to confirm these predictions. Received levels that might cause injury (*e.g.*, hearing damage) are uncertain. Since 1995, IHAs issued for high-energy seismic surveys in California and Alaska have required immediate interruption of airgun operations when pinnipeds were seen within the estimated 190 dB re 1 μPa (rms) radius (*e.g.*, NMFS 1995, 1996*b*). The rms level of a seismic pulse is the average broadband level during the duration of the pulse (see Methods).

During the summer and autumn of 1996, BP Exploration (Alaska) Inc. and

its seismic contractor Northern Geophysical of America Inc. conducted a 3-dimensional (3-D) seismic survey in shallow, nearshore waters of the Alaskan Beaufort Sea near Prudhoe Bay. Ringed seals are common in the area. Bearded seals (*Erignathus barbatus*) and a few spotted seals (*Phoca largha*) are also present. None of these species is listed as endangered, threatened, or a strategic stock (Hill and DeMaster 1998). This seismic program was conducted under the provisions of an IHA (NMFS 1996*b,c*). We stationed marine mammal observers aboard the source vessel to monitor the numbers and reactions of seals and other marine mammals, and to call for the airguns to be shut down when mammals were seen within a specified radius. For seals, this was the 190 dB re 1 μPa (rms) radius. Levels and characteristics of the sound pulses were also measured (Greene 1997). This paper describes the observations of seals near the seismic operation, and discusses the monitoring and mitigation implications.

Methods

Study Area and Season

Seismic exploration occurred on 49 of 57 d from 24 July to 18 September 1996. Seismic surveys were suspended when wind speed exceeded ~65 km/h, when there was too much ice for operations, and for other logistical reasons. Drifting ice pans were present at most times, usually covering 1%–5% of the surface but occasionally up to 20%. New ice began to form after 11 September.

Up to 8 August seismic operations were ~30 km east of Prudhoe Bay near the McClure Islands, mainly in a lagoon inshore of the barrier islands (water depths 3–8 m). Thereafter, seismic operations occurred 10–50 km northwest of Prudhoe Bay, from 0 to 13 km offshore of the barrier islands (water depths 3–17 m).

Seismic Operations and Sounds

This 3-D seismic program employed a conventional array of airguns as the energy source, but used the Ocean Bottom Cable (OBC) method to receive seismic data. The receiving hydrophones were in a series of six 5.9-km cables placed parallel to shore (and to one another) on the ocean bottom. In contrast to the more typical "streamer surveys," a seismic vessel conducting an OBC survey does not tow any hydrophone streamers. The OBC method allows use of a smaller source vessel and smaller-radius turns. However, support vessels are needed to deploy and retrieve receiver cables.

The source vessel was a 27-m tugboat, the *Pt. Barrow,* powered by two diesel engines totaling 2,100 hp and driving two propellers in nozzles. The source vessel moved back and forth at 7–9 km/h along source lines 7.3 km long. Source lines were oriented perpendicular to shore and to the OBCs, and were spaced 330 m apart.

The airgun array consisted of 11 Bolt 1900LX airguns, each of 120 in^3, for

a total array volume of 1,320 in^3 or 21.6 litres. At times, seismic work continued with fewer than 11 operating airguns. We considered an array of 8–11 operating airguns to be a "full array"; 2–7 operating guns were a "partial array." The guns were suspended from floats and positioned in a 5 × 5-m array. Most guns were at the relatively shallow depth of 3.5 m, as required for work in shallow waters. Nominal gun pressure was 2,000 psi (13.8 MPa). All airguns fired simultaneously, with the usual interval between shots being 15–18 sec (44 m).

The airgun array used in this project was low-powered by modern standards, and the shallow gun depth also reduced the effective source level. The measured effective source level for *horizontal* propagation was ~222 dB re 1 μPa-m (rms), 230 dB re 1 μPa-m (instantaneous peak), and 236 dB re 1 μPa-m or 6.3 bar-meters peak-to-peak (Greene 1997). This was well below the expected source level for vertical (downward) propagation, 242 dB re 1 μPa-m (instantaneous peak) or 26.4 bar-m. The rms received levels from the 11-gun array diminished to 200, 190, 180, and 160 dB re 1 μPa (rms) at ranges not exceeding, respectively, 44 m, 257 m, 1,020 m, and 4,900 m. More typically, those levels were attained at ranges of 31, 240, 960, and 3,600 m (Greene 1997).

Different workers have used varying procedures in measuring source and received levels of airgun sounds, making it difficult to compare results. Procedures and terminology used here are those of Greene (1997), which have also been used by McCauley *et al.* (1998). The rms pulse levels quoted here are broadband (10–4,000 Hz) sound pressure levels averaged over the duration of the pulse. Duration was defined as the time interval including 90% of the pulse energy, *i.e.,* from the time when the 5th to the time when the 95th percentile of the energy was received. In this study rms received levels averaged ~10 dB lower than the instantaneous peak level and ~16 dB lower than the peak-to-peak level, all measured in dB re 1 μPa. The rms levels averaged ~15 dB higher than the total pulse energy, measured in dB re 1 μPa^2-s (Greene 1997).

At times, a single airgun was used to localize positions of the bottom cables. It usually fired at intervals of ~8 sec (22 m) along shot lines parallel to the OBCs. Also, a single airgun or partial array (2–7 airguns) often operated while the source vessel turned from one line to the next. The received levels from a single airgun diminished below 190 dB re 1 μPa (rms) within several meters of the source (Greene 1997).

Whenever airgun operations began after an interruption of more than 1–2 min, the number of guns being fired was increased ("ramped up") progressively over about 3–4 min. The ramp-up procedure varied. Sometimes one additional airgun began firing every 20 sec until all guns were firing. At other times, one gun fired for the first minute, 2 guns for the 2nd minute, 4 guns for the 3rd, 8 guns for the 4th, and then all 11 guns.

Observation Procedures

Watches were conducted from the source vessel in 4-h shifts by a team of 2–3 biologists plus one Inupiat observer. An observer was on watch during

all periods with airgun operations (585.5 h), and during many periods when the source vessel was underway but not shooting seismic (300.1 h). A second observer was also on watch 5%–10% of the time.

Whenever shooting was underway, or was expected to begin within the next 30 min, the on-duty observer watched continuously for mammals. Observations were from the glass-enclosed wheelhouse—the highest useable vantage-point (eye level ~7.5 m above water). There was a 360° view with only minor obstructions toward the stern. The airgun array was towed ~30 m behind the observer. The observer scanned around the vessel using unaided vision and 7 × 50 Fujinon FMTRC-SX binoculars. Although the observer scanned all around the boat, effort was concentrated in a 180° arc ahead and to the sides because one objective was to detect seals before they were within 150–250 m of the airguns (see Shutdown Procedures, below). A reticle in the binoculars was used to measure depression angle relative to the horizon, and thus distance. Also, a Bushnell Lytespeed 400 laser rangefinder with 4× optics was used to test and improve the observers' abilities to estimate visually the distances to objects in the water. It did not provide direct measurements of distances to seals.

Daylight was continuous until mid-August, but thereafter the duration of darkness increased rapidly, reaching almost 9 h/night by 18 September (civil twilight counted as daylight). At night the observer used the 7 × 50 binoculars and a Bushnell/ITT Night Ranger 250 binocular night vision device (NVD) with up to 6× optics. No seals were detected *via* this "Generation 2+" NVD. The one seal seen at night was sighted 60 m away in a floodlit area during full-array seismic. Overall, the observers' abilities to detect marine mammals were severely reduced at night. Also, we had no method for detecting or tracking seals that were below the surface.

Survey Effort

Of the 885.6 h of observation, 751.9 h were in daylight and 133.7 h in darkness. There were 585.5 h of watches during airgun operations, including 332.8 h when 8–11 airguns were firing ("full array") and 105.2 h with a single airgun. This paper emphasizes daylight observations during full array, single airgun, and no airgun conditions, which were the most common (Table 1).

Data Recorded

The observer recorded, on a data sheet, information about watch times, vessel location/speed/heading, seismic status (full array, partial array, *etc.*), and environmental conditions (visibility, wind, sea state, ice cover). For each mammal sighted, we recorded species, number, sighting cue, bearing and distance from boat when first sighted, seal heading, initial and subsequent behavior, and seismic status. Initial behavior categories were dive, swim (directed), mill, thrash, look, and unknown. Seals that "milled" swam sedately in a limited

[a] One additional seal was seen at night with the full airgun array operating.

area with no consistent direction of movement. Seals that "thrashed" plunged below the surface head-first in a particularly vigorous way, often accompanied by a splash. Seals that "looked" floated at the surface and faced the source vessel. Subsequent behavior categories were no change, dive, swim away, swim toward, swim parallel, look, and other (with description).

The seal's radial distance from the source vessel was estimated visually and, usually, determined more accurately using the reticle binoculars. Distance and bearing were measured from the observer location in the wheelhouse, ~30 m ahead of the airgun array.

Shutdown Procedures

The IHA required that the airgun array be shut down immediately when a seal was seen within, or about to enter, a safety zone around the source vessel. The safety radius was the distance within which received levels of seismic pulses were expected to be ≥190 dB re 1 μPa (rms). Up to 30 August, the designated safety radius was 150 m—the predicted 190 dB radius for the full array. Underwater sound measurements taken near the full array during August 1996 showed that, at times, the received level was ≥190 dB out to ~250 m (Greene 1997). On 30 August, the safety radius was increased to 250 m for full or partial array operations. It remained 150 m for one-airgun work, although the actual 190 dB radius around one airgun was <<150 m (Greene 1997).

When a seal was seen within the safety radius, the airguns were shut down, normally within 3–5 sec (*i.e.*, usually either no shots or one shot between the sighting and the shutdown). A total of 112 shutdowns occurred because of seals sighted within or near the safety zone. Procedures after a shutdown varied. Sometimes the source vessel circled (diameter ~400 m), beginning a ramp-up halfway around the circle if the seal was not resighted, and returning to the original course along the source line with gun(s) firing. On other oc-

casions, the vessel continued along the source line (missing shot points) and began firing when the seal was beyond the safety zone. The IHA did not require suspension of seismic operations during times with poor visibility or at night, and work continued during such periods.

RESULTS

Detection of Seals

A total of 422 seals were seen by observers on the source vessel—421 during 751.9 h of daylight observations but only one at night (133.7 h). Of the 331 seals identified, 304 (91.8%) were ringed seals, 24 (7.3%) were bearded seals, and three (0.9%) were spotted seals. The 421 seals seen in daylight involved 381 separate sightings; 23 sightings consisted of groups of 2–5 seals. All seals except one were in the water, although many were near ice pans or amidst new ice. The only dead or injured seal noted was a ringed seal carcass on an ice pan with polar bear (*Ursus maritimus*) tracks.

Seals were first sighted at estimated radial distances of 2–1,491 m from the wheelhouse (Fig. 1A). However, only 70 (19.3%) of 362 daylight sightings at known distances were beyond 250 m. Distances were not determined for 19 sightings. Part of the reduction in sightability beyond 250 m occurred because observers concentrated on searching for seals within or near the safety radius (150 m or 250 m). Also, two types of evidence showed that the observers missed many seals within 250 m: (1) The numbers of daylight sightings in the various 50-m annuli out to 250 m were generally similar (Fig. 1A) even though the areas of those annuli increased with increasing distance. (2) The number of daylight sightings declined rapidly at lateral distances beyond 0–50 m (Fig. 1B). Detectability also undoubtedly varied with glare, sea state, and ice cover.

Sighting Rates and Distances

During daylight, seals were seen at nearly identical rates during periods with no guns firing (0.63 seals/h), one gun firing (0.60/h), and full array firing (0.63/h)—the three common seismic categories (Table 1).

Absolute sighting rates at different distances should be interpreted with caution because (1) the areas under observation at the three distances were not equal, and (2) sightability decreased with increasing distance. However, it is appropriate to compare sighting rates at a given distance under different seismic states, the pattern of change in sighting rate with increasing distance, and the median sighting distances.

The daytime sightings tended to be farther from the seismic vessel during full-array seismic than during no-seismic or single-gun seismic periods (Fig. 2). The sighting rate within 150 m was higher during no-seismic and one-gun seismic (0.37 and 0.34 seals/h) than during full-array seismic (0.21 seals/h). The sighting rate declined with increasing distance during no-seismic and

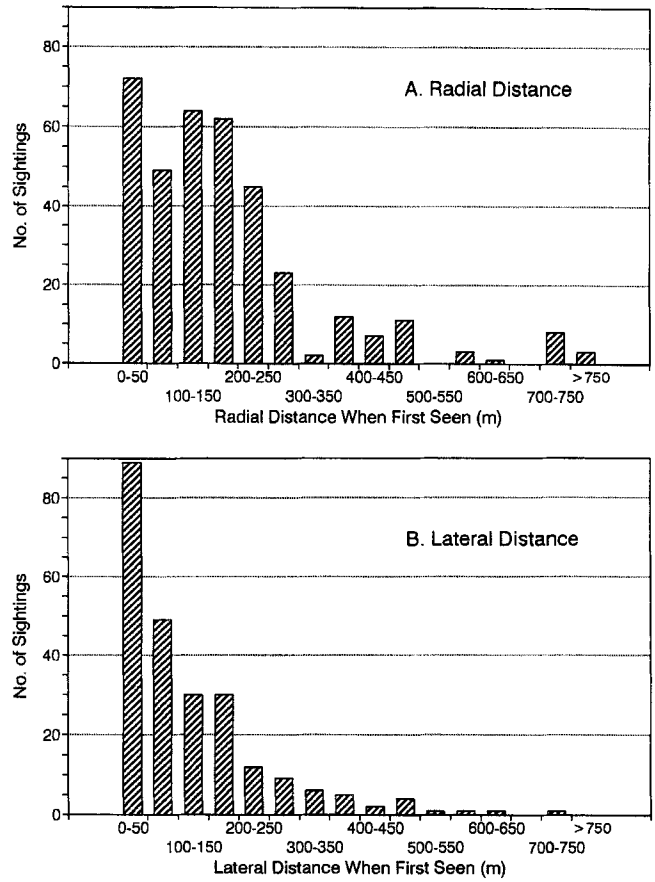

Figure 1. Numbers of seal sightings during daylight by 50-m distance intervals from source vessel, based on approximate bearing and distance from vessel when seal was first sighted. *(A)* Radial distance from vessel (n = 362). *(B)* Lateral distance from vessel's trackline (n = 240).

single-gun seismic, but not with full-array seismic (Fig. 2). Sighting rates in the >250 m distance category were lower with no seismic or single-gun seismic (0.10 and 0.07 seals/h) than with full-array seismic (0.17/h). Consistent with these patterns, the median sighting distance was significantly greater with full-array seismic than no seismic (Mann-Whitney U = 8,408, n = 150 *vs.* 161 sightings; $P < 0.0001$). The mean sighting distance was 234 m with full array seismic *vs.* 144 m with no seismic.

These results suggest that seals tended to avoid at least the zone closest to the boat (<150 m) during full-array seismic, possibly combined with a tendency to come to (or spend more time at) the surface at greater distances. There was no such indication during single-gun seismic. Seals apparently did not move much beyond 250 m, as the sighting rate at all ranges combined

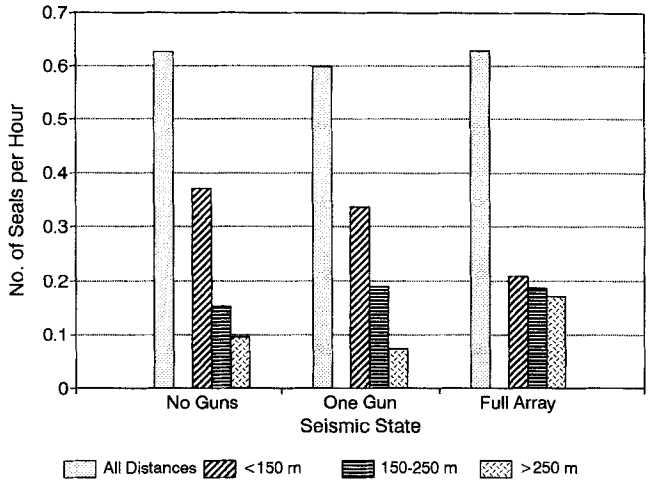

Figure 2. Numbers of seals observed per hour of daylight observation by seismic state and distance category. "All Distances" category includes a few seals at undetermined distances (*i.e.*, not included in any specific distance category).

was the same with full-array seismic as with no seismic (0.63/h; Fig. 2). Seismic operations did not cause many (if any) seals to desert the general area of operations.

Some seals did not move outside the 150-m zone around the operating full array. During daylight, we saw 55 seals in those conditions (0.21 seals/h). Seals were not seen behind the source boat near the airguns when airguns were in operation, but were often seen just ahead of, or alongside, the vessel. The closest seal sightings under various seismic states, as measured from the wheelhouse, were as follows: 16 m during full-array seismic, 30 m during partial array, 12 m during ramp up, and 20 m during single gun.

The distributions of seals, when first seen, were nearly symmetrical on the port and starboard sides. The majority of the seals seen were to the front and sides of the vessel (85% with no seismic; 89% with full-array seismic). This pattern reflects the fact that the observers concentrated their search for seals ahead and to the sides of the approaching boat.

Behavior

Seals in the water were difficult to observe for extended periods because of their small sizes, often-brief surfacings, and the need to maintain a watch for other seals. Consequently, behavioral observations were brief. Figure 3 shows the percentages of all seals seen in a given seismic state that were classified as exhibiting each behavior. For example, of those sighted when the full array was firing and for which behavior was recorded (n = 143), 18% looked, 2% approached, 5% swam parallel to the boat's track, 36% dove, and 39% swam away (Fig. 3).

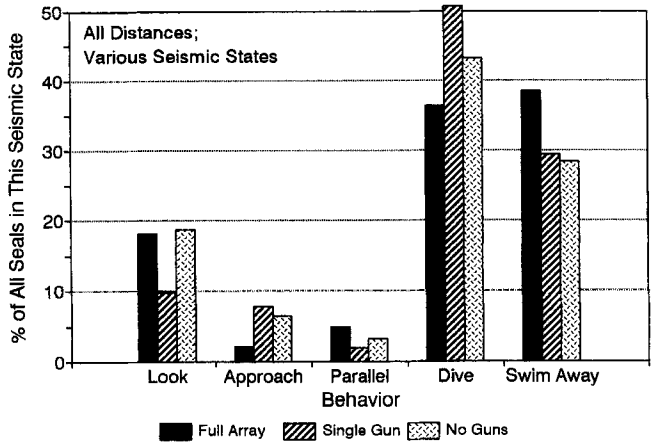

Figure 3. Frequencies of various types of seal behavior during full array (n = 143 seals), single airgun (n = 51), and no airgun (n = 155) conditions, with all distances combined. For each seismic state, bars show percentages of seals that showed each type of behavior.

All distances combined—All five behaviors were seen during each of the three common seismic states (Fig. 3). For each of those seismic states, the most commonly recorded behaviors were dive and swim away. Looking occurred at intermediate frequency; approaching and swimming parallel to the boat's track were uncommon. Overall, the frequencies of the various behaviors were not significantly different under different seismic states (χ^2 = 11.57, df = 8, $P \approx 0.17$). However, during full-array seismic, proportionally fewer seals dove or approached and more swam away as compared with no seismic and single-gun seismic.

Distance effects—When the vessel was underway with no guns firing, the overall frequencies of the five behaviors were not significantly related to distance (Fig. 4A; χ^2 = 5.86, df = 8, $P \approx 0.66$). However, the frequency of swimming away diminished with increasing distance, and the frequency of looking increased.

If proximity to airgun operations causes some seals to swim away, as the sighting distance data suggest, we would expect to see differences in the proportional frequencies of some behaviors for seals sighted at various distances under full array conditions. Swimming away would be expected to be more common for seals close to the operating airgun array. Also, seals might also reduce exposure to strong airgun sounds by remaining at the surface (see Discussion). If so, frequency of diving might be low within 150 m, and frequency of surface behaviors such as looking might be higher.

With full-array seismic, distance did not seem to have major effects on the frequencies of the five behaviors (Fig. 4B; χ^2 = 6.98, df = 8, $P \approx 0.54$). The frequencies of swimming away and looking were not strongly related to distance. Seals swimming away underwater were, of course, not visible. Most

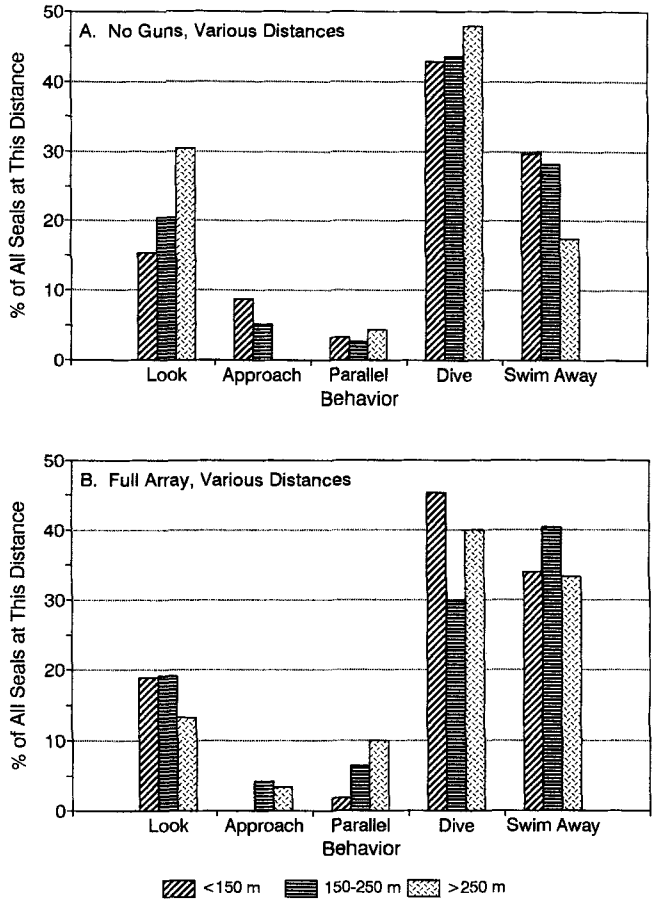

Figure 4. Frequencies of various seal behaviors in each of three distance categories when source vessel was underway with *(A)* no airguns firing, and *(B)* full array firing. For each distance category, bars show percentages of seals that showed each behavior. In (A), n = 91, 39 and 23 seals for <150 m, 150–250 m, and >250 m. In (B), n = 53, 47 and 30 seals, respectively.

seals dove or swam away at all distances. However, swimming away was more common at all distances during full-array seismic than with no seismic (Fig. 4B *vs.* A). Also, approaching was not seen within 150 m of the vessel during full-array seismic, and swimming parallel became somewhat more common as initial sighting distance increased (Fig. 4B).

Discussion

Seal Responses and Tolerance

Overall, seals did not react dramatically to seismic operations insofar as we could see. Seals remained in the general area as airgun operations continued.

Only a fraction of the seals swam away, and even this avoidance was apparently quite localized.

A total of 422 seals were seen from the source vessel during the 1996 seismic surveys: 91.8% ringed seals, 7.3% bearded seals, and 0.9% spotted seals. Of these, 169 seals were seen during periods of full-array seismic, most within 500 m of the airgun array. Overall, vessel-based observers saw seals at nearly identical rates regardless whether no airguns, a single airgun, or 8–11 airguns (full array) were firing. Received levels of noise pulses from the full array were ≥180 dB re 1 μPa (rms) out to a radius of about 1 km when measured at least a few meters below the surface (Greene 1997). Therefore, most if not all seals seen from the source vessel during full-array seismic were exposed to pulses with levels above 180 dB when they dove. Despite this, many seals showed little or no obvious avoidance and no obvious tendency to avoid diving. We could not observe behavior while the seals were below the surface. However, many seals remained near the trackline as the operating airguns approached, and those seals that did move away apparently did not move beyond visible range (a few hundred meters at most).

Seals that remained near the trackline as the operating airguns passed received a sequence of about 45 pulses from the time the source vessel was 1 km away and approaching until it was 1 km away and moving away. (The usual shot interval was 44 m.) These seals received additional strong pulses as the full array was towed along the adjacent seismic lines (spaced 330 m apart), and weaker pulses when the vessel was operating on lines >1 km away.

Seals were often seen within 150 m even during full-array seismic. This, plus the similar overall sighting rates with and without seismic, indicates that seals did not vacate the region around the approaching seismic vessel. However, the median distances of the observed seals were significantly greater ($P < 0.0001$) with full-array seismic than no seismic (means 234 m *vs.* 144 m, respectively). Sound levels received from the full array typically diminished by ~3 dB from 144 m to 234 m (Greene 1997). Thus, the horizontal avoidance reaction by the average seal resulted in only a slight reduction in sound exposure during dives.

An alternative potential explanation for the distributional observations might be that seals close to the source boat (<150 m away) behaved in ways that made them less detectable during full-array seismic than at other times. Seals often dive when exposed to disturbance. However, if anything, we expected that seals might spend more time at the surface when close to the seismic vessel ("vertical avoidance"). Received levels of low-frequency underwater sounds diminish as the receiver approaches the surface because of the pressure-release or "Lloyd mirror" phenomenon (Urick 1983, Richardson *et al.* 1995). For example, Greene and Richardson (1988) found that measured levels of airgun sounds at depth 3 m averaged 7 dB less than the simultaneous levels at depths 9 and 18 m. The reduction would exceed 7 dB for a seal closer to or especially at the surface. To achieve that much reduction in received sound level by swimming horizontally away, a seal 10s or 100s of meters from the airguns would have to travel a much greater distance.

Most seals within a few hundred meters of the seismic vessel would have been exposed to many pulses as the vessel approached and/or traveled along nearby seismic lines. Thus, most seals would have had an opportunity to learn that received levels diminish rapidly as the seal approaches the surface. Despite this, there was no clear tendency for diving to be less common, or for looking (a surface behavior) to be more common, in seals close to the operating airgun array. Also, although the frequency of various behaviors was not significantly different under different seismic states ($P \approx 0.17$), swimming away was somewhat more common with full-array *vs.* no seismic, and approaching was less common with full-array seismic, especially within 150 m (Fig. 3, 4).

Thus, the differences in apparent distribution with full-array *vs.* no seismic were probably mainly a result of local horizontal avoidance by some seals. However, avoidance reactions were not universal even within 150 m. Given the similar overall sighting rates with and without full-array seismic, avoidance was probably limited to a radius of a few hundred meters. Within that distance, received sound levels below the surface were well above 180 dB re 1 μPa (rms), and sometimes >190 dB.

Full-array seismic influenced the local distribution of seals within a few hundred meters of the source vessel, and (in some cases) may have affected their behavior. In contrast, when a single 120 in^3 airgun was in use, seal numbers, distribution, and behavior were similar to those when seals were exposed to the source vessel without airgun operations. The difference between the full-array and single-airgun results is at least partly understandable on the basis of the large differences in the received levels (see Methods).

Estimated "Take by Harassment"

The Incidental Harassment Authorization (IHA) under which the seismic program was conducted authorized disturbance ("take by harassment") of small numbers of seals, but did not authorize serious injuries or deaths (NMFS 1996*b,c*). This study was conducted, in part, to satisfy the IHA's requirement to estimate how many seals were harassed. The following describes some possible ways of making such estimates.

Direct counts—It is not known whether seismic pulses can cause injury to the auditory or other systems of seals. However, based largely on extrapolation from studies in terrestrial mammals (Richardson *et al.* 1995:372*ff*), the IHA required suspension of seismic operations when seals were within the estimated 190 dB re 1 μPa (rms) radius. This was initially estimated as a radius of 150 m around the full array. Sound measurements during August 1996 showed that, at 150 m, the actual received level was sometimes as high as 195 dB re 1 μPa (rms) (Greene 1997). Some seals seen within the 150–250-m annulus were exposed to received levels of 190–195 dB (rms). Before 30 August airgun operations were not necessarily suspended in these cases. After 30 August a shutdown radius of 250 m was used. Both before and after 30 August seals often were not seen until they were well within the shutdown radius. These

seals were exposed to strong sound pulses if they were below the surface just before the time of sighting, when airgun operations were interrupted.

During daylight 128 seals were first sighted within 250 m during full-array, partial array, or ramp-up operations, and thus were potentially exposed to strong sounds at least briefly. During single-airgun operations, an additional 32 seals were seen within the 150-m radius defined (very conservatively) as the safety radius around one airgun. Measured levels 150 m from the single airgun were almost always <175 dB re 1 μPa (rms) (Greene 1997). Another 33 seals were estimated to have been present within these radii during nighttime seismic operations, assuming that the numbers present at night were the same as during the day. Thus, ~193 seals would have been detectable within the final safety radii if all seismic operations had been conducted during daylight. This total no doubt includes some resightings of the same individual seals along adjacent seismic lines.

Indirect estimates based on density—The detectability of seals diminished rapidly with increasing distance from the seismic vessel, and we undoubtedly did not see all seals that were within 250 m of the vessel's trackline (Fig. 1B). The observed rate of decline in sightings with increasing lateral distance was similar to that shown by Leopold *et al.* (1997) in a vessel survey of harbor seals (*Phoca vitulina*). The minimum density of seals in our study area, based on the numbers seen within 50 m of the trackline when seismic operations were not underway, was 0.30 seals/km^2. This figure can be used to derive more realistic estimates of "take by harassment," although it does not allow for the unknown number of unseen seals within 50 m of the trackline.

Seismic operations in 1996 totaled about 3,787 km of airgun array operations and 884 km of single-gun work. Based on these figures, the respective 250-m or 150-m safety radii, and the minimum density of 0.30 seals/km^2, we estimate that at least 648 seal "takes" occurred during the entire seismic program. This assumes that all seals occurring within the safety radii, or that moved out of those areas as the seismic vessel approached, were "taken by harassment." Because of the proximity of adjacent seismic lines, and the overlapping grids of full-array *vs.* single airgun lines, many seals would be "taken" more than once. The total area surveyed in 1996, including a 250-m buffer around the outside, was about 629 km^2. Based on the minimum density of 0.30 seals/km^2, ~189 different seals may have been "taken by harassment" during the project.

Recently, NMFS (1999) indicated that the zone of influence of airgun sounds for marine mammals should be considered to include the area where received levels exceed 160 dB re 1 μPa. The 160 dB (rms) level has no known special significance for seals; it is the approximate rms level above which some baleen whales show obvious avoidance reactions to seismic pulses (Richardson *et al.* 1995). In this study the received level sometimes was ≥160 dB re 1 μPa (rms) at distances out to 4.9 km from the full array. The total area of water within 4.9 km of the regions surveyed in 1996, excluding areas "shadowed" by intervening barrier islands, was about 1,348 km^2. The minimum

estimated number of seals within that area, assuming 0.30 seals/km^2, would be 404 seals.

Management Implications

This study showed that arctic seals (mainly ringed seals) exhibit no more than localized avoidance of an approaching seismic vessel. Many remain close enough to a seismic line to be exposed to received levels exceeding 190 dB re 1 μPa (rms) when they dive. During daytime some of these seals can be seen by an observer aboard the seismic vessel, whereupon seismic operations can be interrupted. However, many seals within 250 m of the vessel apparently are not seen. Some reduction in the proportion of the nearby seals that are missed is possible if more than one observer is on duty (LGL Ltd., unpublished data). However, logistics, living space, and financial constraints often make it difficult to provide two on-duty observers on a 24-h per day basis. Also, if a larger array of airguns were used, the safety radius would need to be increased, further compounding the "undetected seals" problem.

The IHA issued for this project placed no special restrictions on seismic operations at night or with poor visibility. Despite use of 7 × 50 binoculars and an image intensifier, nighttime visual monitoring for seals was not effective under the conditions of this study. It is unlikely that passive acoustical monitoring would be of any value in detecting ringed seals near a seismic vessel at night. Thermal infrared methods may warrant investigation if effective nighttime monitoring is required. We have considered the possibility of using an active high-frequency sonar to detect seals under water (*cf.* U.S. Navy 2001). However, interference from surface and bottom reverberations would be severe if an active sonar were used in shallow nearshore waters such as those where this project was done.

The IHA provisions, especially for night and poor-visibility periods, were designed on the assumption that, if strong seismic sounds are aversive, seals will move away as the seismic vessel approaches or as the airgun array is "ramped up." If they did so, this would limit their exposure to noise. However, the daytime results show that only a fraction of the seals moved out of the safety radius as the sound level increased, and they apparently did not move far. Presumably the same occurs at night. Whether the seals that remain within the safety radii are affected deleteriously by the strong sound pulses is not known.

Although not all seals within the safety radii were detected, there were sufficient detections to result in 112 temporary shutdowns of the airguns during 585.5 h of airgun operations (Table 1). During full-array operations, a shutdown and the subsequent ramp-up typically required 4–6 min. During single-airgun operations, shutdowns usually required only 1–2 min, mainly because no ramp-up was needed while resuming operations. The total operating time lost to these 112 shutdowns was 8 hours. This was a significant disruption to this OBC seismic operation. It would have been much more disruptive if the seismic vessel had been towing long streamers, which would

prevent the circling maneuver sometimes used during shutdowns in this project.

There is an urgent need for more data on the actual effects of sequences of strong seismic pulses on seals. If deleterious behavioral or auditory effects occur near received levels of 190 dB re 1 μPa (rms), improved monitoring and mitigation measures may be desirable to protect seals. Conversely, if seismic pulses have no negative effects on seals, or if the effects occur only at received levels well above 190 dB, seismic programs are unnecessarily impeded by some procedures required by recent IHAs.

Studies of Temporary Threshold Shift (TTS) in captive marine mammals could be useful in addressing the possibility of auditory damage (NRC 1994, Kastak *et al.* 1999, Finneran *et al.* 2000*a*). TTS data can establish the received level below which there is no likelihood of injury, and above which there is reason for concern. TTS measurements are underway for odontocetes exposed to single pulses of water-gun sound, which are similar to airgun pulses (Finneran *et al.* 2000*b*). For maximum relevance in assessing the effects of ongoing seismic surveys, TTS studies would need to expose marine mammals to sequences of repetitive low-frequency sound pulses consistent with those received from an approaching seismic vessel.

Acknowledgments

This study was funded by BP Exploration (Alaska) Inc. (BPXA) and conducted with the cooperation of Northern Geophysical of America (NGA), Crowley Marine Services, and Pelagos Corp. The work was done under an Incidental Harassment Authorization issued to BPXA by the U.S. National Marine Fisheries Service (NMFS), Office of Protected Resources. We thank C. Herlugson and A. Ross of BPXA, J. Hastings and S. Nish of NGA, and K. Hollingshead of NMFS. A stakeholder group including representatives of NMFS, the Alaska Eskimo Whaling Commission, Minerals Management Service, and North Slope Borough Department of Wildlife Management provided valuable advice on plans and draft reports. For comments on this manuscript, we thank M. Gilders, C. Greene, C. Herlugson, J. Lawson, V. Moulton, A. Ross, and an anonymous referee.

The marine mammal observers included, at various times, Inupiat observers A. Napageak, M. Solomon, and S. Franklin, plus LGL biologists A. Balla-Holden, B. Haley, L. Martin, and M. Bentley (as well as REH and GWM). Others who helped in the field included K. Kinden and L. Wyman of BP; J. Gardner, F. Hall, K. Karn, and R. Stjernholm of NGA; the crew of the *Pt. Barrow,* including B. Kinder (captain), T. Robinson, D. Lemke, P. Martinez, and B. Harker; and D. Millar, D. Mingo, D. Sarty, and B. Jimmo of Pelagos Corp. J. Carey (Crowley Marine Services) and P. Crosbie and S. Hulse (Peregrine Marine) were also very helpful. We thank them all.

R. E. Elliott of LGL Ltd. helped with data analysis. C. Greene of Greeneridge Sciences provided data on the underwater sounds. A. Bishop and W. Wilson (LGL Alaska) and T. Jarvie, B. Griffen, K. Hester, and V. Moulton (LGL Ltd.) provided administrative and technical assistance.

Declining Extent of Open-water Refugia for Top Predators in Baffin Bay and Adjacent Waters

Global climate change is expected to severely impact Arctic ecosystems, yet predictions of impacts are complicated by region-specific patterns and nonuniform trends. Twentyfour open-water overwintering areas (or "microhabitats") were identified to be of particular importance for eight seabird and marine mammal species in the eastern Canadian High Arctic and Baffin Bay. Localized trends in the available fraction of open-water were examined in March during 1979–2001, derived from approximate sea ice concentrations from satellite-based microwave telemetry. Declines in the fraction of open-water were identified at microhabitats in Baffin Bay, Davis Strait, coastal West Greenland, and Lancaster Sound. Increases in open-water were observed in Hudson Bay, Hudson Strait, and Foxe Basin. The biological importance of each microhabitat was examined based on species distribution and abundance. Potential consequences of reduced open-water for top marine predators include impacts on foraging efficiency and oxygen and prey availability.

INTRODUCTION

The waters adjacent to the Arctic Ocean are generally perceived as barren and inaccessible, completely covered in sea ice and darkness during winter months. However, in this white stretch of frozen Arctic sea, winter refugia or "microhabitats" exist for millions of air-breathing marine animals. The refugia range widely in size, existing as cracks or leads only a few hundred meters long to hundreds of kilometers of vast open-water. They remain ice-free during even the coldest period of winter and are generally surrounded by solid sea ice. These areas can be annually recurrent 'polynyas' (the Russian word for 'open-water area surrounded by ice') driven by upwelling or wind, variable shore leads and cracks, or tidal- and wind-driven openings in the consolidated pack ice (1). These microhabitats occur predictably in the same locations year after year, despite the variety of ways in which they are physically generated and maintained. The geographical and temporal predictability permits numerous Arctic seabirds and marine mammals to utilize open-water during winter when survival in the sea ice is most critical. Large-scale upwelling events occur along the ice edge, driven by the absence of ice, providing early availability of light for photosynthesis (2). Consequently, the high levels of production found in many of these open-water habitats are used by predators seeking to benefit from high densities of zooplankton and associated fish abundance.

Species utilizing open-water winter refugia include cetaceans, pinnipeds, seabirds and polar bears (*Ursus maritimus*). Their winter habitat preferences are diverse and unique to their species-specific requirements for survival and reproductive success. One of the largest Arctic winter refugia, the North Water, is utilized by approximately 13 000 belugas or white whales (*Delphinapterus leucas*) (who undertake a northbound migration to this locality from Lancaster Sound in the fall) during winter and spring, thousands of narwhals (*Monodon monoceros*), and 30 million breeding pairs of little auks (*Alle alle*) (3–6). In other areas, alternate and smaller open-water localities of great importance are situated over shallow banks, such as Store Hellefiske Bank in West Greenland. This region contains vast benthic resources utilized by species with limited diving abilities like king eiders (*Somateria spectabilis*), common eiders (*Somateria mollissima*), and walrus (*Odobenus rosmarus*) (7–10). Hundreds of thousands of thick-billed murres (*Uria lomvia*) from Canada, Greenland, Iceland, Svalbard, and eastern Russia overwinter in smaller regions along the productive coastal open-water area in West Greenland (7–9). Other microhabitats occur in offshore areas of Baffin Bay and Davis Strait, where leads and cracks in the ice over deep waters serve as the primary wintering grounds for narwhals utilizing benthic fish and squid resources (11, 12).

Global warming, predicted with considerable certainty (13), is assumed to severely impact sea ice formation in the Arctic. The extent of sea ice has declined in the past 20 years, at a rate of about 3% per decade in the Northern Hemisphere (14). However, this trend is not uniform throughout the Arctic and several regional deviations from the general warming pattern have been observed. For example, the length of the sea ice season and the concentrations of sea ice have increased in the past two decades in the Baffin Bay and Davis Strait (14–16). Passive microwave telemetry and mapping of sea ice distribution over the past 5 decades demonstrate a significant increase in sea ice amounting to about 600 km^2 or 1.3% per decade in Baffin Bay (17). The causes of the cooling trend in Baffin Bay are uncertain but are likely due to simultaneous changes in the thermohaline circulation (causing changes in the relatively warm northward flowing West Greenland current), the North Atlantic Oscillation, and the formation of the sea ice bridge in Smith Sound (17, 18). In Hudson Bay and Foxe Basin a non significant sea ice extent decrease of 1.8% per decade was observed between 1979–1996 (14). However, the length of the sea ice season declined in northwestern Hudson Bay and increased in central Hudson Bay and in Foxe Basin (16, 18).

There have been scattered attempts to study the biological importance of winter refugia in the Arctic. Most have focused only on the larger polynyas (e.g. the North Water or the Northeast Water in East Greenland (19)). Generally, the importance of the smaller high Arctic microhabitats has not been well understood or studied because of obvious logistic problems with field research in dark, cold, and ice covered regions. Due to the importance of open-water pack ice refugia for marine mammals and seabirds, it is critical to identify the changes in these microhabitats and develop predictions of how changes will alter the trophic web or biological resources. Baffin Bay and the eastern Canadian High Arctic have a complex coastline, an influx of warm Atlantic water along the West Greenland coast, and a restricted opening to the polar basin through Robeson Channel, which results in numerous microhabitats in the region. In addition, the abundance of animals overwintering in the dense pack ice in this region is large, making it important for examination of

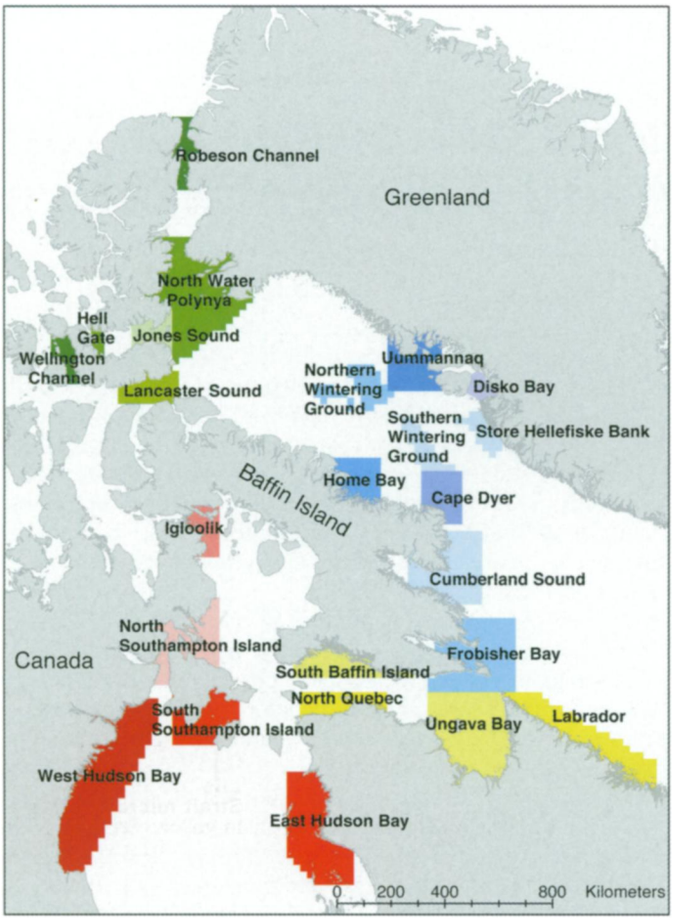

Figure 1. Map of selected microhabitats examined for trends in the fraction of open-water (regions with less than 85% sea ice on 15 March for more than two years within the study period). Regions are indicated by shades or colors; Foxe Basin and Hudson Bay microhabitats are in red, Hudson Strait microhabitats are in yellow, Baffin Bay-Davis Strait microhabitats are in blue, and Northern Baffin Bay and Lancaster Sound microhabitats are in green.

trends in sea ice conditions. In this study, changes in the fraction of open-water in 24 pack ice microhabitats were examined over a 23-year time series using remotely-sensed microwave sea ice data. Observed trends were related to the relative importance of each wintering microhabitat for eight marine indicator species and potential impacts on winter success and survival were examined.

MATERIAL AND METHODS

Selection of Localities and Dates

The overall study area was chosen to encompass the year-round range of selected birds and marine mammals, including Baffin Bay, Davis Strait, Hudson Strait, northern Hudson Bay, Foxe Basin, Lancaster Sound, and Robeson Channel (Fig. 1). Specific microhabitats were selected based on visual investigation of the sea ice time series on 15 March each year (Fig. 2). Recurrent open-water areas were identified and delineated, where 85% or less sea ice was found on 15 March for more than two years within the study period. Some additional areas were selected based on the literature, where specific areas have been documented to harbor wintering populations of marine mammals and seabirds.

SSMR/SSMI Methods

Sea ice concentration data were obtained from passive microwave telemetry available in two datasets from the National Snow and Ice Data Center (NSIDC). The Nimbus-7 Scanning Multichannel Microwave Radiometer (SMMR) dataset extending from 1979 through 1987 and the Defense Meteorological Satellite Programs Special Sensor Microwave/Imager dataset covering the period from 1987 through 2001 were used. Sea ice concentration was derived using the Bootstrap algorithm following Comiso (20), where daily sea ice concentrations for the Northern Hemisphere were mapped to a polar stereographic projection (true at 70°N) at a 25 km resolution. Sea ice data obtained from the NSIDC were converted from raw binary to ASCII format using a program written in Compaq Visual Fortran 90 and imported into a geographic information system (ESRI ArcINFO 8.3) as raster grids. The center of each cell received the estimate of average sea ice concentration in that 625 km² (a constant approximation for pixel areas) area and pixels were consistently classified as land or sea ice across all years. A March composite was created as the product of the vertical spatial and temporal average ice concentration for each cell for all days in March each year and used to calculate the fraction (or percentage) of open-water.

The fraction of open-water, the 'ice-free'portion of each microhabitat, (F) was modeled as:

$$F = \left(\sum_{i=1}^{h} (PC^{*}(1-(IC/100)) \right) / MHA$$

where i indexes the lowest sea ice concentration in the microhabitat to h, the highest sea ice concentration, IC is specific sea ice concentration calculated in full integer units and recorded as a percent, PC is pixel count for each specific sea ice concentration, and MHA is the microhabitat area in number of pixels. Trends in the fraction of open-water were examined for each microhabitat between 1979–2001. Open-water localities smaller than 7 pixels were not examined because the sea ice data were not of sufficient resolution to describe the ice formation at those localities. Several microhabitats were, however, composed of a mosaic of many smaller areas.

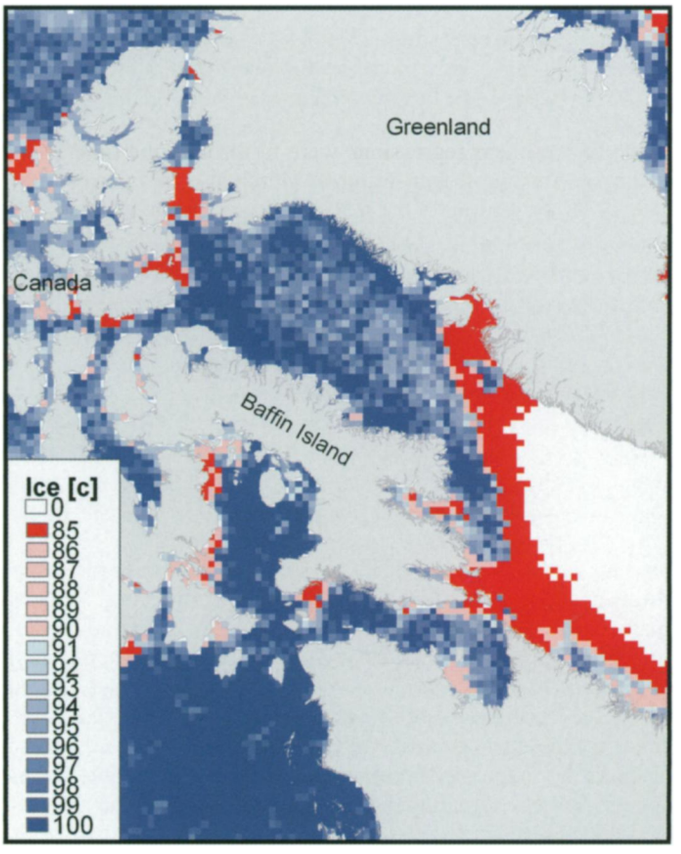

Figure 2. Example of SSMI/SSMR sea ice concentration readings from 14 March 1986. Red regions are 85% sea ice concentration or less and pixels are approximated at 25 km².

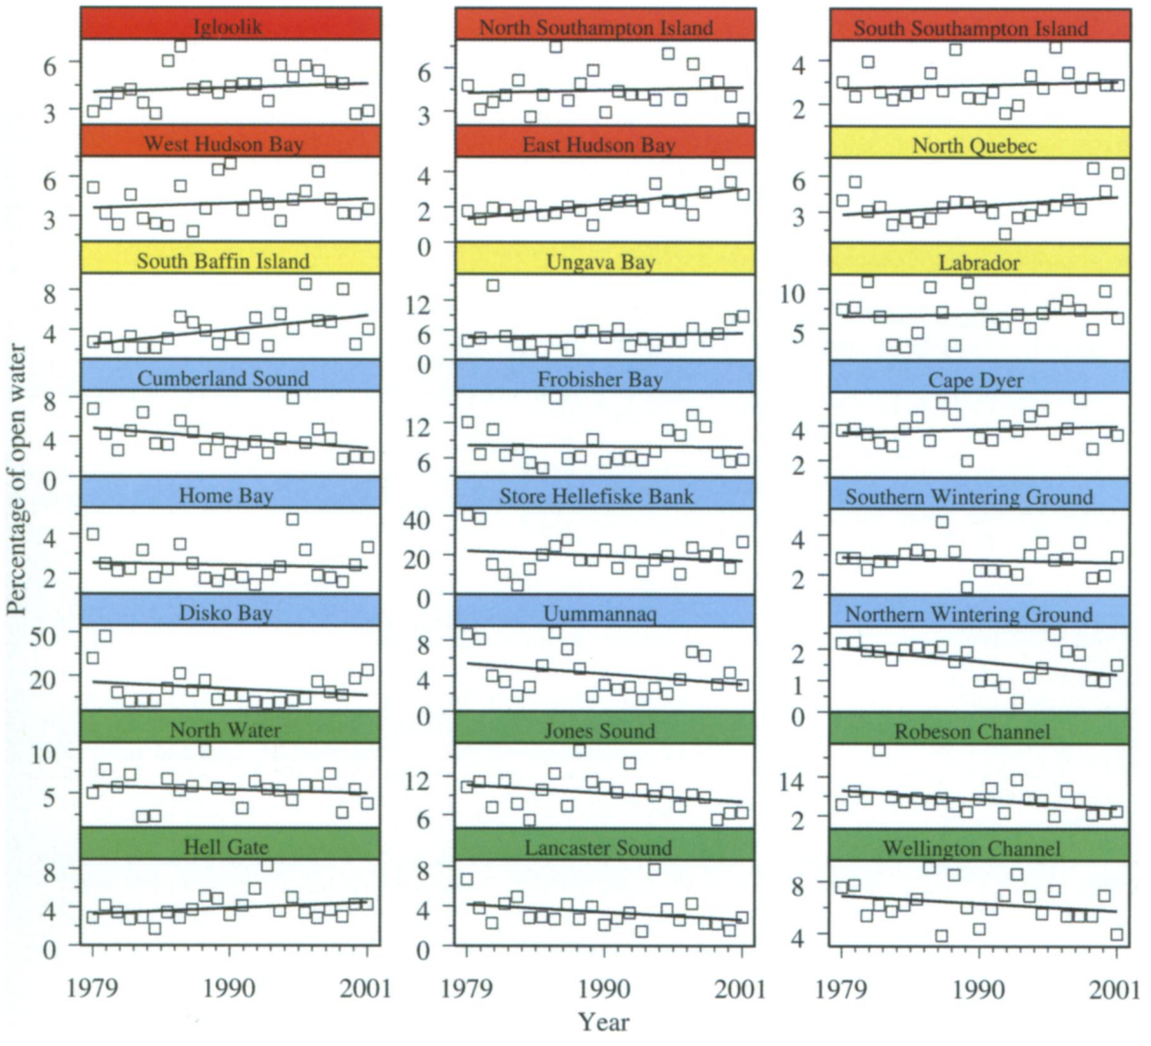

Figure 3. Trends in the fraction of open-water at 24 microhabitats in Canada and West Greenland. Regions are indicated by colors (following Fig. 1) where Foxe Basin and Hudson Bay microhabitats are in red, Hudson Strait microhabitats are in yellow, Baffin Bay-Davis Strait microhabitats are in blue, and Northern Baffin Bay and Lancaster Sound microhabitats are in green.

Statistical Analyses of the Extent of Open Water

Least square linear regressions were fit through the time series of the proportion of open-water in March at each microhabitat. The probability of each trend was assessed from the marginal posterior distribution of the Bayesian regression of the fraction of open-water over time. This method was chosen to provide a specific probability for the observed trends rather than a standard significance level.

Biological Importance of Microhabitats

The biological importance of each pack ice microhabitat was determined based on the occurrence and abundance of eight High Arctic indicator species: the walrus, the bowhead whale (*Balaena mysticetus*), the narwhal, the beluga, the king eider, the common eider, the little auk, and the thick-billed murre. These species were chosen because of their specific dependence on open-water localities during winter. Other Arctic species such as the black guillemot (*Cepphus grylle*), gull species (Laridae), Northern fulmar (*Fulmarus glacialis*), bearded seal (*Erignathus barbatus*), ringed seal (*Phoca hispida*), and polar bear were not included either because little is known about their occurrence (e.g. gulls and bearded seals) or because they are found virtually at all the open-water localities (e.g. black guillemot) or in the coastal fast ice (e.g. ringed seals and polar bears). Basic information on distribution, abundance, and habitat use was compiled from existing literature and used to document the dependence on open-water areas during winter and potential effects of changes in open-water on success and survival.

RESULTS

Trends in Open Water

Within the overall study area, six large regions were identified and examined: Foxe Basin, Hudson Bay, Hudson Strait, Baffin Bay-Davis Strait, northern Baffin Bay, and Lancaster Sound. Within these six regions, 24 specific pack ice microhabitats were identified based on open-water in March (Table 1, Fig. 1). Regionally, Foxe Basin, Hudson Bay, and Hudson Strait showed increasing trends in the fraction of open-water and the trend at all microhabitats combined ranged from 0.2 to 0.7% per decade. Regions of Baffin Bay-Davis Strait, northern Baffin Bay, and Lancaster Sound showed overall decreasing trends in the fraction of available open-water in March. The trend in all microhabitats combined in Baffin Bay-Davis Strait and northern Baffin Bay was -1% per decade and the trend in Lancaster Sound microhabitats was -0.6% per decade.

The two pack ice microhabitats in Foxe Basin (North Southampton Island and Igloolik) were equivalent to an area of approximately 50 000 km^2. These two microhabitats showed slight increasing trends in the proportion of open-water between 1979–2001 (Table 1). Approximately 200 000 km^2 were examined in the Hudson Bay region and trends in the fraction of open-water in the three microhabitats were also slightly increasing. In the region of Hudson Strait, four localities were examined, approximately 200 000 km^2, and increasing trends in the fraction of open-water were detected in all four (Fig. 3 and Table 1).

In the region of Baffin Bay-Davis Strait (total area of 280 000 km^2), eight out of nine microhabitats demonstrated declines in available open-water. Decreasing trends ranged widely, from -0.01 in Frobisher Bay to -0.40% per year in Disko Bay. Four of these eight had high probabilities of a negative trend > 0,86 (Cumberland Sound, Disko Bay, Uummannaq, and the Northern Wintering Ground, Table 1) and four other localities (Home Bay, Store Hellefiske Bank, Frobisher Bay) also had moderately high probabilities of a decline (> 0.56). Only the locality of Cape Dyer in central Baffin Bay showed a trend for increasing open water (0.02% yr^{-1}) (Fig. 3, Table 1).

In the northern Baffin Bay region, three of four microhabitats (110 000 km^2) had high probabilities of a negative slope (> 0.73) and only Hell Gate had an increasing proportion of open-water with a low probability (0.1) that the trend is actually negative. The small size of Hell Gate (only 7 pixels) and substantial amount of land surrounding the microhabitat probably affected the results. Finally, both the microhabitat of Lancaster Sound and Wellington Channel (in the Lancaster Sound region) (30 000 km^2) demonstrated declines in open-water (- 0.05 to - 0.07% yr^{-1}) with probabilities > 0.88.

Arctic Species Diversity and Abundance

Of the eight selected species of Arctic birds and marine mammals, abundance and diversity supported conclusions on the most important wintering regions within the study area. In the case of marine mammals, important microhabitats included South Baffin Island (in the region of Hudson Strait), Cumberland Sound and offshore, the North Water, Store Hellefiske Bank, and Disko Bay (Table 1). In the case of seabirds, important winter microhabitats included Store Hellefiske Bank, the North Water, Lancaster Sound, and Jones Sound (Table 1). As expected, there was considerable overlap of important areas for seabirds and marine mammals.

Walrus

Walrus make seasonal movements from coastal areas to offshore wintering grounds where open-water can be predictably found in the pack ice. Walrus depend on shallow water banks with open-water (< 80 m), where they can access benthic prey and oxygen. Data on numbers of walruses distributed across the 24 pack ice microhabitats were based on counts made during summer surveys at haul-out sites. The location of wintering preferences is unknown for most of these summering aggregations, as the stock delineation of walrus in West Greenland and eastern Canadian Arctic is incomplete. Due to this, correct allocation of the already sparse information to the wintering localities was uncertain. Two major winter aggregations of walrus are known for certain: those within the microhabitats of Store Hellefiske Bank and the North Water. Of these, only Store Hellefiske Bank has been systematically surveyed for walrus abundance in winter (10). The North Water is probably supplied by animals that summer in the Canadian High Arctic or in Kane Basin. Due to the large proportion of walrus that are not accounted for at the two winter microhabitats, the data indicate that many animals must use other unidentified open-water areas (e.g. Foxe Basin, Hudson Bay and Hudson Strait, especially the areas around North and South Southampton Island) during winter (Table 1).

Table 1. Important microhabitats used by wintering sea birds and marine mammals. Slope of regression for annual trends (1979–2001) in the percentage point (fraction) of open-water are reported with probabilities of slopes being negative. Estimated winter and spring abundance of selected marine mammals and birds are indicated based on past surveys reported in the literature. Within each region the microhabitat names refer to the map in Figure 1. The term 'some' refers to the presence of the species however in unknown numbers.

Bowhead Whale

In winter, bowhead whales are generally found in association with dense pack ice or at the ice edge. During spring migration periods, bowheads have been observed penetrating severe pack ice in Baffin Bay and apparently have the ability to break breathing holes (21, 22). The low abundance of bowheads in Baffin Bay is a result of past exploitation, however, there are recent indications of an increase in population size (23). The most important wintering microhabitats for bowhead whales are in West Greenland (Store Hellefiske Bank and Disko Bay) and in the region of Hudson Strait in Canada. Bowheads may also be found in low numbers in winter in the North Water, off Cape Dyer, and off Cumberland Sound. The two microhabitats in West Greenland display declining trends in open-water, however, in Canada the trends in the region of Hudson Strait are increasing (Table 1). In spring, bowheads are dependent on opportunities for feeding on zooplankton blooms in Disko Bay, the North Water, northern Foxe Basin and Lancaster Sound.

Narwhal

Narwhals are the most abundant cetaceans in Baffin Bay, with an estimated abundance exceeding 50 000 (24). Narwhals depend heavily on open-water for their winter survival and build up of fat deposits. Narwhals winter in the regions of Hudson Strait and Baffin Bay-Davis Strait, as well as Disko Bay. Narwhals wintering in Hudson Strait in smaller numbers however are assumed to belong to the Northern Hudson Bay summer population (25). The largest abundance of narwhals is found in the offshore areas of Baffin Bay and Davis Strait, and within this region, two offshore microhabitats have been identified (the Northern and Southern Wintering Ground) (11). The narwhal population in Baffin Bay is presumed to be separate from that in Foxe Basin and within Baffin Bay, several subpopulations occur each with high site fidelity to separate wintering grounds (11). There is sufficient evidence to detect a clear decline in the amount of open-water in several narwhal wintering microhabitats, including the Northern Wintering Ground, Southern Wintering Ground, Disko Bay, Store Hellefiske Bank, North Water, and Cumberland Sound and adjacent offshore areas (Table 1). The increase in the extent of open-water at some localities in Hudson Strait, where narwhals from Foxe Basin are believed to winter, indicates that different subpopulations experience different sea ice trends.

Beluga

Arctic belugas have been found in most types of sea ice but appear to prefer loose pack and avoid longer stays in dense ice. Discrete stocks of belugas are found across Arctic Canada and in West Greenland, all of which have specific wintering grounds. The 20 000 belugas summering in the Canadian High Arctic (near Somerset Island) (24) move out of the area in fall to either the North Water (where the largest abundance overwinters) or the coast of West Greenland (in the microhabitats of Disko Bay and Store Hellefiske Bank) (3). A fourth microhabitat is occupied by a resident population of belugas in Cumberland Sound, which moves offshore with forming fast ice for the winter. All four of these microhabitats show a declining trend in the extent of open-water. Other distinct beluga stocks occupy eastern and western Hudson Bay in summer numbering up to 25 000 animals (26). The exact area where these whales overwinter is unknown, however, there are increasing trends in open-water in Hudson Strait where a large majority likely is found.

The King and Common Eider

King eiders breed in northern Canada and North Greenland. Nearly the entire population from eastern Canada and Greenland winters in the dense pack ice on Store Hellefiske Bank, West Greenland (> 100 000 pairs, Table 1) (27, 28). In this area king eiders can find ideal feeding opportunities during winter on the shallow banks, as they can dive to the bottom and take mussels. Common eiders also breed in West Greenland and Canada, however, this species is more coastal in its distribution and occurrence during winter (7). In eastern Hudson Bay, a sedentary population of common eiders also winters in the shallow open-water areas (29). A large proportion of common eiders from the Canadian Arctic and Northwest Greenland winter in the coastal areas of West Greenland and Store Hellefiske Bank (8). Here, they similarly utilize shallow coastal open-water areas for feeding.

Little auks at bird cliffs in Northwest Greenland. Photo: M.P. Heide-Jørgensen.

The Little Auk

The wintering areas for little auks extend from Davis Strait to Newfoundland. Many birds are found along the West Greenland coast, especially on Store Hellefiske Bank. It is likely that both little auks from North Greenland and Svalbard winter in southwest Greenland waters, however, the total number of little auks wintering in southwest Greenland is unknown (9). The little auk is planktivorous and is highly dependent on primary and secondary production in their feeding areas. In spring, little auks move north to breed in colonies in Northwest Greenland in the North Water and adjacent waters. When the birds arrive at breeding sites in early May, they feed in the offshore open-water in the North Water utilizing the rich abundance of copepods (primarily *Calanus hyperboreus* and *C. glacialis*) (5, 30). Recent surveys have estimated the population to number at least 33 000 000 breeding pairs in the North Water during this time (6). The ice-free areas of the North Water and Lancaster Sound are declining and less water is available for the little auks in May.

The Thick-billed Murre

In winter, large numbers of thick-billed murres move to West Greenland from areas as far as Svalbard, East Greenland, East Baffin, the Canadian High Arctic, Iceland, and eastern Russia (8). Later in spring, these birds return from their wintering grounds in southwest Greenland to their breeding grounds

where they require open-water for feeding. Thick-billed murres breed at bird cliffs in Northwest Greenland, along the east coast of Baffin Island, in Hudson Strait and in the Canadian High Arctic. In these areas they are dependent on open-water with high productivity close to the colonies.

DISCUSSION

Regional increasing trends in sea ice coverage in Baffin Bay and Davis Strait (resulting in declining open-water) were as high as 7.5% per decade between 1979–1999 (14, 16, 18, 31, 32) and comparable significant increases have been detected back to 1953 (17). Similar trends in sea ice have also been detected locally along the West Greenland coast, with slightly lower increases of 2.8% per decade ($p < 0.07$) (17). Until now, regional trends have not been detected on microhabitat scales and little has been done to investigate the effect on aggregations or sub-populations of marine predators dependent on these localized areas. Several species rely heavily on open-water during winter periods, which is often critical to their survival or survival of their offspring. With respect to resource management of Arctic marine predators, it is necessary to incorporate understanding of the impacts of climate change on habitats into decisions for resource use.

Open-water wintering areas smaller than 25 km^2 were not examined in this study because the coarse resolution of the sea ice data prevented localized trend detection. It is likely that marine mammals and seabirds also use very small open-water areas during winter (e.g. shore leads < 1 km in width). The extent to which they rely on these areas is unknown and most likely, these species utilize larger or more predictable areas most frequently. It is reasonable to assume that the 24 microhabitats examined here represent the majority of the intensively utilized wintering areas in the Canadian High Arctic and West Greenland. It is also likely that the smaller areas, not examined here but adjacent to larger localities, have similar trends in the proportion of open-water and that these trends may be inferred from their larger neighboring localities.

In this study, contrasting trends in the fraction of open-water were observed. The eastern Canadian High Arctic microhabitats generally showed an increase in open-water, whereas microhabitats in Baffin Bay-Davis Strait showed decreasing open-water. Although trends varied across regions in this study, the 'biologically' most important wintering areas were found in regions with increasing sea ice, with the exception of Hudson Strait. This increase has both obvious direct effects on oxygen access as well as indirect effects on marine productivity. It is, however, important to note that top marine predator vulnerability may not merely lie in the gradual reduction of open-water, as it must be assumed that the animals have some ability to adapt to long-term changes in their environment. What may be more important is the increasing sea ice coverage in combination with environmental variability, which leads to an increased frequency of periodic complete freeze-over. This can result in catastrophic mortalities that can affect population trajectories. For example, in Disko Bay, less than 5% open-water was observed on 89% of the days (n = 124) in March between 1992–1995, and during this period, 15% of these days had complete freeze-over of Disko Bay (< 0.1% open-water).

Vulnerability of Marine Mammals

Failure to maintain access to oxygen has been documented to cause immediate mortality in Arctic cetaceans (33, 34). Narwhals and belugas are not capable of breaking breathing holes in the ice and are occasionally found trapped in large numbers. Marine mammals are more capable of tolerating longer periods with nutritional stress than seabirds as they have thick blubber layers, which can be used as a reserve during periods with little forage. Despite this, density dependent effects of nutritional stress on reproduction and survival for marine mammals cannot be discarded regardless of their relative resilience (e.g. 35, 36). Seabirds, in contrast, have an active strategy for avoiding nutritional stress due to a much higher mobility, easily travelling several hundred km a day in search of favorable feeding areas.

The walrus is the only one of the four marine mammal species examined here that is truly capable of breaking thick ice for access to air (37). Walrus are often found in small leads or open-water created by tidal movements around icebergs. There are no reports of fatal ice entrapments of walruses and they are clearly well adapted to life in the sea ice, flexible in their selection of foraging sites and prey. Walruses do depend heavily on shallow banks for feeding on bivalves but are reported to occasionally take seals over deeper water (38, 39). The walrus may be less vulnerable to reduced open-water space in the pack ice than the other marine mammal species.

Bowhead whales travel long distances over short time periods and have less firm migratory patterns than observed for belugas and narwhals. Furthermore, bowhead whales often travel alone and are widely dispersed during both summer and winter, so only a small fraction of the population will, at any given time, be susceptible to ice entrapments. Although bowhead whales can break thick new ice, they are also occasionally trapped in sea ice together with either narwhals or belugas. Bowhead whales depend on access to zooplankton, and changes in marine productivity may either have nutritional effects or cause changes in movement patterns. The timing and composition of the zooplankton blooms, related to extension and residency of sea ice, is critical for optimal feeding opportunities for bowhead whales.

Bowhead whale and belugas at an ice entrapment in Lancaster Sound in May 1999. Photo: M. Ramsay.

Narwhals utilize leads and cracks for access to air in dense ice and are occasionally found in ice entrapments in the thousands. Narwhals feed heavily on the wintering grounds and are dependent on access to open-water for breathing between deep foraging dives. The large numbers of narwhals on the Northern Wintering Ground are assumed to be geographically isolated from those on the Southern Wintering Ground. Due to their strong site fidelity, the narwhal aggregations must be considered functionally separate units, highly sensitive to any further

increase in pack ice, as they inhabit areas with the least amount of open-water. On the wintering grounds, the fraction of open-water can be as low as 0.5–2.0% at the end of March. The regional decrease of open-water of 1.0% per decade detected in Baffin Bay will clearly impact this species.

In Baffin Bay, belugas overwinter in the four microhabitats with the largest fractions of open-water: the North Water, Jones Sound, Disko Bay, and Store Hellefiske Bank. These microhabitats all show declining trends in open-water with high probabilities of slopes less than zero. Like narwhals, belugas are occasionally trapped in sea ice in large numbers, especially in Disko Bay and Jones Sound (33–35). Belugas also winter offshore in Cumberland Sound, where they may face reduced amount of open-water at the wintering site. The belugas wintering in West Hudson Bay and Hudson Strait do not appear to be at risk of ice entrapments as open water is increasing in their wintering areas.

Vulnerability of Seabirds

The vulnerability of Arctic seabirds diverges from marine mammals in that reduced open-water generally only limits access to prey. Common eiders, little auks, and thick-billed murres have, however, been reported to occasionally succumb in ice entrapments (29, 40). Seabirds have high metabolic rates and require dependable year-round access to rich prey resources for survival, reproduction, and chick rearing. Several species of seabirds rely heavily on the open-water areas in the Arctic for overwintering and feeding during critical periods determining success for their breeding cycle. Reduced marine production may have immediate effects on seabirds as their fat deposits cannot sustain them through a season with intensive nutritional stress. Seabirds wintering in West Greenland appear to rely heavily on a few specific localities, one of which is Store Hellefiske Bank. This locality is important because access to shallow water is available in winter, when most coastal shallow areas are covered with fast ice.

Store Hellefiske Bank is particularly important for king and common eiders, which must reach benthic prey at depths < 50 m and < 20 m, respectively (7, 8). The declining trend in open-water on Store Hellefiske Bank may significantly inhibit successful benthic foraging for these species. Even though the total amount of the open-water on Store Hellefiske Bank is still large (> 10%), the area shows a strong decline in the amount of open-water and some critical feeding grounds for the sea ducks may be disappearing. Further reduction of the open-water will force the eiders to move south, to areas with deeper water and less available prey. Store Hellefiske Bank is also host for several species of alcids during winter and spring migration. These alcids differ from sea ducks in that they rely on pelagic prey and can take advantage of deeper open-water further south in Davis Strait if sea ice continues to increase on Store Hellefiske Bank.

Other important regions for seabirds are northern and southern Baffin Bay and Hudson Strait, used for intensive feeding in spring by the little auk and the thick-billed murre during the early stages of the breeding cycle. In spring, the North Water, Jones Sound, and Lancaster Sound are completely surrounded by pack ice when the birds arrive at the bird cliffs, which are strategically located close to the productive open-water areas. Increased distance from colonies to open-water will impact the energetic costs. Further, a reduction of open-water with a subsequent reduction in productivity will affect the feeding success of the millions of little auks and hundreds of thousands of thick-billed murres that rely on these resources for successful breeding. Failure to breed due to extended sea ice cover has been reported for little auks and thick-billed murres (41).

Marine Productivity

The timing and extent of primary production is strongly related to the patterns of ice formation. Extensive and prolonged ice coverage cools the water column during the critical spring period when herbivorous zooplankton graze on phytoplankton (42). Late ice break up of sea ice may delay phytoplankton production and may disrupt the connection between the phytoplankton and copepod grazers that ascend from depth at specific times of the year (43, 44). A cold upper layer of the water column would slow the production of copepods and make the surface waters less productive. Species such as little auks and bowhead whales, which rely on predictable copepod resources during spring in the open-water areas, will be affected by extended ice coverage during this critical feeding period. Fish species like polar cod (*Boreogadus saida*), Arctic cod (*Arctogadus glacialis*), capelin (*Mallotus villosus*), and the larvae of Greenland halibut (*Reinhardtius hippoglossoides*) are also dependent on the spring production of zooplankton. A negative influence from poor production on these forage fish species will ultimately affect top predators such as the thick-billed murre, beluga, and narwhal. If the timing of the coupling between phytoplankton and zooplankton is disrupted by sea ice, changes in the benthos are also to be expected. Phytoplankton that is not consumed by zooplankton will ultimately sink to the bottom and contribute positively to benthic production. This may benefit benthic feeders such as walrus and eiders if they have access to the feeding grounds.

CONCLUSION

Among the pan-Arctic responses to climate change, Baffin Bay and Davis Strait are regions that uniquely deviate from warming patterns and decreasing sea ice. This creates an opportunity for comparing and contrasting effects of climate change on top predators. Here, two types of vulnerability have been identified relative to increasing sea ice: *i)* the direct physical impact of sea ice as a barrier for air-breathing foraging animals; and *ii)* the cascading effects of changes in marine productivity.

Generally the cetaceans are the most vulnerable to a reduction in available open-water, because they urgently require oxygen after dives that cannot exceed 25 minutes. Horizontal displacement within the pack ice is limited to *i)* their maximum swimming speeds (approximately 2 m sec^{-1}); *ii)* available leads and cracks; and *iii)* their ability to detect alternative open-water areas. The frequency of occurrence and fate of whales in ice entrapments outside the inhabited coastal areas of West Greenland and Arctic Canada may even go undetected. Little is known about the ability of cetaceans to react to decreased marine production.

Given the severity of the detected trends in increasing sea ice coverage at important wintering areas, it remains pertinent to focus research efforts on the fate of the eight indicator species examined here. Future studies should specifically address questions related to changes in phenology of migration, alterations in focal areas of importance, signs of nutritional stress, and effects on survival and reproduction for top predators utilizing the Arctic ecosystem during periods of extensive sea ice coverage. Finally, harvest management of top predators must account for the additional risk introduced by reduction in carrying capacity caused by increased sea ice coverage, which may naturally adjust populations downward in response to environmental change.

An estimate of the fraction of belugas (*Delphinapterus leucas*) in the Canadian high Arctic that winter in West Greenland

Received: 20 July 2002 / Accepted: 25 January 2003 / Published online: 7 March 2003
© Springer-Verlag 2003

Abstract Five belugas, or white whales (*Delphinapterus leucas*), were tracked by satellite from Creswell Bay, Somerset Island, in the Canadian high Arctic towards West Greenland in autumn 2001. After 1 October, three of the whales stayed in the North Water polynya and the other two whales moved to West Greenland. One of the whales that moved to Greenland migrated south along the west coast, following a route and timing similar to another beluga tracked in 1996. The belugas that moved towards West Greenland from Canada did so before or near 1 October. The movements of both these whales followed a similar timing and assumed migratory route of belugas hunted in autumn in West Greenland. In Greenland, the hunt begins in September, where the first whales are taken in the northernmost community of Qaanaaq. Hunting takes place farther south in Upernavik in October, and finally in November and December, belugas are taken even farther south in Uummannaq and Disko Bay. The whales that remain in the North Water after 1 October most likely do not contribute to the harvest in West Greenland. Based on the total number of belugas satellite-tracked in Canada between 1995 and 2001 with tags that lasted beyond 1 October, approximately 0.15 (95% CI 0.06–0.35; $n = 26$) of the summering stock of belugas in the Canadian high Arctic move to West Greenland for the winter. Genetic studies have indicated that belugas moving east through Lancaster Sound are significantly differentiated from belugas taken in the autumn hunt in West Greenland. These conflicting results suggest molecular genetics cannot be solely relied on to reveal the stock identity of these belugas.

Introduction

Historically, it has been assumed that the majority of belugas, or white whales (*Delphinapterus leucas*), summering in the Canadian high Arctic move to West Greenland for the winter. It has been proposed that only a small proportion remain in the North Water polynya (referred to here as the "North Water"), situated at the entrance to Smith Sound between Northwest Greenland and the northeastern Canadian high Arctic (Vibe 1967; Finley and Renaud 1980; Reeves and Mitchell 1987; Richard et al. 1998a). However, results from recent satellite-tracking studies of belugas have revealed that a large number of tagged belugas actually remain in the North Water, long after the major migratory pulse arrives in West Greenland (Richard et al. 2001a).

The seasonal timing of beluga catches and observations of beluga arrival in hunting areas in West Greenland suggest that a large pulse of whales arrive in the northernmost municipalities of Qaanaaq in late September and Upernavik in early October. Whales appear to be passing through these areas throughout October, and arrive farther south in the Disko Bay area in November (Heide-Jørgensen 1994). Furthermore, belugas are frequently seen and caught from

January to March south of Disko Bay, and are only occasionally seen south of 65°N. Visual observations and catches indicate that belugas remain between Maniitsoq and Disko Island until mid-May, after which they move north. Belugas are occasionally taken along the ice edge in Upernavik in spring, supporting the idea of this northward movement.

Satellite telemetry, genetic studies and organochlorine analyses show belugas have strong site fidelity to certain fjords, estuaries and wintering grounds (O'Corry-Growe et al. 1997, 2002; Richard et al. 2001a; de March et al. 2002; Innes et al. 2002a, 2002b; Palsbøll et al. 2002). To date, two different beluga wintering grounds have been identified in the Baffin Bay region: one in Central West Greenland between Maniitsoq and Disko Island, and the other in the North Water. A large decline in beluga abundance was detected in the area between Maniitsoq and Disko Island between 1981 and 1999 (Heide-Jørgensen and Acquarone 2002). The cause of the decline has been attributed to unsustainable beluga hunting in West Greenland (Butterworth et al. 2002; Innes and Stewart 2002). No data are available to detect changes in population abundance in the North Water, where only limited hunting takes place (Richard et al. 1998a).

There is a need to develop catch levels, which can be applied to abundance estimates, to adjust catches to sustainable levels or levels that would allow a recovery of the depleted beluga stock in West Greenland (cf. Butterworth et al. 2002; Innes and Stewart 2002; Sejersen 2002). It is important to know from which locality a harvested stock of a migratory animal originates, and also what fraction of the source population is subjected to a hunt (or multiple hunts in different areas). Belugas follow strict spatial and temporal patterns of movements and display a high degree of site fidelity to seasonal habitats. Because of these tendencies, beluga stock or sub-population discreteness must be evaluated on a small geographical scale. This study presents results of satellite-tracking studies of belugas in the Canadian high Arctic from August 2001 to February 2002, and links relevant evidence on movement patterns to population discreteness within Canada and Greenland. Additionally, an estimate of the fraction of belugas from the Canadian high Arctic that move to West Greenland for the winter is calculated, based on satellite-tracking studies conducted between 1995 and 2001 (Richard et al. 1998b, 2001a; present study).

Materials and methods

Satellite tracking

Six belugas were live captured at Creswell Bay, Somerset Island, Canada (Fig. 1) in August 2001 using hoop nets (cf. Orr et al. 2001). The whales were instrumented with satellite-linked radio-transmitters attached to the dorsal ridge with stainless-steel wires and either 6-mm nylon pins or 5-mm titanium rods (see Table 1 for specifications). The satellite transmitters (SPOT1 and SPOT2, Wildlife Computers, Redmond, Wash.) provided geographic positions of the whales and were either programmed to transmit on the 5th, 15th and 25th day of each month, or to transmit every 4 days. Data from the transmitters were collected via the ARGOS system (Service Argos 1989; Harris et al. 1990). Only good-quality positions were used in the analysis. Positions from ARGOS were examined visually and dates of passage between different landmarks or geographic coordinates were compiled. The data were compared to departure and passage dates for specific localities from other satellite-tracking data collected from belugas tagged in the Canadian high Arctic in 1995 and 1996 (Richard et al. 1998b, 2001a).

Harvest statistics

Statistics on monthly distribution of catches of belugas in West Greenland were obtained from the Directorate of Hunting and Fisheries under the Greenland Home Rule (Piniarneq 1993–2000). Direct observations of catches and reports collected from hunters were extracted from unpublished reports (Greenland Institute of Natural Resources, Nuuk). Catches were examined on a monthly scale, and peaks for each of the regions where belugas were taken in Greenland were identified. These data were compared to the temporal scale of the migratory path taken by the belugas that travelled to Greenland.

Data analysis

The probability that a beluga moved to West Greenland for the winter (or stayed in the North Water) was assumed to be binomially distributed where $\hat{p}$ was the proportion of whales moving to West Greenland with standard deviation

$$\mathrm{sd}(\hat{p}) = \sqrt{\frac{\hat{p}(1-\hat{p})}{n}}$$

Confidence limits (95%) were calculated by log-odds transformation where:

$$\hat{P}_{lower} = \frac{\hat{p}}{\hat{p} + (1-\hat{p}) * C}$$

and

$$\hat{P}_{upper} = \frac{\hat{p}}{(\hat{p} + (1-\hat{p}))/C}$$

where

$$C = \exp\left[\frac{1.96 * sd(\hat{p})}{(\hat{p}(1-\hat{p}))}\right]$$

(Burnham et al. 1987)

Table 1 List of instrumented belugas in Creswell Bay, 2001. Transmitter 7931 was programmed to transmit every 4 days and all other tags were programmed to transmit on the 5th, 15th and 25th day of each month

Animal ID	Date in August 2001	Sex	Length (cm)	Fluke width (cm)	Colour	Last day with positions
7931	8	Male	320	–	Grey	1 February
20160	8	Male	370	–	White	15 October
20688	10	Female	373	79	White	5 November
20689	10	Male	325	68	Grey	5 October
20693	10	Female	375	90	White	15 August
26712	14	Female	390	89	White	15 October

Results

Belugas in 2001–2002

Between 8 and 14 August, six belugas were tagged at Creswell Bay (Somerset Island) on the west side of Prince Regent Inlet. All whales immediately left the area and travelled to Peel Sound or Barrow Strait, where they headed east towards Lancaster Sound as late as 25 August (Figs. 1, 2). They continued in this direction to the end of September. At this time, four of the remaining five whales were either in the eastern part of Lancaster Sound moving north along the east coast of Devon Island, or had reached Jones Sound (Figs. 2, 3). The whales with the latest departure date from Lancaster Sound were the last to arrive in Jones Sound (arrival on 5 October), and one whale remained in Barrow Strait longer than the others (20688).

Of the five whales that provided positions beyond 1 October, three (7931, 20160, 26712, Fig. 2) reached the coast of Northwest Greenland (north of 76°N) at approximately 76°N, 72°W between 2 and 5 October 2001. One of these whales (26712) remained in Northwest Greenland until 15 October, while a second whale (20160) was further southeast in Melville Bay, West Greenland at approximately 75°N, 61°W on 5 October. The third whale (7931) provided more detailed movements along the West Greenland coast because the tag was programmed to give positions every 4 days and batteries had greater longevity. Between 2 and 12 October 2001, this whale travelled close to the coast of the Qaanaaq and Upernavik municipalities (Fig. 3) and stayed in the northern part of Upernavik (> 74°N) until 1 November. Between early November to mid-December, it frequented coastal areas of southern Upernavik (between 72° and 74°N). It passed offshore of Uummannaq municipality by mid-December, and reached the entrance to Vaigat Strait on 28 December. It continued south offshore of Disko Island and approached the coast of West Greenland south of Disko Bay in mid-January. Finally, the beluga reached its southernmost position on 24 January, just north of the town of Sisimiut. From there, it moved northwest until contact was lost in early February 2002.

Timing of catches in West Greenland

According to catch statistics based on catches of 4,807 belugas collected between 1993 and 2000, catches show a pronounced peak in October in Upernavik, after a broader catch period farther north in Qaanaaq between September and October (Fig. 4). Catches in Uummannaq are concentrated in November and in Disko Bay, and farther south, peaks appear in November and April.

The range of dates of the first and last autumn catches of belugas in Upernavik (based on data from jaw collections, hunters, or other observations) show a clear temporal pattern. No catches occur before 28 September, and most catches take place during the 1st week of October (Fig. 5). This suggests whales are taken as they move south from Qaanaaq.

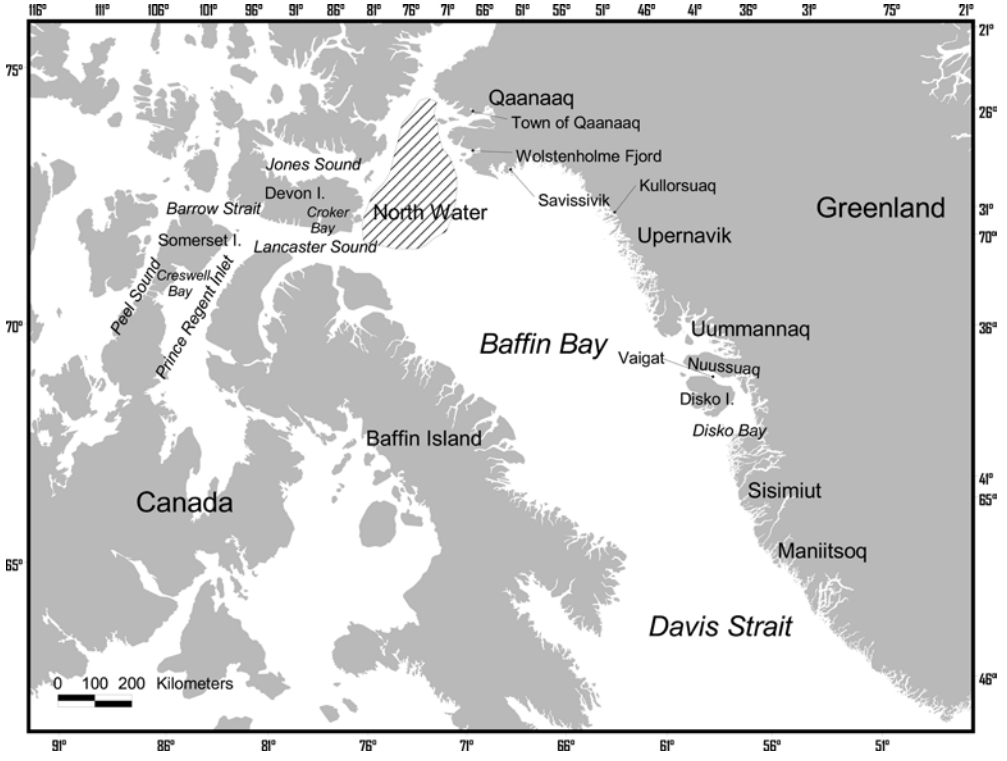

Fig. 1 Map of localities mentioned in the text and the location of the North Water polynya

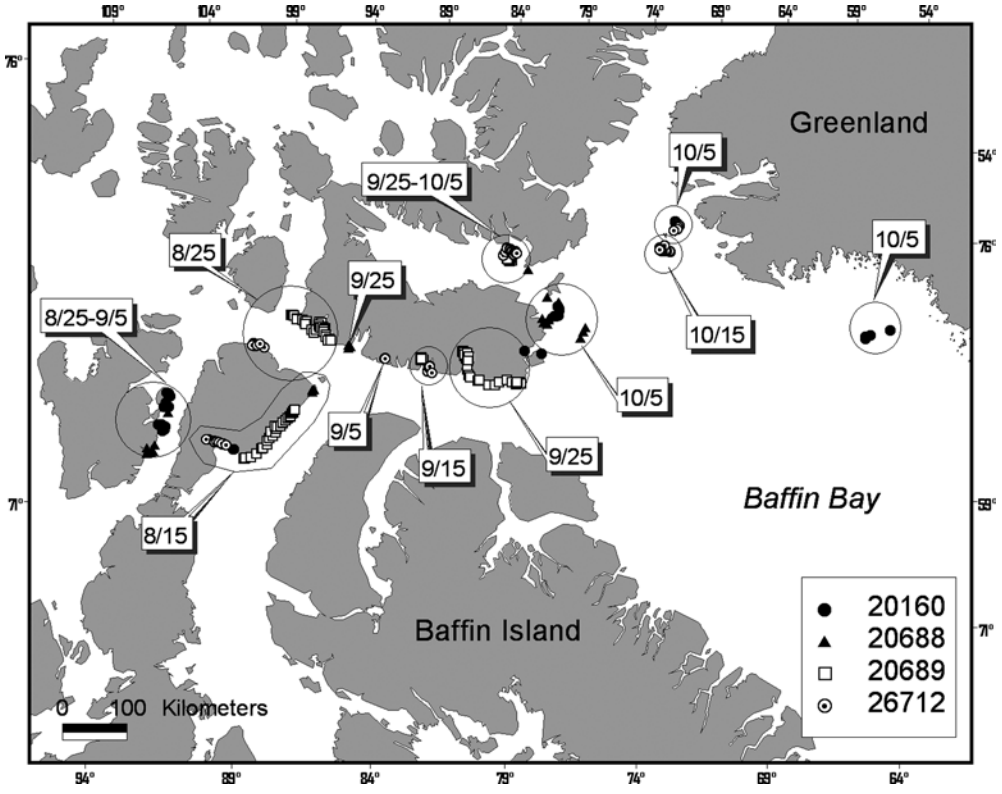

Fig. 2 Geographic positions of four belugas satellite tracked from Creswell Bay, Somerset Island, 2001. All whales were tagged in August. Whale 26712 is included in the fraction of whales that were considered to remain in the North Water in the winter because the whale did not reach West Greenland (south of 76°N) by early October. Whale 20160 was included in the fraction that move to West Greenland because it left the North Water and travelled east before early October

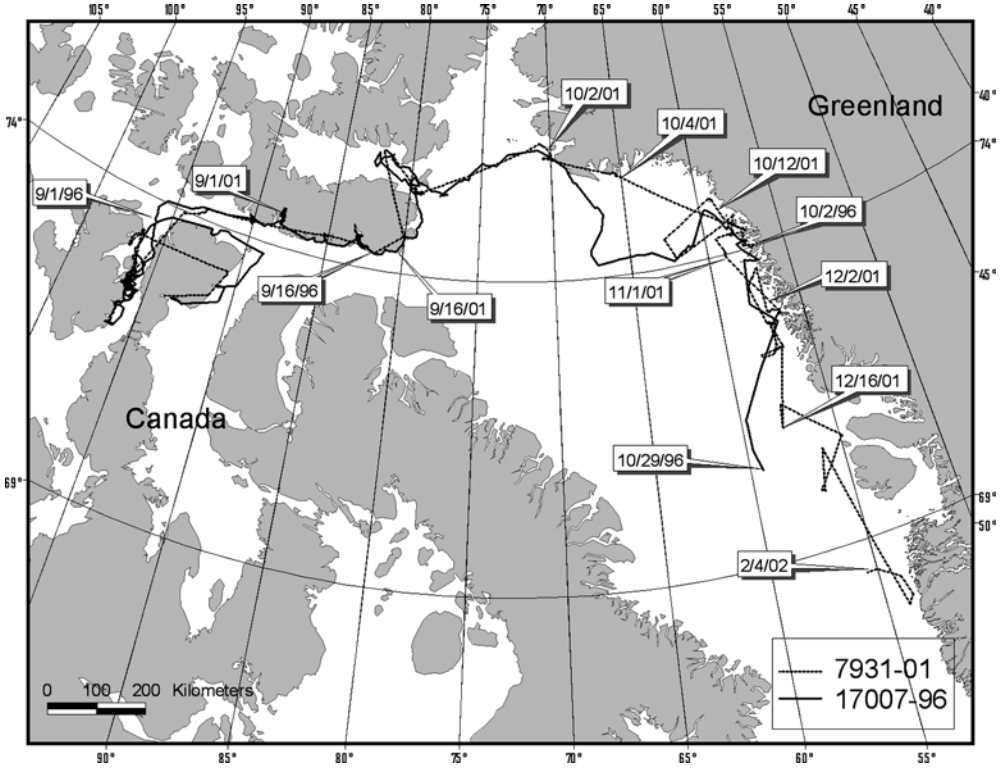

Fig. 3 Tracklines of beluga 7931 tagged in 2001 (present study) and whale 17007 tagged in 1996 (results reported in Richard et al. 2001a). The total distance travelled for whale 7931 was 8,679 km when distances between all positions between 8 August 2001 and 4 February 2002 were used, 4,814 km when only good-quality positions (LC > 0) were used for the same time period, and 4,037 km when average daily positions were used. Whale 17007 travelled 17,748 km between 22 July and 30 October (100 days) when all position qualities were considered and 5,160 km when only good-quality positions (LC > 0) were used for the same time period

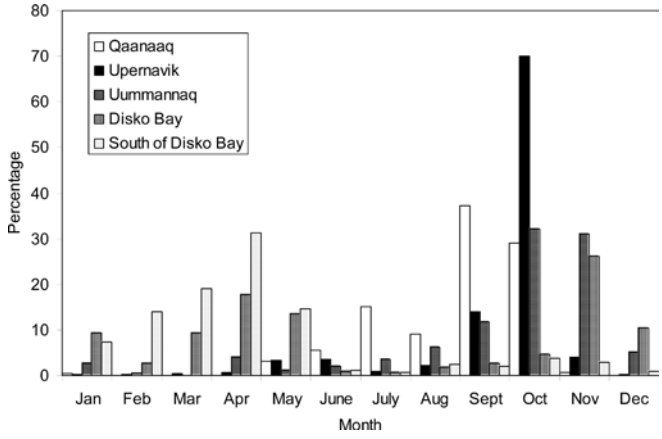

Fig. 4 Distribution of reported beluga catches by month in West Greenland between 1993 and 2000 ($n = 4{,}807$). Catches were reported for the municipalities of Qaanaaq, Upernavik, Uummannaq, Disko Bay, and south of Disko Bay (Piniarneq 1993–2000)

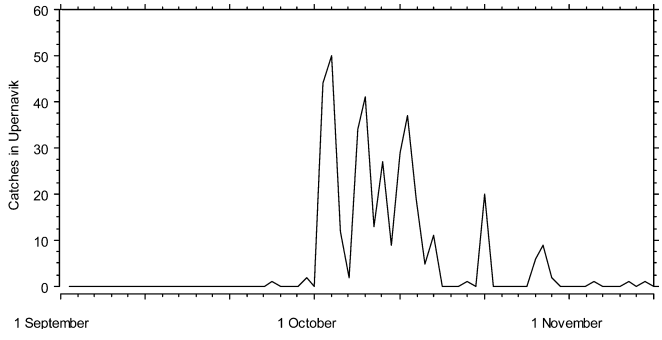

Fig. 5 Peak period of catches of belugas from direct observations of date and number of whales killed in Upernavik 1989–1999

Review of previous autumn tracking of belugas from Canada to Greenland

Approximately 33 belugas have been satellite-tracked in the Canadian high Arctic during 4 studies at 4 different localities between 1995 and 2001. Six of the 33 whales failed to provide positions beyond 1 October (the date after which belugas are expected to reach the West Greenland coast, based on the occurrence of belugas in the coastal hunt), and were excluded from the analysis. The remaining 26 tags, used in this analysis, provided positions well into October (beyond 10 October), with 5 tags lasting at least into November.

In mid-September 1995, six belugas were instrumented on the south coast of Devon Island (Croker Bay) and tracked for several months. They remained in the North Water from mid-October to mid-November, when contact was lost (Richard et al. 1998b). In early September 1996, nine belugas were tagged in Croker Bay and tracked to the North Water. None of the whales moved towards Northwest Greenland (i.e. passed 73°W) even though they were tracked for several weeks after 1 October (tags stopped between 16 October and 18 November; Richard et al. 2001a).

In mid-July 1996, 12 belugas were tagged in 3 different estuaries around Somerset Island (Cunningham Inlet, Elwin Bay, and Creswell Bay). Seven tags provided positions after 1 October (Richard et al. 2001a). Six of the seven whales stayed in the North Water area until contact was lost between 12 October and 28 November. The last remaining whale (17007) moved east on 23 September and reached the Greenland coast south of Wolstenholme Fjord on 25 September (Fig. 3). Around 2 October, it approached the northernmost settlement (Kullorsuaq) in Upernavik and followed a route and timing that were both similar to the movements of the belugas tracked in the present study, and similar to the sequence of hunting events in West Greenland. The last locations from this whale were obtained on 29 October when it was offshore of Disko Island, Greenland (Fig. 3).

The belugas tracked in our study closely followed the migratory schedule observed during previous tracking studies; the whales moved to Peel Sound in mid-August, left Lancaster Sound in mid-September, and moved north into Jones Sound in late September (Tables 2, 3). The tracks indicate that whales can apparently be segregated into two groups in the second half of September: some whales head towards the banks off Jones Sound, and others continue towards Northwest Greenland, where they appear in early October.

Fraction of Canadian high-Arctic belugas that move to West Greenland

Of the 26 beluga tags that lasted beyond 1 October, 4 individuals reached the West Greenland coast (south of 76°N) around 5 October, and 22 individuals stayed in the North Water. All four whales that went to Greenland were tagged in Creswell Bay, on Somerset Island. Of the 22 that stayed in the North Water, 8 (1995: 2, 1996: 5, 2001: 1) gave positions in this area well into November, indicating there was not a delayed migration from the North Water to West Greenland. Therefore, it can be assumed that the belugas that stayed in the North Water in November also stayed there during the winter. When results from all 3 years were combined, the fraction of whales that moved to West Greenland was 0.15 (95% CI 0.06–0.35).

Discussion

The departure of belugas from the central Canadian high Arctic follows a regular schedule that has apparently not changed much over the past century. Based on aerial surveys, Koski et al. (2002) found that most belugas left Lancaster Sound in mid-September in the 1970s. A similar timing was also observed at Croker Bay in 1934, where the beluga hunting peaked between 20 and 22 September (Reeves and Mitchell 1987).

Table 2 Details on the travel distances, duration of tracking and the arrival at certain positions for 5 whales tracked in 2001. Data were compared to averages of the 6 whales tracked in 1995 (Richard et al. 1998b) and the 20 whales tracked in 1996 (Richard et al. 2001a). *NA* indicates "not applicable" and *dashes* indicate that the whales did not move to those localities or the tags stopped transmitting. Dates are in Julian days after 1 January

The timing of the autumn movements of belugas in Northwest and West Greenland also follows a regular pattern. Beluga whales arrive and are hunted in the municipality of Qaanaaq (either at the settlements of Qaanaaq or Savissivik) in late September (usually around 20 September in Qaanaaq and 25 September in Savissivik) (Heide-Jørgensen 1994). The settlements of northern Upernavik take their first belugas around 28 September, and catches peaked in this area in the first 2 weeks of October during the 1990s. Catches farther south in Uummannaq and Disko Bay occur in November and December, and belugas are taken in winter and spring south of Disko Bay.

The whale that was tracked in this study through February 2002, was located near the West Greenland communities during times that are consistent with knowledge on beluga phenology obtained from catch statistics, aerial surveys and observations. The whale arrived in northern Upernavik exactly when autumn catches peak, and also in the very same area where the majority of the catches took place during the 1980s and 1990s. In January, the whale was found outside Disko Island at the same time when belugas are hunted in this area. In February, the beluga appeared in the same concentration area where multi-annual surveys have been conducted for trends in beluga abundance (Heide-Jørgensen et al. 1993; Heide-Jørgensen and Reeves 1996; Heide-Jørgensen and Acquarone 2002). The track of the whale in this study was consistent with that from the beluga tracked from Creswell Bay between July and November 1996 (Richard et al. 2001a).

Satellite-tracking studies of belugas were conducted in three estuaries in the Canadian high Arctic (Creswell Bay, Elwin Bay, Cunningham Inlet); however, only whales tagged at Creswell Bay moved to West Greenland. Based on these results, there appears to be some segregation within the beluga population in Canada and, possibly, within a single summering locality. Tagging at Devon Island (Croker Bay) in September most likely included whales from all summering grounds around Somerset Island (including the three estuaries above), and possibly even localities where tagging studies have not yet been conducted. This is because the general pattern is such that most whales (from all areas around Somerset Island) move out through Lancaster Sound and pass this area in September, visiting Croker Bay (Richard et al. 2001a). It should also be noted that the two belugas that went to West Greenland passed Croker Bay on 15 September, the peak time of the capture operations at this locality. Thus the autumn tagging at Croker Bay is likely a

random sample, which constituted more than half of the whales in this study.

Current knowledge on molecular genetics of high-Arctic belugas shows that belugas from Lancaster Sound are significantly different from those caught in West Greenland (Upernavik and Disko Bay) based on mitochondrial DNA haplotype distribution (de March et al. 2002). This contradicts the evidence presented here collected by satellite tracking of known individuals moving between the two areas. An overall genetic difference was also reported for belugas between Creswell Bay and West Greenland in 1996 (where the beluga that moved from Creswell Bay to West Greenland was included in the genetic analysis reported by de March et al. 2002); however, a difference was not found for samples taken in Creswell Bay in 1993. No whales were tagged in that year. In both 1996 and 2001, the satellite-tagged whales visited several West Greenland beluga hunting grounds. These results question how clearly genetic studies can discriminate between wintering stocks of belugas that summer in the same area. One explanation, suggested by Palsbøll et al. (2002), is that due to the nature of the genetic sampling programs, genetic studies are more likely to discriminate pods of related whales, rather than stocks in different areas. The samples for genetic studies are often collected from harvest events, where whales from the same pod are killed. Consequently, there is a high risk of obtaining samples from related individuals. This same sampling bias may be true for whales from satellite-tagging studies at a specific site; however, in many harvest situations, entire pods of a single family unit are sampled for genetic studies, which results in a higher degree of interrelatedness than individual whales that are live captured over a period of days in estuaries.

Regardless of sample size, the satellite tracks presented here provide direct evidence that there is a link between the belugas summering in the Canadian high Artic and those in the West Greenland wintering area. Therefore, to assess the contribution of the summering population to the hunted West Greenland winter stock, it seems more effective to examine the probability that whales from a single summering ground move to one of two wintering grounds. This is especially important in situations (like the present) where most hunting occurs in the wintering area. Satellite tracking provides an opportunity for direct estimation of movement probability, and pooling tracks from several years (and localities if justified) can augment sample size. Our estimate of 0.15 (4/26) of the belugas from the Canadian high Arctic moving to West Greenland for the winter updates the estimate of 0.04 (1/21) based on earlier tracking studies with smaller sample sizes (Richard et al. 1998b, 2001a). It is important to note the percentage of whales moving to West Greenland can be variable. None of the whales from the two Devon Island studies moved to Greenland, yet as many as two-thirds of the whales from Creswell Bay in 2001 did. This variability stresses the need for additional studies to elucidate the inter-annual and inter-region differences in movement probability. If the 2001–2002 data alone had been used to calculate a fraction, as many as 60% would have been estimated to move to Greenland.

Only 4 of the 26 whales that were tracked after 1 October could have been subjected to hunting in West Greenland in October or later. If the remaining 22 belugas were available for the Greenland hunt, they would have had to move east later in the season (i.e. in December) after contact was lost. Although such a late movement of belugas from the Canadian high Arctic cannot be entirely excluded, it is highly unlikely. The geographic positions where contact was lost were in an area where belugas are known to occur and most likely remain in winter. Heavy pack ice surrounds the North Water polynya from December to May (Canadian Ice Service 2002), and belugas have not been found outside this area from March to May, except for the coastal open-water areas in West Greenland and some coastal leads in Lancaster Sound (Heide-Jørgensen and Reeves 1996; Heide-Jørgensen and Acquarone 2002). Furthermore, the belugas that were tracked through November did not suggest a secondary pulse of whales moving to Greenland. Thus, there is presently little support for the idea of additional whales moving to Greenland beyond those that leave in October.

Another possibility that could explain the results presented here is that the belugas may alternate between wintering grounds. This possibility is considered unlikely because monodontids are creatures of habit, with extreme site fidelity to their selected summering and wintering grounds in the Arctic (O'Corry-Growe et al. 2002). Additionally, comparisons of organochlorine profiles in the blubber of belugas caught in Jones Sound (probably North Water animals) and in Upernavik-Disko Bay (West Greenland animals), corrected for age and sex differences, have revealed significant differences in the relative composition of organochlorine contaminants between the two areas, which indicates whales are segregated during the winter season (Innes et al. 2002a).

The most recent estimate of beluga abundance in the Canadian high Arctic is 21,213 whales (SE 5,359) in 1996, corrected for the proportion of whales submerged (availability bias) and those missed by the observers (perception bias) (Innes et al. 2002b). Using the fraction of whales that move to West Greenland (0.15, $n = 26$), the actual number wintering in West Greenland can be derived by resampling the lognormal distribution of the population size and the binomial fraction ($\hat{p}$) that move to Greenland and taking their product. Repeating this procedure 1,000 times provides mean abundance estimates of 3,156 (95% C.L.: 643–7,334) belugas wintering in West Greenland, and 18,057 (95% C.L.: 13,879–20,570) belugas wintering in the North Water and adjacent areas.

The wintering stock of belugas in West Greenland was estimated to be 7,941 (95% CI 3,650–17,278) in 1998–1999 (Heide-Jørgensen and Acquarone 2002). This wintering stock is approximately 37% of the estimate of

the summer population in the Canadian high Arctic (Innes et al. 2002b), and implies that 13,000 whales winter in the North Water and adjacent areas. Both methods of estimating the number of whales in the North Water indicate that substantially more belugas winter in the North Water than what was estimated from reconnaissance surveys in the area. Finley and Renaud (1980) and Richard et al. (1998a) gave counts of approximately 500 whales at the surface in leads and cracks in the North Water in winters 1978 and 1994, respectively. These figures were not corrected for whales that were submerged and overlooked by the observers, which could be a factor of 5–6 times the numbers reported (cf. Heide-Jørgensen and Acquarone 2002). Furthermore, the estimates do not include numbers of whales from unsurveyed areas. Recent evidence of ice entrapments in northern Baffin Bay (Heide-Jørgensen et al. 2002) indicate that belugas also occur in shore leads in Lancaster Sound and Jones Sound, and perhaps in other areas adjacent to the North Water. The figures for the population sizes presented above are both associated with considerable uncertainty and if the range of the uncertainty is considered, the expected number of whales wintering in the two areas, derived from the fraction that move to West Greenland, does not deviate from the abundance estimates.

Regardless of the uncertainty about population size or the specific fraction of belugas that move to West Greenland, it appears that less than 50% of the total beluga population in the Canadian high Arctic winter in West Greenland, based on a combination of satellite telemetry, genetic and organochlorine data. Most of these whales may winter in the North Water or use leads in Lancaster Sound, which have not been adequately covered by past surveys. Belugas are creatures of habit, following strict migratory patterns with strong fidelity to certain areas despite being intensively hunted at these localities. The estimated fraction that moved to West Greenland based on the studies reported here may be an artefact of the decrease in winter abundance in West Greenland, and may not reflect the natural equilibrium between the fraction wintering in West Greenland and the fraction in the North Water. A natural equilibrium could possibly be close to 50% wintering in Greenland, or even higher, since the beluga abundance in West Greenland historically was substantially higher than that observed today (Butterworth et al. 2002).

Acknowledgements Two Inuit hunters, Mosesie Keenainak and Randy Itdlout, participated in the capture and handling of the belugas. Karen Motzfeldt kindly provided the hunting statistics from Piniarneq. The study was funded by the Greenland Institute of Natural Resources, the National Environmental Research Institute, the Department of Fisheries and Oceans, the Nunavut Wildlife Management Board, the Danish Natural Research Council (51-00-0131) and the Danish Environmental Protection Agency as part of the environmental support program Dancea (Danish Cooperation for Environment in the Arctic). Polar Continental Shelf Program supplied logistics for the fieldwork. Brigitte de March and two anonymous reviewers improved the manuscript.

From Greenland to Canada in Ten Days: Tracks of Bowhead Whales, *Balaena mysticetus*, across Baffin Bay

M.P. HEIDE-JØRGENSEN,[1,2] K.L. LAIDRE,[3] Ø. WIIG,[4] M.V. JENSEN,[1] L. DUECK,[5] L.D. MAIERS,[5] H.C. SCHMIDT[1] and R.C. HOBBS[6]

(*Received 16 October 2001; accepted in revised form 18 March 2002*)

ABSTRACT. Five bowhead whales (*Balaena mysticetus*) were instrumented with satellite transmitters in northwestern Disko Bay, West Greenland, in May 2001. Best results were obtained when tags were deployed with a pole rather than a pneumatic gun. At least three of the tagged whales remained in the northwestern part of the bay for one to two weeks after tagging. A male and a female whale moved from Disko Bay to northern Canada. They left Disko Bay 11 days apart and took different routes across Baffin Bay to the southern part of the North Water polynya, just east of the entrance to Lancaster Sound. The whales crossed the central part of Baffin Bay relatively rapidly (travel time of 9–10 days, 3.1 and 4.5 km/h). Dive behaviour of one whale was monitored and showed changes in dive depths, dive rates, and surfacing times in different localities, indicating behavioural changes probably related to feeding. The whales were presumably feeding in both Disko Bay in May and in the southern part of the North Water (southeast of Bylot Island) in June. This study confirms whalers' observations that bowhead whales move between West Greenland and the east coast of Baffin Island.

Key words: bowhead whale, *Balaena mysticetus*, satellite telemetry, dive behavior, sea ice, Baffin Bay, Canada, Greenland

RÉSUMÉ. En mai 2001, cinq baleines boréales (*Balaena mysticetus*) ont été équipées d'émetteurs spatiaux dans le nord-ouest de la baie de Disko (Groenland occidental). Les meilleurs résultats ont été obtenus lorsque les marqueurs ont été apposés avec une perche plutôt qu'avec un fusil à air comprimé. Au moins trois des baleines marquées sont restées dans la partie nord-ouest de la baie pendant une à deux semaines après le marquage. Deux individus, un mâle et une femelle, se sont déplacés de la baie de Disko au nord du Canada. Ils ont quitté la baie à 11 jours d'écart et ont emprunté des trajets différents pour traverser la baie de Baffin et rejoindre la partie méridionale de la polynie de l'Eau du Nord, située juste à l'est de l'entrée du détroit de Lancaster. Les baleines ont traversé la partie centrale de la baie de Baffin assez vite (en 9 et 10 jours, soit 3,1 et 4,5 km/h). On a suivi le comportement de plongée d'une baleine, qui a montré des changements dans la profondeur des plongées, leur fréquence et le temps en surface à divers endroits, révélant des modifications du comportement probablement associées au nourrissage. On suppose que les baleines s'alimentaient dans la baie de Disko en mai aussi bien que dans la partie méridionale de l'Eau du Nord (au sud-est de l'île Bylot) en juin. Cette étude confirme les observations des baleiniers à l'effet que les baleines boréales se déplacent entre l'ouest du Groenland et la côte est de l'île de Baffin.

INTRODUCTION

The population of bowhead whales, *Balaena mysticetus*, in the Baffin Bay and Davis Strait area numbered at least 12 000 individuals in the 1800s (Woodby and Botkin, 1993). The population was severely depleted by commercial whalers before 1900 and is now considered to be between 250 and 350 whales (Finley, 1990; Zeh et al., 1993). Most of the information on the migration routes and former high-density areas in Canada and Greenland is based on observations from whalers in the 1800–1900s and Inuit hunters (e.g., Reeves et al., 1983; Ross, 1993; NWMB, 2000). The general hypothesis is that bowhead whales spend the winter distributed from the northeast coast of Labrador to the east

coast of Baffin Island across to West Greenland. In the spring, the bowhead whales are found at the ice edge of Davis Strait and Hudson Strait, in localized areas in West Greenland, and along the east coast of Baffin Island. Whales from West Greenland are thought to cross Baffin Bay (at approximately 72˚ N) and reach Lancaster Sound between May and July, while the whales on the east coast of Baffin Island move north. During the summer, bowhead whales are widely distributed and enter many fjords and bays of the Canadian High Arctic. The fall migration begins in September and continues through October, when whales either move south along the east coast of Baffin Island or cross over to the West Greenland coast, appearing there in September and October (Reeves et al., 1983).

Over the past 20 years, scattered observations of bowhead whales have been reported from West Greenland, suggesting that bowhead whales still occupy their historic locations (Born and Heide-Jørgensen, 1983; Kapel, 1985; Reeves and Heide-Jørgensen, 1996; Heide-Jørgensen and Acquarone, 2002). The winter abundance of bowhead whales along West Greenland (derived from aerial surveys of belugas, *Delphinapterus leucas*) has been estimated to be at least "a few tens" of bowheads between 1981 and 1994 (Reeves and Heide-Jørgensen, 1996). This crude estimate was not corrected for whales that were submerged during the surveys, a phenomenon also known as availability bias. In 1998, Heide-Jørgensen and Acquarone (2002) produced an estimate of 233 bowheads (SE = 165) that included a correction for availability bias.

Studies of the migratory behaviour of bowhead whales in Baffin Bay are of interest for stock delineation, especially in the light of renewed hunting in Canada (Finley, 2001). The only direct evidence of a relationship between bowhead aggregations in eastern Canada and western Greenland is the photographic documentation of a whale in Isabella Bay, NE Baffin Island, in September 1986 being re-sighted near Disko Bay in April 1990 (Heide-Jørgensen and Finley, 1991). Bowhead whales inhabit areas with extensive ice cover and may be affected by habitat variability that results from climate change. Information on the plasticity of the migratory routes of bowhead whales provides insight on their vulnerability to changes in available habitats, and determination of migration routes also elucidates stock discreteness. The purposes of this study were to improve satellite tracking techniques for bowhead whales, to document the spring movements of bowhead whales from Disko Bay, West Greenland, and to investigate diving behaviour and habitat use over the course of the migration period.

METHODS

Daily searches for whales were conducted from four small boats between 28 April and 7 May 2001 near the town of Qeqertarsuaq, Disko Island. The overall ice coverage in the western part of Disko Bay was about 10% during the field period, which was unusually light for this time of the year. Most of the ice consisted of broken pieces of fast ice that drifted with the current. When a whale was sighted, the boats moved towards the whale until it dove. While the whale was underwater, the four boats spread out to search for the next surfacing location. When the whale was re-sighted, the process was repeated again until the whale was surfacing in a predictable manner, which usually took less than half an hour. When a whale was first approached (within 4–5 m), a skin biopsy for genetic studies was taken using a crossbow.

Bowhead whales were instrumented with three different types of satellite-linked radio transmitters: ST15 and ST16 (Telonics, Mesa, Arizona) and SPOT1 tags (Wildlife Computers, Redmond, Washington). The ST16 was modified by Wildlife Computers to include binned information on dives. All transmitters were equipped with lithium thianyl batteries and were glued to a cup-shaped stainless steel base, mounted to a titanium spear (diameter 8 mm) with three barbs and a sharp pointed tip. The ST15 tags were deployed with the 'ARTS' (Air Rocket Transmitter System; see detailed description in Heide-Jørgensen et al., 2001a). The ST16 and SPOT1 tags were deployed with an 8 m fiberglass pole approximately 4–5 m from the whale. The tag was mounted on the tip of the pole, secured by a nylon line. The titanium spear was pushed through the skin and into the blubber using the pole to attach the tag. When the tag was implanted in the whale, the nylon line was cut by a sharp edge on the pole. It was important to position the satellite tag high on the whale's back to ensure it was above the water, so that the satellite could receive its transmissions. The tag delivery system was designed so that a biopsy of the whale skin was taken simultaneously (with a 10 mm hollow cylinder, 28 mm in length with internal barbs). Tags were deployed only when the whale was positioned alongside the boat 4–5 m away, and when the whale remained at the surface long enough for us to place the tag in a good position.

Compressed and summarized dive data were transmitted to the satellite for one whale (ID 24638). A dive was defined as submergence below 8 m, and the surface was defined as above 9 m, following sampling schemes also used for narwhals and belugas (Heide-Jørgensen et al., 2001b). The tag sampled depth every 10 seconds, accumulating information on depth of dives, duration of dives, and time spent at different depths across four six-hour periods each day. Time spent was coded in 10 duration classes (0–1, 1–3, 3–6, 6–9, 9–12, 12–15, 15–18, 18–21, 21–24, > 24 min), and depth in 14 depth classes (8–19, 20–35, 36–51, 52–99, 100–151, 152–199, 200–299, 300–399, 400–499, 500–599, 600–699, 700–799, 800–900, > 900 m). The maximum depth of dives for each 24-hour period was also determined. Dive data were examined for temporal variability. Vertical speeds were calculated from dive duration through depth classes of known length to 'destination depths' where the dives ended (see Heide-Jørgensen et al., 1998). Every fifteenth transmission

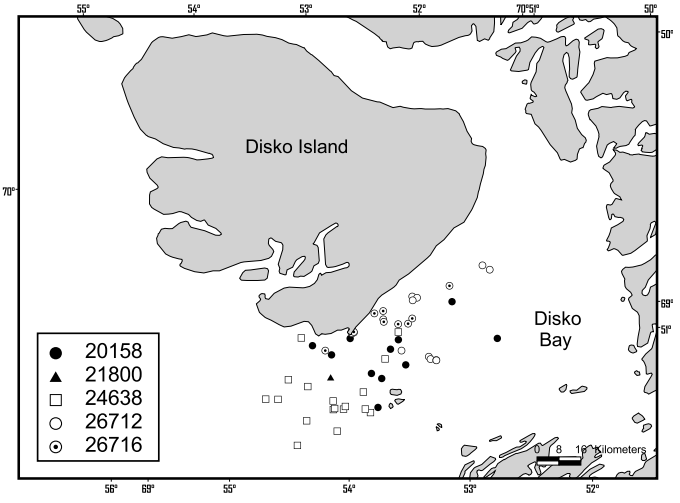

FIG. 1. Map of positions received for all bowhead whales (n = 5) tagged in Disko Bay in May 2001. Only positions with quality of 0 or better are reported.

provided readings of voltage and the cumulative number of transmissions.

Locations and dive data were collected using the Argos System (see Harris et al., 1990). Location qualities were provided by Service Argos and coded according to predicted accuracy. Location codes (LC) were B, A, and 0–3 in order of increasing accuracy of position. All location qualities were used to calculate an average daily position for each whale over the entire tracking period. The average positions were also used to calculate distance and speed over each 24-hour period and provide mean distances and speeds for selected periods during the movements of the whales.

DNA was extracted from the skin samples using DNeasy tissue extraction kits (QIAGEN). The sex of each animal sampled was then determined using a polymerase chain reaction (PCR)-based method that amplifies a portion of the X-chromosome and a portion of the Y-chromosome (if present) (Bérubé and Palsbøll, 1996). Animals were scored as female if there was only a single amplification product corresponding to the X-chromosome fragment and male if there were two products, one from the X-chromosome and one from the Y-chromosome.

Standard descriptive statistical analyses of the dive data were conducted and the level of significance was determined at $p = 0.05$. Since the dive data were categorized and summarized over six-hour periods, independence between samples was assumed, and ANOVA and ANCOVA were used to determine the effects of periods and day on the diving activity.

RESULTS

From 29 April through 8 May 2001, bowhead whales were observed in the northwestern part of Disko Bay daily (or whenever weather conditions permitted searches). All sightings consisted of single whales. Skin biopsies were collected from 15 whales, including all those that were tagged. Molecular sex identification of the samples revealed that 8 of the 15 were females.

Movements

Five bowheads, all estimated to be 12–15 m long (Table 1), were tagged with transmitters during this period. Tags provided locations for a minimum two days. The tagged whales appeared to prefer the northwestern part of Disko Bay (Fig. 1). Tags deployed on two whales (ID nos. 24638 and 26716) transmitted data for 44 and 50 days, and results from those tags are presented in detail here.

On 3 May 2001, an ST16 tag was implanted on a male whale (ID 24638) on the right side, 35 cm below the dorsal line and halfway down the long-axis. This whale (tagged at approximately 69˚12′ N, 53˚08′ W) left the Disko Bay area (69˚30′ N) on 10 May and headed northwest directly towards the east coast of Baffin Island (Fig. 2). Travelling a distance of 846 km, it reached an area only 100 km from Bylot Island, Canada, on 20 May, ten days after departing from Disko Bay (Table 2). Once this male crossed 73˚ W, it slowed down and moved to the southern margin of an area called the North Water polynya, east of Bylot Island. It made localized movements in this area (approximately 74˚ N, 75˚ W) from 30 May until 17 June, when transmissions stopped. Approximately 12 000 transmissions were obtained from this tag, which is about its maximum longevity, and the tag stopped transmitting because of declining voltage.

On 7 May 2001, a SPOT1 tag was implanted on a female whale (ID 26716) 20 cm below the dorsal line, halfway

TABLE 2. Total distance and mean rate of travel for whales 24638 and 26716 in three areas. Standard deviations are shown in parentheses. Since the two whales took different migratory paths, the arrival in the North Water was defined as crossing 73˚ N for 24638 and crossing 76˚ W for 26716.

Whale ID No.		Tagging to Departure from Disko Bay	Travel Across Baffin Bay	In the North Water	Average Speed and Total Distance
24638	Speed km/h	1.15 (0.8)	3.11 (1.6)	0.93 (0.7)	1.53 (1.4)
26716		0.87 (0.5)	4.53 (1.1)	2.41 (2.0)	1.96 (1.8)
24638	Distance km	120	846	622	1590
26716		287	1063	809	2159

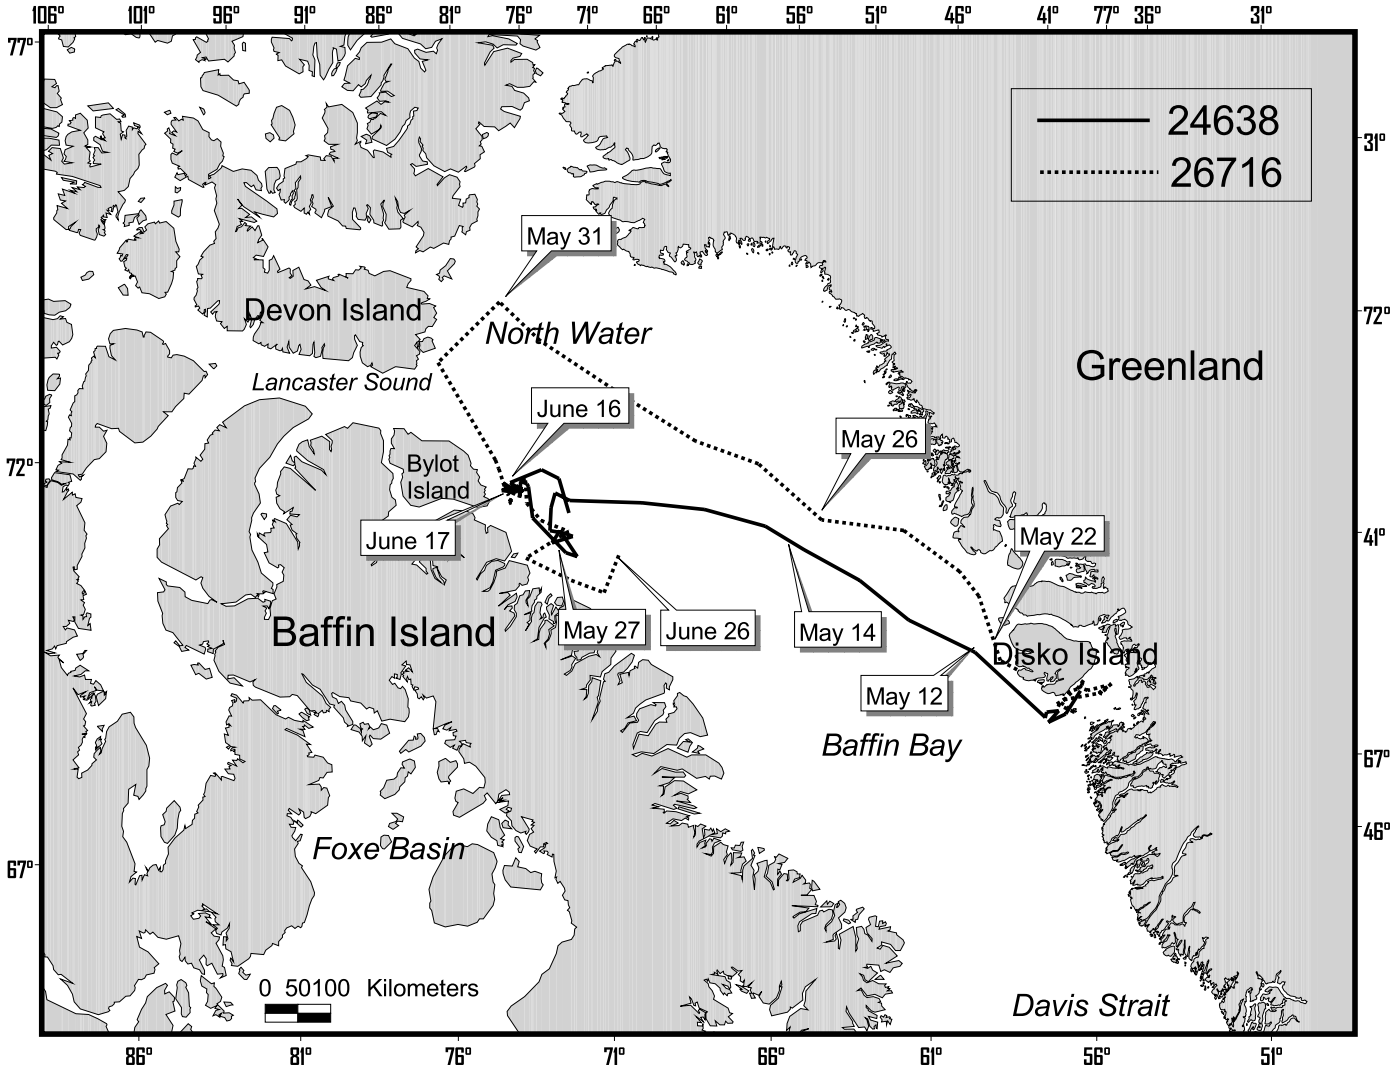

FIG. 2. Movements of two bowhead whales (24638, solid line; 26716, dashed line) from West Greenland to Canada in May–June 2001.

down the long axis. This whale (tagged at 69˚15′N, 53˚30′W) remained in Disko Bay for a longer period than the other whale and departed on 21 May (Fig. 2). It headed farther north closer to the Greenland coast and turned west towards Lancaster Sound at 72˚ N. It passed 73˚ W and reached an area off Devon Island in the central part of the North Water on 30 May, 10 days after departing from Greenland. From here it moved south, across the entrance to Lancaster Sound and frequented the same area as the other whale, an area approximately 100 km southeast of Bylot Island (Fig. 2). It continued moving south and spent approximately three days near Buchan Gulf. It then moved offshore (where there was a five-day period of no transmissions from the tag), and the final position was received on 26 June near the 500 m depth contour off the east coast of Baffin Island. This tag provided the expected 25 000 transmissions before its battery voltage dropped, causing the tag to stop transmitting.

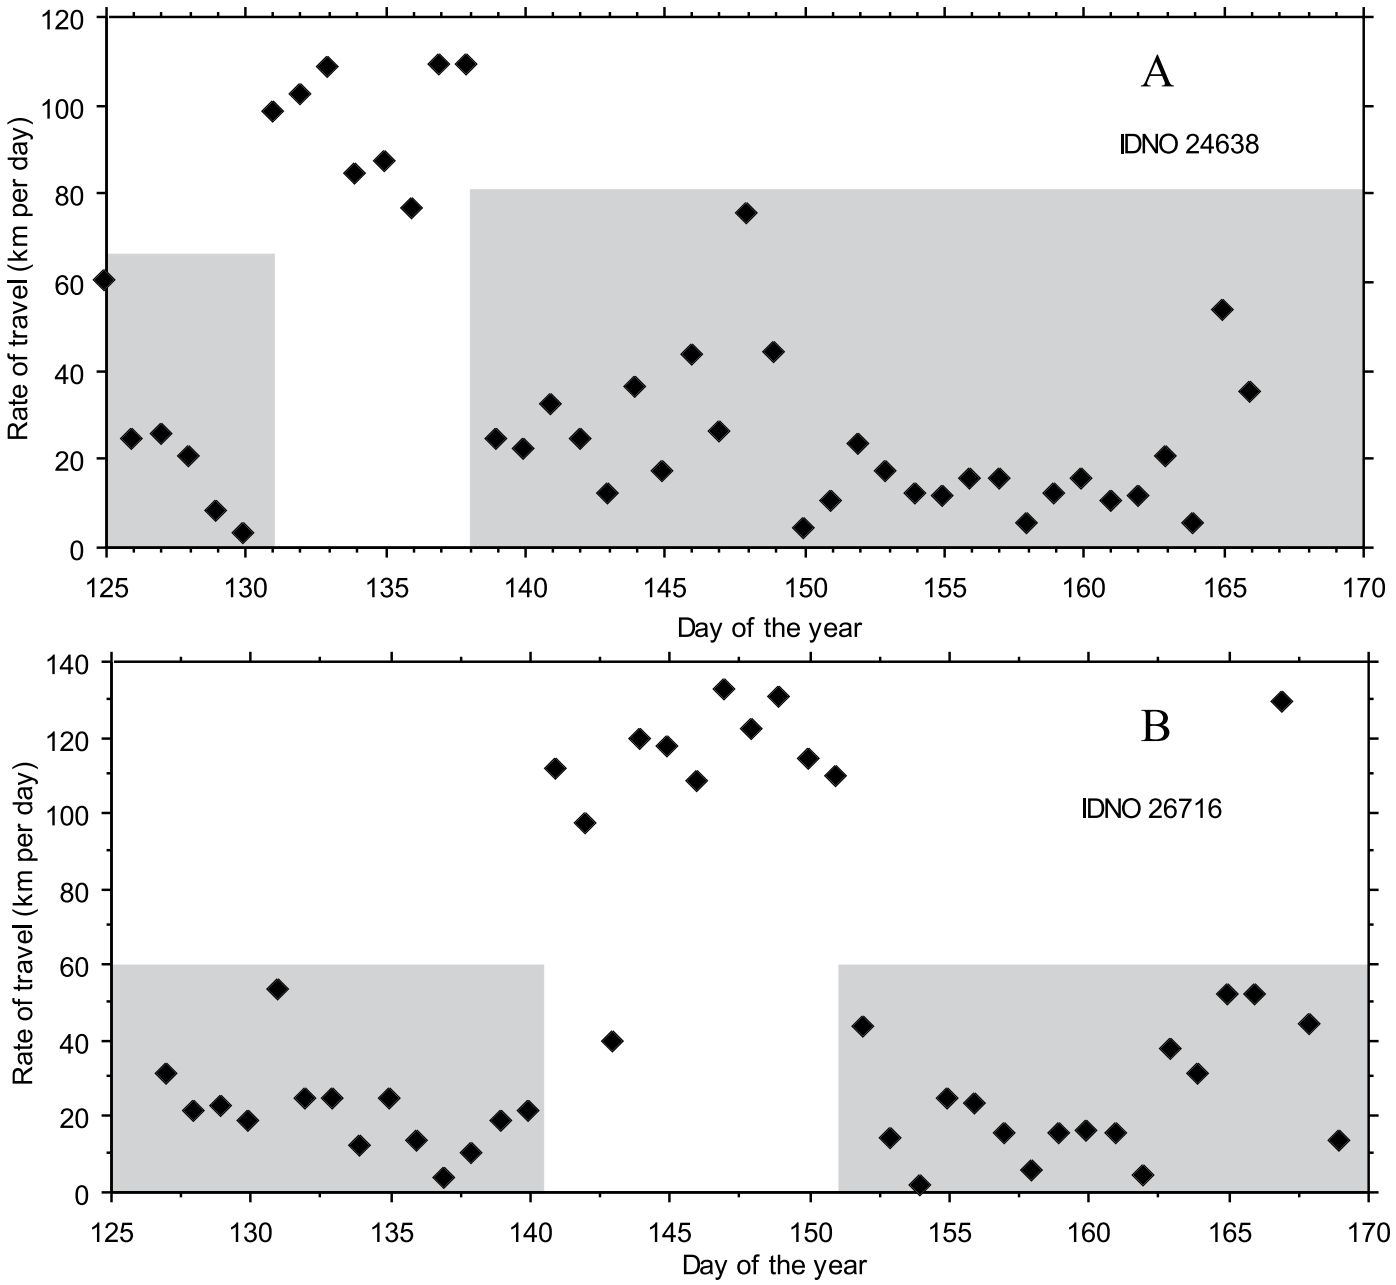

FIG. 3. Graphs of rate of travel (in km per day) relative to Julian day for (a) whale 24638 and (b) whale 26716. The shaded areas represent the whales' presence in Disko Bay after tagging (24638: 5–10 May, 26716: 7–21 May) and in the North Water-Southeast Bylot Island after crossing Baffin Bay (24638: 20–30 May, 26716: 22–30 May). The unshaded area represents the travel period across Baffin Bay (24638: 10–20 May, 26716: 31 May–26 June). Note the increase in travel rate as the whales moved west to Canada and the decrease in travel rate once they arrived in the North Water area.

The two whales were tagged approximately 10 km from each other in Disko Bay, and left Disko Bay 11 days apart. The whales took different routes with different timing across Baffin Bay. On the west side of Baffin Bay, the whales were approximately 350 km from each other on 31 May, with whale 26716 farther north on the east coast of Devon Island and whale 24638 at the southeastern corner of Bylot Island. Sixteen days later, the whales were less than 50 km from each other off the southeastern tip of Bylot Island.

The distance and speeds travelled by the two whales differed for both localized movements (in Disko Bay and the vicinity of Baffin Island) and long-distance travel (across Baffin Bay) (Table 2). Using average positions for each day, whale 24638 travelled a total of 1590 km during a 44-day tracking period, and whale 26716 travelled 2159 km during a 50-day tracking period. Average speed for the entire tracking period was calculated as 1.53 km/hr for whale 24638 and 1.96 km/hr for whale 26716.

Both whales maintained low speeds in Disko Bay and near Baffin Island, but increased their speeds when travelling across Baffin Bay. The rate of travel (based on average positions each day) demonstrated that whale 24638 travelled between 3 and 60 km per day when it was in Disko Bay and the vicinity of Baffin Island (Fig. 3a).

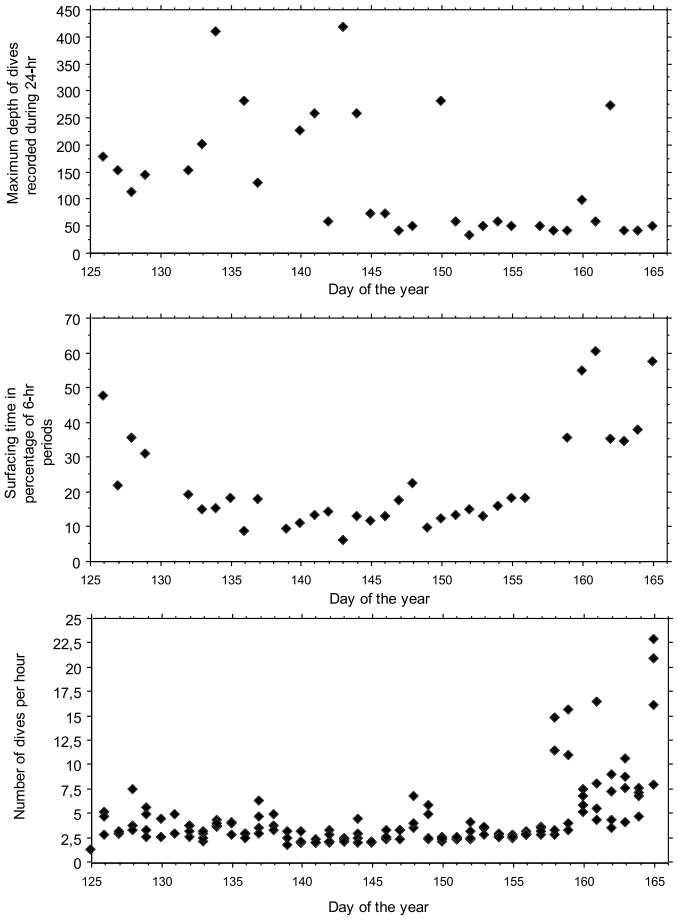

FIG. 4. Maximum daily dive depths (upper panel), surfacing time in percentage of 6-hour periods (middle panel), and dive rate in dives per hour (lower panel) for whale 24638.

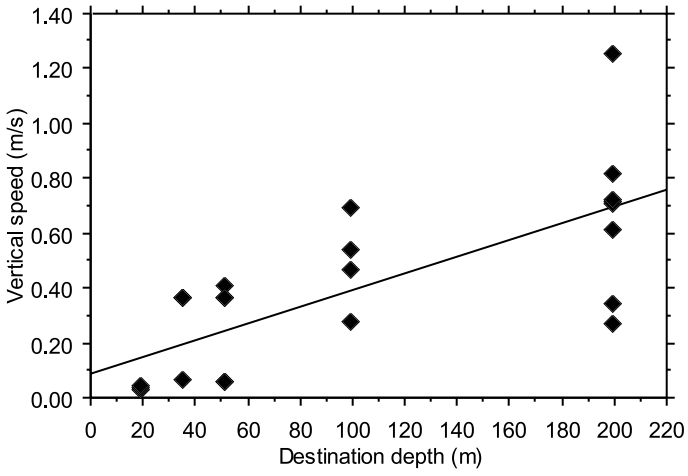

FIG. 5. Vertical speed by destination depth recorded for whale 24638 during the tracking period. The equation for the regression line is $y = 0.087 + 0.003 \times$ ($r^2 = 0.53$).

When the whale was travelling across Baffin Bay, its speed increased to over 100 km per day. Whale 26716 displayed a similar pattern, maintaining low speeds within Disko Bay and the North Water and travelling at higher speeds across Baffin Bay (Fig. 3b).

Diving Behaviour

One whale (24638) provided dive data for the entire tracking period. The mean of the maximum dive depths in Disko Bay (where water depth > 300 m) was 146 m (n = 4). En route to Baffin Island (water depth > 2000 m), maximum dive depths increased to 235 m (n = 7). After the whale arrived at Bylot Island (depth > 500 m), maximum dive depths declined to 155 m (n = 8) and to 67 m (n = 15) after 1 June (Fig. 4). The deepest dive depth recorded during the entire tracking period was 416 m. The dive rate remained relatively constant from the tagging date to 5 June, with a mean of 3.0 dives/hr below 8 m (SD 1.1, range 1.2–7.3). However, after 5 June the dive rate increased to 7.9 dives/hr (SD 5.0, range 2.7–22.8) (see Fig. 4).

Fewer than 15% of the dives were deeper than 152 m. There was a significant shift in the number of dives to all depth categories with time (ANOVA). The number of dives shallower than 36 m increased significantly from May to June, whereas the number of dives to deeper depth categories declined during this period. The steep rise in dive rate (after 5 June) was related to increased diving activity in the 8–20 m depth category, although dives to the depth category between 20–36 m also contributed to the increase. Dives to depths between 100 and 200 m almost ceased after 15 May, with infrequent dives to these depths until 9 June.

Percent of time spent above 20 m was 65% in Disko Bay, 49% while traveling across Baffin Bay, and 54% during the stay off Bylot Island, increasing after 1 June to 81%. The average time spent above 20 m for the entire tracking period was 64%. In all three areas, the whale spent more than 90% of its time above 50 m depths.

In Disko Bay the surfacing time averaged 34% (SD 10.7, n = 4). En route to east Baffin Island this declined to 14% (SD 3.9, n = 9, $p = 0.0004$), and it remained low (13%) after the arrival at the area off Bylot Island (SD 4.4, n = 10, $p = 0.6568$). Surfacing time increased again after 1 June to 33% (SD 16.7, n = 13, $p = 0.0013$) (Fig. 4). The vertical speeds were significantly correlated with the destination depth of the dives and only once exceeded 1 m/s (Fig. 5).

There was no discernible difference between the four six-hour periods in dive rate, duration of dives, time spent at different depths, or the number of dives to different depths (ANOVA). Diurnal patterns of dive activities did not emerge over the two months of data collection (ANCOVA with day as covariate). Most dives lasted less than one minute, and the number of dives decreased as the duration categories increased (Fig. 6). Only 5% of the dives lasted more than 24 minutes.

DISCUSSION

Performance of Tags

Two of the five tags deployed on bowhead whales performed as expected, providing positions for up to 50 days

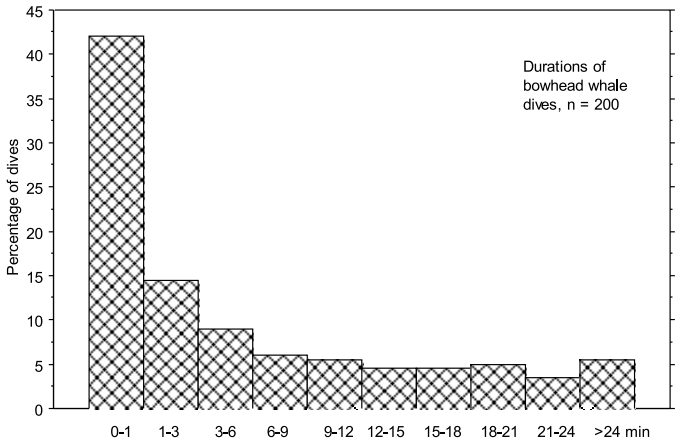

FIG. 6. Percentage of dives in different duration bins for whale 24638.

and ultimately draining their batteries. The reasons that some tags transmit longer than others are unclear. Failure is most likely related to poor implantation of the tag in the blubber, improper placement of the tag on the back of the whale (positioned too low for transmissions), or failure of the satellite tag itself. The tags deployed with the pole performed better than the tags deployed with the pneumatic gun (the 'ARTS'). During the instrumentation, both whales were close to the boats (< 10 m) and moving slowly, which facilitated the use of the pole. The use of the ARTS at short distances may harm the tags because of the impact upon implantation (i.e., the deceleration). The optimal tool for deploying satellite tags on baleen whales may depend on species, distance to the whale, and speed of the whale.

There have been no previous studies of satellite-monitored movements of tagged bowhead whales in Greenland, Baffin Bay, or Canada. In 1992, 12 juvenile (< 13 m body length) bowhead whales were satellite tagged in the Beaufort and Chukchi Seas and tracked for periods ranging from 3.1 to 32.5 days (Mate et al., 2000). The tagging procedure differed from the one reported here: whales were tagged in the open-water season in very shallow water (< 10 m depth) from a large vessel. Tags consisted of a cylinder with two 14 cm stainless steel rods, each with folding toggles, and tags were implanted using a crossbow. The tagging conducted in our study occurred in deep water (200 m) that was partially covered with ice. The whales were pursued from fast boats, and the tags were implanted using a pole. Tags in this study also differed in design, as only one rod was used to anchor the tags deep in blubber. These differences make it difficult to compare the technical performance of the two methods. The longest recorded track in Mate et al. (2000) was from one bowhead whale that moved 3886 km over the course of 33 days, with an overall speed of 5 km/h. The whale rapidly moved west from the Beaufort Sea to the western Chukchi Sea, only occasionally leaving the continental shelf.

In the present study, only whale 24638 provided a large number of good-quality positions (Table 1). Consequently, all position qualities were used, and an average daily position was calculated for both whales with long-term tracking records. A comparison of the trackline created from good-quality positions (LC 0–3) with the trackline created from average daily positions indicated that the poor-quality positions had only marginal influence on the bearing and length of the trackline.

Occurrence in Disko Bay

Eschricht and Reinhardt (1861) collected information on the time of departure (latest observations in spring) of bowhead whales from Qeqertarsuaq from 1780 to 1837. Their mean date for the last observations of whales in the Disko Bay area was 1 June, with a range from 26 April to 25 June. The two whales that were tracked in the present study left Disko Bay in mid-May, approximately 11 days apart. Information collected from local hunters before and after the field season confirmed that bowheads were present in the area at least from mid-April through 20 May. It appears that bowhead whales in Disko Bay may still maintain their historical patterns of distribution and movement, in spite of the severe reduction in numbers.

Bowhead whales feed on crustacean zooplankton, primarily large copepods of the genus *Calanus* and euphausiids (Brown, 1868; Lowry, 1993). In spring, the largest concentrations of copepods in Disko Bay are found in the upper 50 m of the water column (Madsen et al., 2001). The observed diving behaviour of the bowhead whale in Disko Bay and along the east coast of Baffin Island is consistent with preying on copepods in the upper part of the water column because the whale spent over 90% of its time above 50 m (water depth > 300 m in both areas). The biomass of copepods is known to reach a peak in Disko Bay in early June, when values of more than 100 mg C m^{-3} have been measured (Madsen et al., 2001). In the upper 50 m of the water column, 90% of this biomass estimate was composed of three *Calanus* species, *C. finmarchicus*, *C. glacialis* and *C. hyperboreus*. The bowhead whales tracked in this study apparently left the Disko Bay area prior to the peak availability of their preferred food species. Bowhead whales in Alaska have been reported to display similar behaviour, leaving the productive Bering Sea each year just before the spring bloom of copepods and migrating 3000 km to the less productive Beaufort Sea (Lowry, 1993). It is unclear why the bowhead whales leave Disko Bay and move to the North Water before the peak of the *Calanus* production in West Greenland.

Baffin Bay

This study demonstrates that bowhead whales are capable of navigating through the heavy pack ice in central Baffin Bay. Most likely the whales move north along the West Greenland coast until they find a suitable lead in the pack ice. These leads are known to intersect Baffin Bay from northwest to southeast (Environment Canada, 1990–2000). If whales find a lead heading northwest, they may

be able to cross from Disko Bay to Lancaster Sound in a short time. Once whales cross the Baffin Bay pack ice, they can expect to find open water in the North Water polynya. It could not be determined which lead (or series of leads) the whales chose for moving across Baffin Bay. There were, however, areas of open water used by the whales at both ends of their movements, in Disko Bay and northeast of Baffin Island. The rate of travel did not appear to indicate that the bowhead whales were feeding in the ice-covered areas in Baffin Bay. While crossing Baffin Bay, the daily maximum dive depth for whale 24638 increased to an average of 235 m. While the dive rate remained constant (3 dives/hr), the surfacing time declined to approximately 14%. The increase observed in maximum dive depths is possibly related to navigation in the dense pack ice (i.e., using deeper depths to localize spots with open water) or low-frequency communication with other whales (low-frequency sounds are known to travel longer distances at deeper depths). Bowhead whales travelling under the ice may spend more time at deeper depths to avoid interacting with the ice (Krutzikowsky and Mate, 2000). The decrease in surfacing time indicates that the whale spent more time in water deeper than 8 m, in the layer between 8 and 50 m.

Average speeds for the two whales were similar for the course of the tracking period. Total distance was slightly lower for whale 24638 than for whale 26716. Whale 24638 may have taken a more direct course across Baffin Bay, which may have been related to available openings in the sea ice. One would assume that a whale would take the shortest distance between two feeding grounds for energetic reasons. Whale 26716, which took the longer route across Baffin Bay, had a higher average total speed than whale 24638 (1.96 km/h vs. 1.53 km/h), as well as a higher speed crossing Baffin Bay (4.53 km/h vs. 3.11 km/h).

The rapid rate of travel for both whales across the Baffin Bay pack ice does not agree with reports that bowhead whales occur in winter in central Davis Strait and southern Baffin Bay (see Brown, 1868; Southwell, 1898; Finley, 1990, 2001). Aerial surveys conducted in March 1981 and 1982 covered Davis Strait and most of Baffin Bay, but encountered bowheads only in the coastal areas off West Greenland and East Baffin Island (McLaren and Davis, 1981, 1983). Most likely bowhead whales occur in seasonal aggregations in coastal areas and traverse offshore areas only when moving/migrating to other concentration areas.

Occurrence in the North Water

Davis and Koski (1980), who surveyed the waters off northwest Baffin Island in spring 1976 and 1978, reported that bowhead whales first arrived at the eastern entrance to Lancaster Sound around 8–11 May. The migration from offshore areas towards Lancaster Sound lasted through 8 August and apparently peaked during 19–30 June in both years. The timing of the arrival of the two whales from Disko Bay seems to coincide well with these observations. In addition, Holst and Stirling (1999) reported 14 sightings of bowhead whales in the North Water, east of Devon Island, between 4 May and 13 June 1998, which coincides with the period when the whales from the present study were in this same area. The North Water polynya is known to be a highly productive area; it is capable of supporting a high degree of primary and secondary production early in the season and, consequently, a high abundance of marine mammals and sea birds (Stirling, 1997). It seems likely that the bowhead whales using the southern part of the North Water in spring are indeed whales from Disko Bay, as also proposed by Holst and Stirling (1999). This implies that the bowhead whales move quickly from one productive area (Disko Bay) to another highly productive area (the North Water) and take advantage of the early productivity blooms in the North Water polynya.

The whales' rapid transit across Baffin Bay makes it unlikely that they were feeding in the pack ice. However, it appears they may be feeding in the North Water polynya, since travel rate decreased and movements became more localized once they arrived there (Table 2, Figs. 4 and 5). Detailed quantitative information on copepod abundance in eastern Lancaster Sound in spring is not available. However, presumably the North Water polynya provides a spring bloom of copepods that is comparable to what is found in Disko Bay. After 1 June, when whale 24638 arrived in the North Water area, daily maximum dive depths decreased (to 67 m), surfacing time increased (to > 80%), and dive rate increased (to 7.9 dives/hr), behavioural changes that may indicate increased feeding. Sampling in eastern Lancaster Sound in July through October 1978 showed that copepods were most abundant between 0 and 50 m depth and declined with increasing depth (Buchanan and Sekerak, 1982). In August 1980, zooplankton were vertically distributed, with peak abundance just below the surface (< 5 m) and a higher abundance at 50–70 m depths in eastern Lancaster Sound (Longhurst et al., 1984). Copepods of the *Calanus* species were the most abundant zooplankton species in both studies.

Dive Behaviour

Krutzikowsky and Mate (2000) reported several dives of bowhead whales in the Beaufort and Chukchi Seas that lasted over 20 minutes, with few lasting more than 60 minutes. The maximum depth of the dives recorded for bowhead whales in Alaska was 352 m. Most dives went to depths above 100 m and most time was spent above 16 m. Despite their differences in bathymetry and seasonality, the two studies showed remarkably similar diving characteristics. The vertical speeds observed for the bowhead whale in this study were significantly lower than those reported for fin whales (*Balaenoptera physalus*) and blue whales (*Balaenoptera musculus*) (Croll et al., 2001).

Plasticity of Movement Patterns

Our observations of the dispersed distribution, solitary occurrence, and presumed solitary migration routes of whales from Disko Bay seem to confirm the reported solitary habits of bowhead whales in West Greenland during this period (cf. Reeves and Heide-Jørgensen, 1996; Heide-Jørgensen and Acquarone, 2002). However, despite the observations of solitary whales (which may be an effect of the past overexploitation of the stock), the whales may still maintain acoustic contact over large distances. The two other High Arctic cetaceans, the narwhal (*Monodon monoceros*) and the beluga, migrate to and from summer and wintering grounds in pods along specific corridors (Dietz et al., 2001; Richard et al., 2001; Heide-Jørgensen et al., 2002). The different routes chosen by the two bowhead whales, as well as the information on the phenology of their occurrence in West Greenland (i.e., variations in departure dates, Eschricht and Reinhardt, 1861) and the North Water (i.e., widespread solitary occurrence, Davis and Koski, 1980; Holst and Stirling, 1999), indicate that bowhead whales may have more plasticity in their migratory patterns than the two other Arctic cetaceans. This would increase the opportunities for widespread genetic exchange and may explain the relatively large genetic diversity among bowhead whales (Maiers et al., 1999). Of the three High Arctic cetaceans, narwhals show the lowest level of genetic diversity (Palsbøll et al., 1997) and the most restricted range of movements (cf. Dietz et al., 2001). Belugas fall between bowhead whales and narwhals in genetic variability (de March et al., 2002; Palsbøll et al., 2002), possibly reflecting their preference for open-water areas (the North Water and West Greenland), where they can sustain a wider range of movements (cf. Richard et al., 2001).

Evidently bowhead whales are dependent on the success of the marine production in focal areas of the North Water and Disko Bay. Although bowheads display characteristics that make them appear flexible in their choice of migratory corridors and the timing of migrations, climatic change could change the nature of the ice, ultimately affecting the distribution and characteristics of leads and polynyas. Reduced ice coverage in one or both of these areas may enhance plankton production and feeding opportunities of bowhead whales. However, the timing of the peak production will determine whether they can take advantage of that productivity.

Implications for Stock Identification

This study confirms the connection between bowhead whales in West Greenland and the east coast of Baffin Island. It appears the movements from one area to the other are accomplished over short time periods, without major stops en route, as proposed earlier by Eschricht and Reinhardt (1861), who based their conclusion on information from whalers that pursued bowheads during their spring migration to Baffin Bay (cf. Southwell, 1898). Prior to this study, the connection between bowheads in eastern Canada and West Greenland was established solely by a single whale photographed in Canada (NE Baffin Island) in late September and re-identified in Greenland in early April four years later (Heide-Jørgensen and Finley, 1991). The relationship between the bowhead whales found near the entrance to Lancaster Sound and those found in summer and autumn farther west in Lancaster Sound and tributaries remains unresolved. Bowhead whales in the eastern part of Lancaster Sound most likely come from Baffin Bay, as suggested by Eschricht and Reinhardt (1861) and by Davis and Koski (1980). However, the bowhead whales found in western Lancaster Sound and tributaries in summer may come either from the east coast of Baffin Island (from Disko Bay) or from Hudson Bay (through Fury and Hecla Strait). Clearly, more data and larger sample sizes are needed to identify the stocks of bowheads found in Canada in summer. Satellite tracking has proved to be a promising tool for studying stock identity and elucidating important information on movement patterns and habitat use of a species.

ACKNOWLEDGEMENTS

We wish to thank Kale Mølgård, Abel Brandt, Kaleeraq Heilmann, Søren Karl Broberg, and Frederik Broberg for their excellent help during the search, pursuit, and tagging of the bowhead whales. The board of the Arctic Station, University of Copenhagen, is acknowledged for providing the facilities at Arctic Station, including the research vessel *Porsild*. This study was funded by the Commission for Scientific Research in Greenland, the Greenland Institute of Natural Resources, the Carlsbergfondet (990379/40), and the Department of Fisheries and Oceans, Canada. This manuscript was improved by comments from Chris Clark and two anonymous reviewers.

Abstract

A model of the metapopulation structure of narwhals *Monodon monoceros* in Baffin Bay, Hudson Bay and adjacent waters is proposed based on satellite telemetry data collected over two decades from six coastal aggregations of narwhals in the eastern Canadian high Arctic, Hudson Bay and West Greenland. In addition, data on seasonal catches of narwhals in 11 Inuit communities are used to provide information on the occurrence of narwhals. The tracking data suggest that disjunct summer aggregations of narwhals are, to some extent, demographically independent subpopulations, with minimal or no exchange with other summering aggregations. We propose that these should be considered separate stocks for management purposes. Year-round satellite tracking of individuals demonstrates that whales return to the same summering areas the following year, suggesting inter-annual site fidelity. We propose that the narwhals in Canada constitute five separate stocks, with limited exchange between three of the stocks. Coastal summer aggregations in Greenland constitute two stocks in addition to two fall and winter aggregations supplied by narwhals from several summering areas. Several narwhal stocks mix on the wintering areas in Baffin Bay, but the metapopulation structure is likely maintained through a combination of life-history traits and migratory routes, as mating most likely occurs after the initiation of the return migration toward summering areas. The metapopulation structure in Baffin Bay narwhals will be impacted differentially by Inuit subsistence hunting, depending on the migratory schedule of narwhals and dates at which whales occur in different seasonal hunting areas. It is therefore important to identify which narwhal stocks contribute to which subsistence hunts in order to assess the sustainability of those hunts. This paper proposes a preliminary stock model for this purpose.

Introduction

Understanding population structure of a species is vital for the conservation and management of factors affecting its demography. This is particularly important in the case of species hunted for subsistence, such as the narwhal *Monodon monoceros*. Metapopulation theory was developed to study population structure and demography of spatially segregated populations of a single species (Levins, 1970; Hanski & Gilpin, 1991). In essence, a metapopulation is a 'population of populations' (Levins, 1970) or a collection of spatially separated subpopulations that have a degree of demographic independence but also some degree of exchange of animals. A species with metapopulation structure may therefore exhibit dynamics that are different from the dynamics of a collection of completely isolated populations or a single extensively mixed (panmictic) population.

The narwhal is an ice-associated cetacean that inhabits Arctic seas bordering the Atlantic Ocean. During summer, narwhals visit inshore bays and fjords in the Canadian Arctic archipelago and Greenland (Fig. 1). In the autumn, upon the formation of fast ice, narwhals are forced to move east and south and spend the winter in ice-covered areas where they are widely dispersed in Baffin Bay and Davis Strait with the highest aggregations between 55–64°W and 68–71°N and off Disko Bay (Heide-Jørgensen *et al*., 1993, 2002, 2003; Koski & Davis, 1994; Dietz & Heide-Jørgensen, 1995; Dietz *et al*., 2001; Heide-Jørgensen & Acquarone,

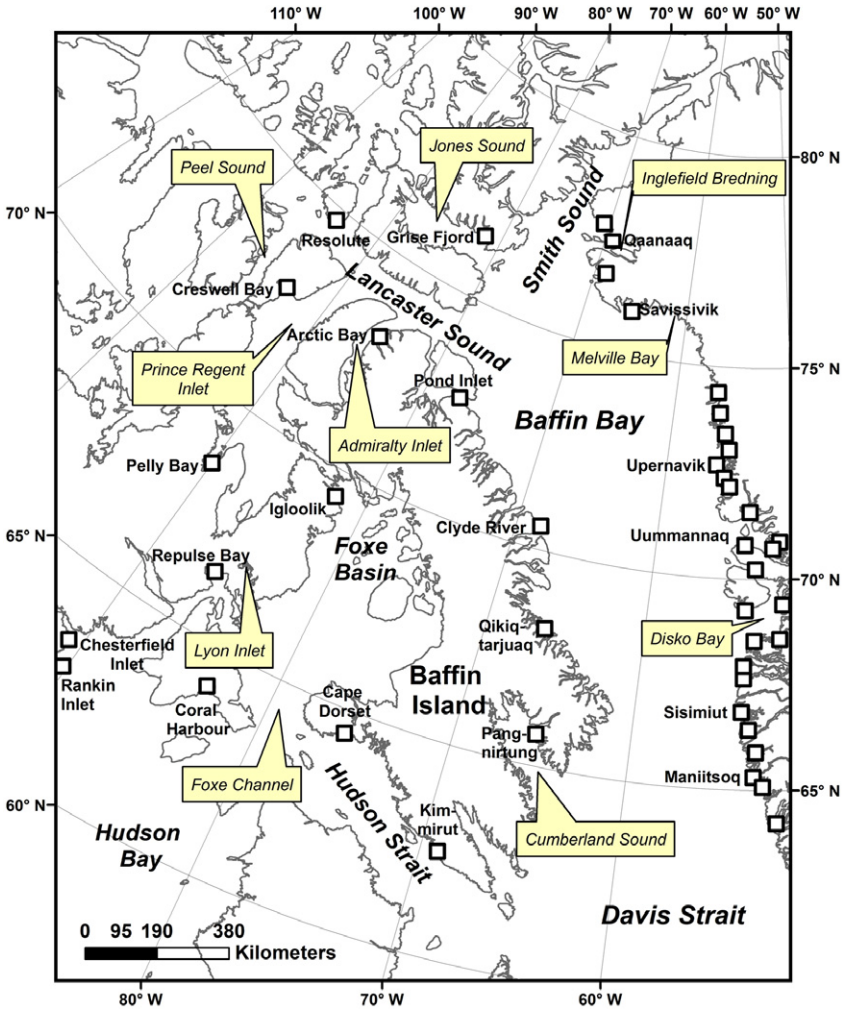

Figure 1 Map of Nunavut and West Greenland with localities, towns and settlements where narwhal *Monodon monoceros* hunting occur indicated. The four towns in Disko Bay where narwhal hunting occurs are Qeqertarsuaq, Ilulissat, Qasigiannguit and Aasiaat.

2002). During spring, aggregations of narwhals are seen along ice edges on the east coast of Baffin Island, at the entrances of Lancaster and Jones Sound, and in Smith Sound (e.g. Bradstreet and Cross, 1982). Narwhals are also known to move along the ice edges along West Greenland and to aggregate in the North Water in spring before entering Inglefield Bredning (Heide-Jørgensen, 2004). Narwhals spend the summer in bays and fiords of north-west Greenland, Hudson Bay and the north-eastern Canadian archipelago (Richard, 1991; Heide-Jørgensen *et al.*, 2010; Richard *et al.*, 2010).

Narwhals in Baffin Bay and adjacent waters are an example of a migratory species, where different stocks are hunted over varying temporal and spatial scales. Narwhals are hunted during both their northbound spring and southbound autumn migrations and during their stay at summering or wintering areas. In addition to summer stocks, there are also segments of the population that are observed as 'aggregations' outside the summer season. Following this, the total allowable narwhal catch should be allocated to individual whaling areas based on the information on the distribution and movement patterns of each stock, reducing the risk of local overexploitation. Allocation of allowable catches to aggregations or stocks can only safely be performed when the relationship between catches and stocks of known abundance has been established. Persistence and integrity of subpopulations rely on reproductive isolation of subpopulations maintained by strong philopatry, that is, seasonal homing to specific habitats.

Metapopulation theory has largely been applied to non-migratory species, where subpopulations are defined geographically. Nevertheless, the theory offers a valuable conceptual framework for migratory species as well (Esler, 2000). In this paper, we present evidence for the metapopulation structure of narwhals in the Canadian Arctic and West Greenland. We propose the distinction of a number of subpopulations or 'stocks' of narwhals to be used for conservation and subsistence hunt management. We also discuss spatial, temporal, genetic and behavioral factors that affect the demographic independence of narwhal subpopulations throughout the year.

Material and methods

Temporal and spatial distribution of the hunt for narwhals in Canada and West Greenland

Data on the seasonal occurrence of the narwhal subsistence hunt in Canada for the period 1979–2002 and for Greenland during 1993–1999 were extracted from Romberg & Richard (2005) and Piniarneq (1993–1999), respectively. Catch data before the installation of quotas were chosen because they show a better picture of the seasonality of both catches and occurrence of narwhals at the hunting localities. In the more recent catch data, the catches are stopped before the whales leave the hunting areas.

Historical data on satellite tracking of narwhals 1993–2004

Satellite-tagging studies of narwhals were initiated in 1993 to determine the movement patterns and migratory routes of narwhals in Canada and Greenland (Dietz & Heide-Jørgensen, 1995; Dietz *et al.*, 2001). In 1993 and 1994, nine whales from Melville Bay, West Greenland (Fig. 1), were tracked from late August to early December. Between 1997 and 1999, 17 narwhals were tracked from Eclipse Sound, Canada (Dietz *et al.*, 2001; Heide-Jørgensen *et al.*, 2002). In 2000 and 2001, 16 narwhals were tagged in Creswell Bay (Prince Regent Inlet), on the coast of Somerset Island, Canada (Heide-Jørgensen *et al.*, 2003). In August 2003–2004, 20 narwhals were tagged in Admiralty Inlet, the third summering aggregation in the Canadian high Arctic (Dietz *et al.*, 2008). These data were analyzed and published in several papers between 1995 and 2009 and provided background on the movements of narwhals from four of their largest summering areas.

Satellite tracking data from narwhals 2005–2009

An additional 22 narwhals were captured and instrumented with satellite-linked transmitters in Admiralty Inlet, Canada, August 2005 ($n = 14$) and 2009 ($n = 8$) as well as five in the Eclipse Sound area in 2010 (Table 1), following methods similar to previous live captures in the Inlet (Heide-Jørgensen *et al.*, 2002; Dietz *et al.*, 2008). Seven narwhals were instrumented at Fisher Islands (7606.965°N, 6142.453°W) Melville Bay, West Greenland in September 2006 and 2007, supplementing the tagging information from the area from 1993 to 1994 (Dietz & Heide-Jørgensen, 1995). Two narwhals were instrumented in Uummannaq in November 2007 and 2008 (Table 1) using nets set at the promontory of Niaqornat (7047.600°N, 5338.600°W). A total of nine narwhals were tagged over 2 years in Repulse Bay and Lyon Inlet using set nets in the same way as the other tagging projects above (Westdal, Richard & Orr, 2010).

The amount and quality of location data obtained from the satellite telemetry studies varied during the studies because of improvements in satellites' transmitter functionality and attachments over time, but also because of improved performance of the Argos Data Collection and Location System. Here, we only use good quality positions, that is, location class 1, 2 and 3 with estimated precision of < 500 m.

Results

Timing, locations and magnitude of the hunting of narwhals

Hunting along the east coast of Baffin Island (Qikiqtarjuaq and Clyde River) occurs between July and October [annual average of catches (AAC) 1996–2000: 18], except for the community of Pangnirtung (AAC = 23), which has an extended hunting period ranging from March to November (Fig. 2; Ditz, 2001). The majority of the Pond Inlet (AAC = 116) hunt occurs between May and September. The hunt in Arctic Bay (AAC = 99) is shorter, taking place between June and September, and the hunt at Somerset Island takes place in July–August (Resolute and Creswell Bay; AAC = 6). The hunt in Grise Fjord (AAC = 7) takes place between July and September. Catches in Pelly Bay, Igloolik and Hall Beach are low (AAC = 11).

Catches in Hudson Bay were taken in Chesterfield Inlet, Coral Harbour, Rankin Inlet and Repulse Bay. Most catches in Hudson Bay were taken by Repulse Bay in July–August. Only 2% ($n = 347$) were taken in June or September.

In West Greenland, catches reported from Sisimiut and south (AAC 1993–1998: 40; Figs 1 and 2) include whales taken further north. Hunting in Disko Bay (AAC = 154) takes place from late autumn throughout the winter and peaks in spring (April–May). The hunting in Uummannaq (AAC = 315) takes place in October–December, with lower catches during winter and spring. Hunting statistics identify that the largest catch in Upernavik (AAC = 81) takes place between August and November. Hunters from Qaanaaq sometimes see narwhals in the Smith Sound area in winter and spring (January–June); however, most hunting takes place between May and September with peaks in July–August (AAC = 106).

Results of narwhal tracking studies in the eastern Canadian Arctic and West Greenland

Satellite tracking data from 107 individual narwhals from six different coastal localities in Arctic Canada (Somerset Island, Admiralty Inlet, Eclipse Sound and North Hudson Bay) and West Greenland (Melville Bay and Uummannaq) were available for this analysis (Figs 3–8).

Somerset Island

For management purposes, we refer to narwhals occupying that area as the 'Somerset Island stock'. Narwhals tagged on

the east coast of Somerset Island in August ranged over waters on both sides of Somerset Island, including Prince Regent Inlet, Peel Sound and adjacent waters (Heide-Jørgensen *et al.*, 2003; Dietz *et al.*, 2008; magenta lines in Fig. 3). In September and October, the Somerset Island stock of narwhals were tracked leaving Peel Sound and Prince Regent Inlet and moving east along the southern and the northern coast of Lancaster Sound. The whales moved further east across Baffin Bay to the western side of the deep basin toward West Greenland and continued south to a wintering area centered at 71°N and 62°W where they remained stationary through March, after which the whales still transmitting ($n = 2$) began a return migration through Lancaster Sound along the southern shoreline of Devon to the Somerset Island summering area (Heide-Jørgensen *et al.*, 2003; Dietz *et al.*, 2008).

Admiralty Inlet

We refer to narwhals in Admiralty Inlet during summer as the 'Admiralty Inlet stock' (black lines in Fig. 3). Tracking studies of narwhals from Admiralty Inlet in 2003–2004

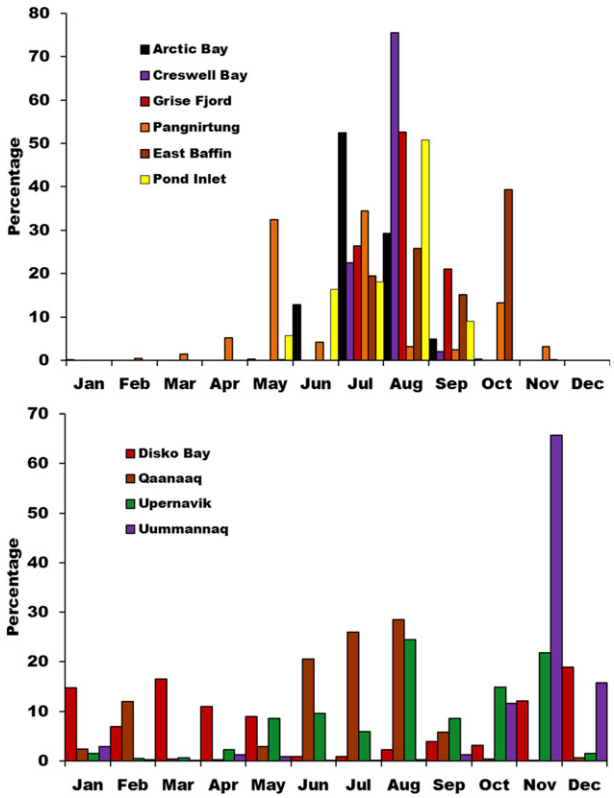

Figure 2 Upper panel: the five primary hunting areas in the Canadian high Arctic and the distribution of catches by month ($n = 2890$). Catches in Pangnirtung are considered part of East Baffin Island catches. Lower panel: the four primary hunting areas in West Greenland and the distribution of catches by month ($n = 4877$). The area from Sisimiut and south is considered mainly to consist of catches in the Disko Bay area because the hunters in this area are highly mobile and narwhals *Monodon monoceros* are rare in the area south of Disko Bay (Sources: Department of Fisheries and Oceans for Canada for the period 1979–2002 and *Piniarneq* for 1993–1999; Greenland Home Rule, http://www.nanoq.gl).

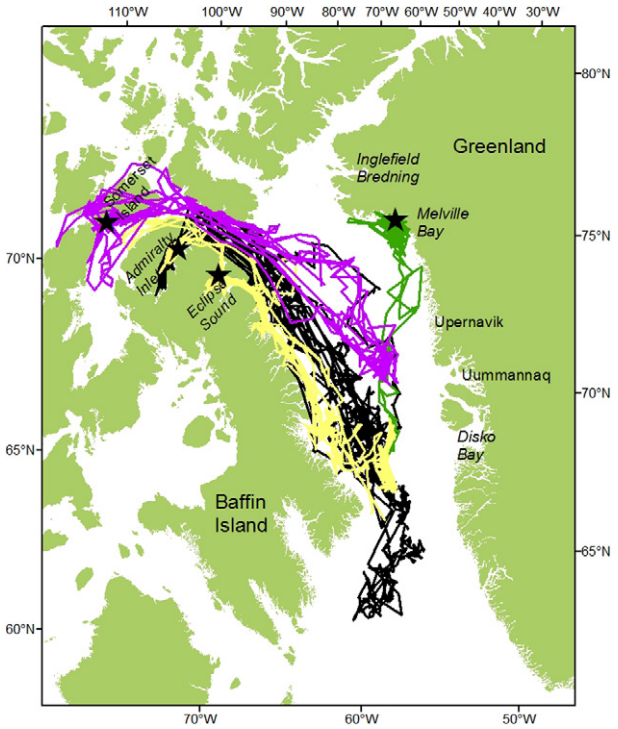

Figure 3 Tracklines of narwhals *Monodon monoceros* tagged from 1993 to 2004 (after Dietz et al., 2008). The black stars indicate the tagging positions.

showed that the whales remained in the Inlet for the summer through August and early September. However, in 2005, one Admiralty Inlet whale visited Prince Regent Inlet ('Somerset Island stock') in early September before heading east with the other whales from Admiralty Inlet (Fig. 4). This was also observed in 2009, where five out of seven tracked whales went to Prince Regent Inlet between early to mid-September before heading east (Fig. 5). Except for one whale that moved through the Furry and Hecla Strait into Foxe Basin in November (and remained there throughout the winter), all other whales from the Admiralty Inlet stock moved eastward through Lancaster Sound in late September, and southward along the east coast of Baffin Island. They eventually terminated their migration offshore in the northern part of Davis Strait. One male moved to the coastal areas close to Disko Island and Uummannaq in West Greenland during the month of January 2006 (Fig. 4).

Eclipse Sound

The geographic range of narwhals from Eclipse Sound did not generally overlap with that of narwhals from other aggregations during August and they are therefore referred to as the 'Eclipse Sound stock' (yellow lines in Figs 3 and 6). One exception to this was, in 1999, three tagged whales from Eclipse Sound moved to Admiralty Inlet and Prince Regent Inlet before returning east toward Baffin Bay (Dietz *et al.*, 2001; Heide-Jørgensen *et al.*, 2002). In late September, tagged narwhals from Eclipse Sound began to depart on their autumn migration. They moved south along the east coast of Baffin Island and visited several of the fjords along the way. In November, several of these whales moved into a wintering area in central Davis Strait (yellow tracks in Fig. 3), whereas others (Fig. 6) continued south toward southern Davis Strait. Two whales entered Cumberland Sound in late fall, and of them, a male crossed Davis Strait and entered Disko Bay in December 2010. Most narwhals from Eclipse Sound wintered in central Baffin Bay, roughly between 69°N and 60°W in the same area as narwhals tracked from Melville Bay, but some chose a more southern wintering area in northern Davis Strait (Figs 3 and 6).

Northern Hudson Bay

Narwhals tagged in northern Hudson Bay in 2005 and 2006 remained in the area between Repulse Bay, Lyon Inlet and western Foxe Channel until the end of October, at which

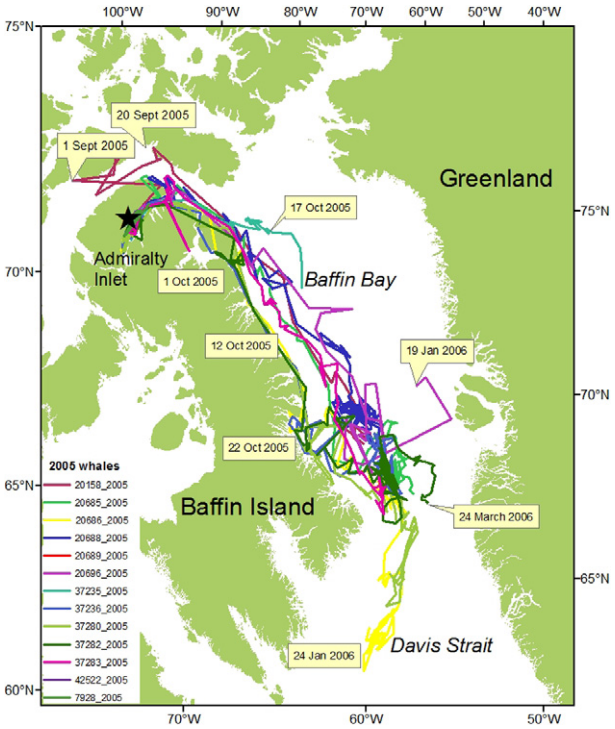

Figure 4 Tracklines of 14 narwhals *Monodon monoceros* tagged in Admiralty Inlet in 2005 (data from this study). The black star indicates the tagging positions.

time they started moving eastward toward Hudson Strait (Westdal, 2008; Westdal *et al.*, 2010; Fig. 7). They transited through Hudson Strait during the months of November and early December. Four animals were tracked throughout the winter months east of Hudson Strait. Two of them transmitted long enough to be tracked returning westward into Hudson Strait in June, which suggests that they were on their way back to their previous year's summering range in northern Hudson Bay. The narwhals that summer in northern Hudson Bay and winter off Hudson Strait do not seem to be overlapping year-round with any of the other stocks. They are referred to as the 'Hudson Bay stock'.

Melville Bay

Narwhals tracked from Melville Bay in 1993, 1994, 2006 and 2007 spent the summer in that bay without visiting other areas with narwhal summer aggregations and we refer to these animals as the 'Melville Bay stock' (Figs 3 and 8). Their fall migration began in October, when some individuals took a southern route along the 1000-m depth contour, while the others moved south but remained closer to land. Most of them arrived in central Davis Strait in mid-November where they presumably spent the winter. One of them left the wintering area late December 2006 and moved to the south end of Disko Bay where it stayed until 13 January 2007 before returning to the central Davis Strait wintering area.

Uummannaq

A male narwhal tagged in November 2007 spent the entire winter inside Uummannaq Fjord or just outside the Uummannaq area after in late January (Fig. 6). On 13 March 2008, it headed north (< 72°N) along the West Greenland coast, but contact was lost on 4 April 2008. A 2008 female also tagged in November immediately left Uummannaq Fjord after tagging and spent December through mid-February 2009 off the banks west of Disko Island (Fig. 6). On 24 March, it started moving north along West Greenland reaching northern Baffin Bay in early April where it remained through May. In late May, it migrated westward, moved through Lancaster Sound and ended in Peel Sound where contact was lost on 24 July. Based on the track of this narwhal, it is reasonable to assume that some narwhals from the Uummannaq fall aggregation belong to the Somerset Island stock.

Evidence for inter-annual site fidelity

Eight satellite-linked tags on narwhals transmitted for a full year, allowing for the assessment of inter-annual site fidelity to be based on individuals that returned in spring to the summering area where they were tagged the previous year (Table 2). At least six of the eight whales re-entered the area where they were tagged the previous year. The two other whales were close to (and heading toward) the summering

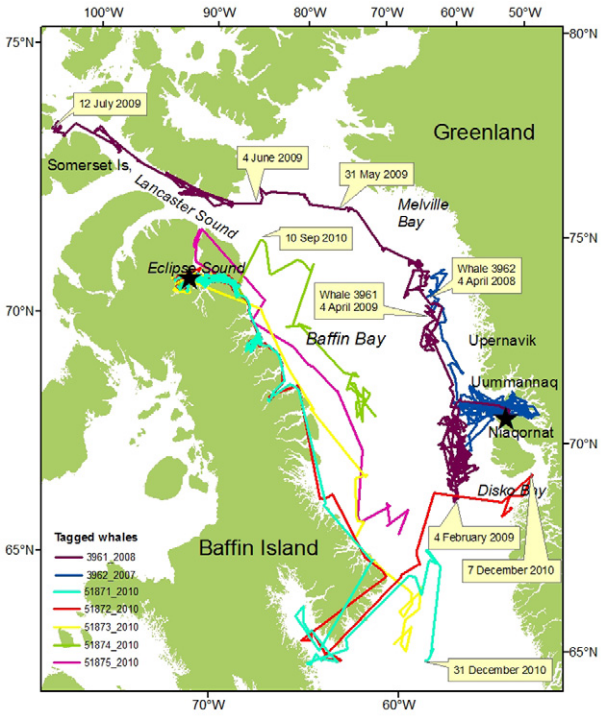

Figure 6 Tracklines of five narwhals *Monodon monoceros* tagged in Eclipse Sound in August 2010 and of two narwhals tagged in Uummannaq: one in November 2007 (blue) in November 2008 (purple). The black stars indicate the tagging positions.

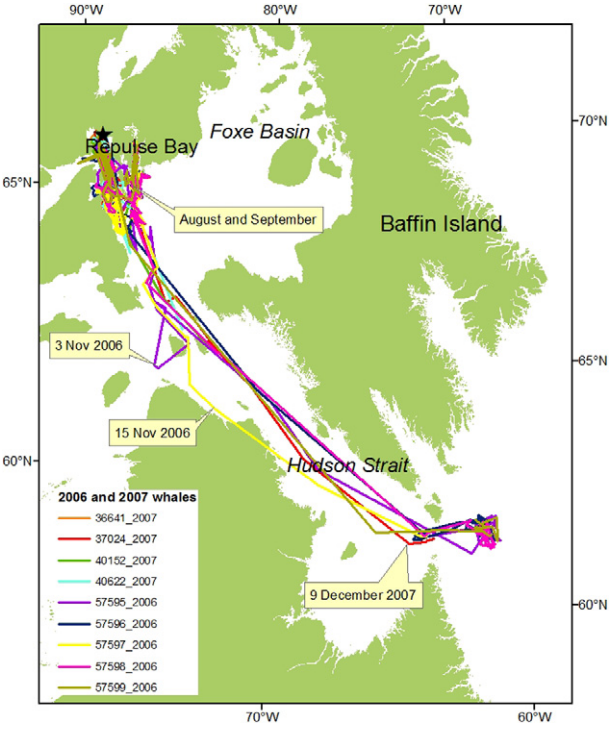

Figure 7 Tracklines of nine narwhals *Monodon monoceros* tagged in Northern Hudson Bay in 2006 and 2007 (data from this study). The black star indicates the tagging positions.

area where they were tagged, but contact with the transmitter was lost before they were inside the summering ground range.

Proposed relationship between summering area and subsistence harvest

The proposed metapopulation structure of the narwhal population in Baffin Bay and adjacent waters (Fig. 9) has important implications for the management of narwhal hunting in Canadian and West Greenland communities (Fig. 10). Occurrence in summering areas defines the stock unit, and the utilization of the narwhals in each stock must be balanced against the productivity of those local summer stocks and their exposure to hunting in other seasons and areas (Table 3). At least two additional putative stocks for the areas of 'East Baffin Island' (east of Pond Inlet to Cumberland Sound) and 'the North Water' (i.e. Smith Sound, Jones Sound and Inglefield Bredning) that have not been studied by satellite-linked tracking need to be considered as well. Three of the hunting communities (Grise Fjord, Qaanaaq, Arctic Bay and Creswell Bay/Resolute) rely on summer catches of these narwhals when their local subpopulations (stocks) are present in the area. However, when narwhals depart from the summering areas, they are exploited in other communities that only have narwhal subsistence harvests during winter months (e.g. Uummannaq and Disko Bay) or communities that hunt them during the fall and spring migrations (e.g. East Baffin Island). In several cases, the hunt outside the summering areas constitutes a mix of whales from different stocks (e.g. Melville Bay, Somerset Island and Eclipse Sound narwhals in Disko Bay, Admiralty Inlet, Eclipse Sound along East Baffin Island); in other situations, the migrations are unknown (e.g. Qaanaaq and East Baffin stocks), and in one case, there is evidence for a connection between a summering ground (Somerset Island) and a fall aggregation that is being hunted (Uummannaq). Only in Hudson Bay and Strait communities are the annual catches attributable to a single stock, the Northern Hudson Bay narwhal stock.

Discussion

Among marine mammal species, metapopulation models has so far only been described for pinnipeds, such as sea lions or gray seals (*Eumetopias jubatus, Halichoreus grypus*) (Harwood *et al.*, 1996; York, Merrick & Loughlin, 1996). Most cetaceans range widely over offshore areas that are difficult to access and it is often a complicated task to observe the underlying population structure. Although metapopulation structures has been suggested for several species of cetaceans (e.g. Pirzl *et al.*, 2009; Heide-Jørgensen *et al.*, 2011), metapopulation models have yet to be developed for cetaceans, and the spatial model proposed here for narwhals is the first attempt to develop such a model. Traditional methods of comparing genetic traits by

hypothesis testing alone have failed to clarify the stock structure of narwhals in the Baffin Bay region (Palsbøll, Heide-Jørgensen & Dietz, 1997); however, the satellite tracking results presented here provide insight into the metapopulation structure for a species that aggregates in coastal areas and island passages in summer.

Esler (2000) suggested that the applicability of metapopulation theory as a conceptual framework for understanding the population structure and dynamics of migratory animals requires consideration of spatial, temporal and behavioral factors that affect demographic independence throughout the year. Following Esler (2000), we propose that narwhal population structure in the eastern Canadian Arctic and West Greenland consists of separate summering stocks, which probably also represent separate breeding units, with little dispersal between them.

This study presents a conceptual model of narwhal population structure. Some narwhal subpopulations may be more isolated than others and there are subpopulations (stocks) for which movements remain unknown (e.g. Inglefield Bredning, East Baffin). Nevertheless, the metapopulation approach is a proposed framework for studying those relationships and should serve as a basis for conservation and management of narwhals.

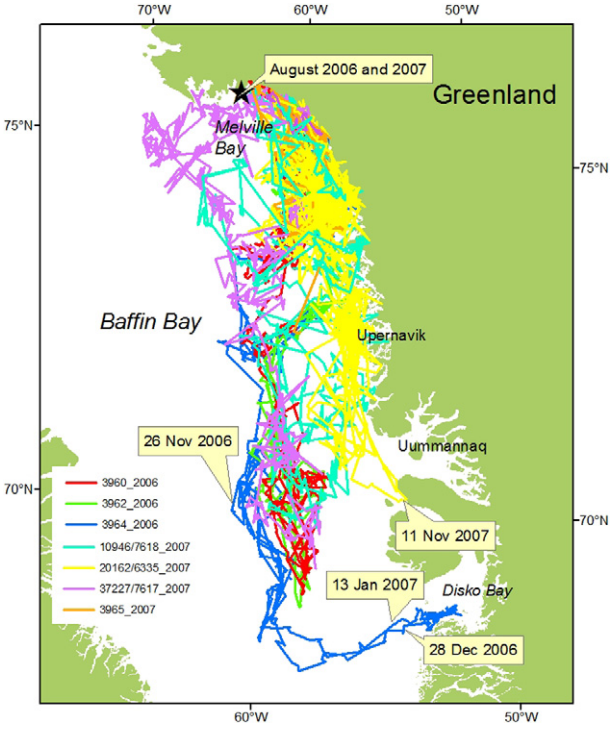

Figure 8 Tracklines of seven narwhals *Monodon monoceros* tagged in Melville Bay in 2006 and 2007 (data from this study). The black star indicates the tagging positions.

Tracking data and observational evidence for population structure

The observations presented here suggest that at least some of the narwhal summer aggregations in eastern Canada and West Greenland are, to some extent, demographically independent subpopulations. The evidence for this includes regular occurrence of stable numbers of narwhal aggregating in summering areas, minimal movements out of summering sites during summer months, fall migration routes that differ between subpopulations and return spring migrations of some animals to the same summering area where they originated. The observation that animals from identified stocks are local in summer and do not appear to overlap in their range with adjacent stocks suggests that narwhals in other not-yet-studied summering areas should also be considered separate summer stocks.

A growing number of satellite tags deployed on narwhals in summering areas have transmitted long enough to show that the majority of them return to the

Table 2 Examples of evidence for site fidelity obtained from satellite-tracked narwhals *Monodon monoceros* returning to the tagging locality the subsequent year or later

Stock	Years	Observation	Reference
Somerset Island	2001–2002	Two whales tagged in 2001 returned to the summering area the following year	Heide-Jørgensen *et al.*, 2003
Somerset Island	2001–2006	One whale tagged in 2001 was resighted in Lancaster Sound 5 years later on its return migration toward Somerset Island	Heide-Jørgensen *et al.*, 2008
Admiralty Inlet	2004–2005	One whale tagged in 2004 returned to the ice edge at Admiralty Inlet in June–July 2005 but departed again and went east in Lancaster Sound passing the ice edge at Navy Board Inlet en route to the north coast of Baffin Island. Contact was lost before the August destination could be determined.	Dietz *et al.*, 2008
Admiralty Inlet	2009	One whale migrated back to the mouth of Admiralty Inlet and was last recorded a few tens of kilometers inside the inlet in June 2010	This study
Melville Bay	2007–2008	One whale tagged in 2007 returned the following year to the exact same area	This study
Northern Hudson Bay	2008	Two whales tagged in and Lyon Inlet in 2006 were tracked back to the same general area in June the following year	Westdal *et al.*, 2010

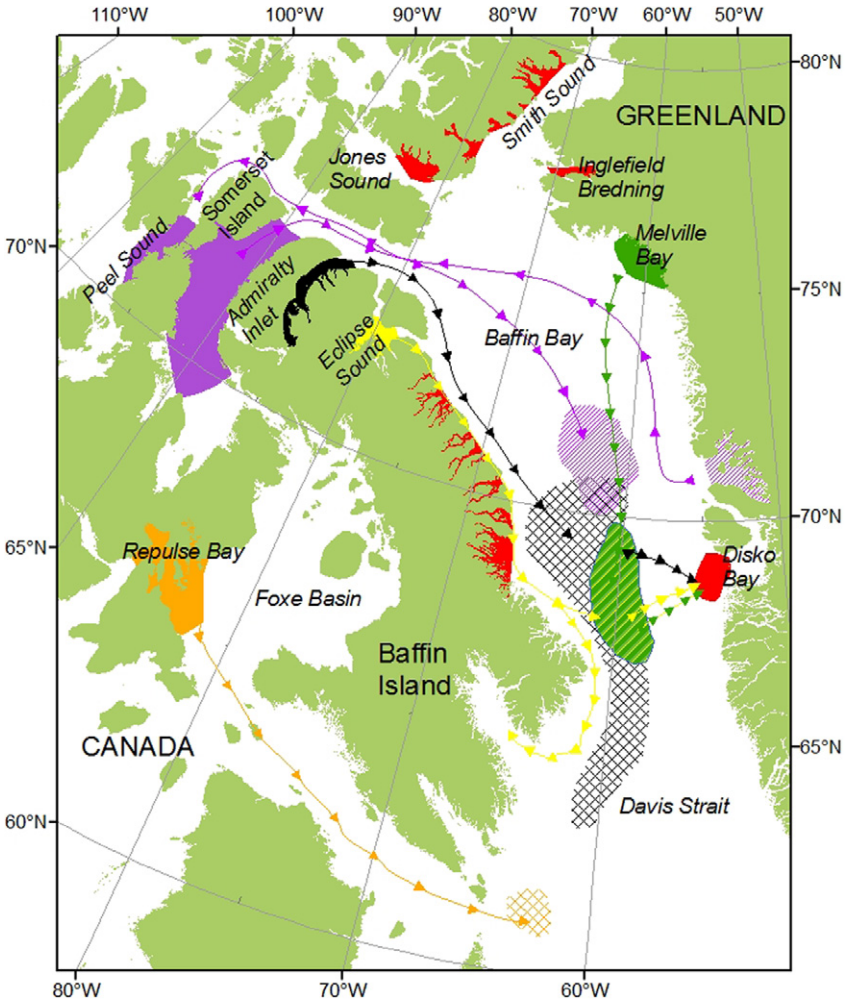

Figure 9 Map of the major summering aggregations (=stocks) of narwhals *Monodon monoceros*. Narwhals from the Melville Bay, the Eclipse Sound, the Somerset Island stock, the Admiralty Inlet and the Hudson Bay stocks (Repulse Bay) have been tracked by satellite and their late summer and autumn movements to four different wintering areas (cross-hatched) are shown. One narwhal from the Uummannaq November aggregation has been tracked to the summering area of the Somerset Island stock. Other localities that have not been studied (marked in red) include Disko Bay, Smith Sound and adjacent fjords, Jones Sound, Inglefield Bredning and fjords along the east coast of Baffin Island.

same summering areas the following summer. These tracking results, combined with the observations of recurring summer aggregations, lend support to the assumption that narwhalsummering stocks are philopatric aggregations and should be considered separate stocks for management and conservation purposes. Tagged narwhals leave these summering areas at about the same time each year and animals tagged in the same summering areas, with few exceptions, follow similar migration routes every year during their autumn, again suggesting philopatry to migration routes.

While summering aggregations are large and recurring in known areas as described earlier, there are occasional sightings of narwhals in areas not known to be aggregation areas. For example, narwhals are occasionally caught in Pangnirtung in August and September, but they are more often caught there in spring and fall. That catch is presumably supplied by narwhals from stocks further north, which winter in or migrate through that area. The low number of winter catches may be due to inclement weather, ice and light conditions. However, an aerial survey conducted in late March has documented the presence of many narwhal pods through the pack ice of Cumberland Sound (P. Richard, unpubl. data).

Genetic and contaminant lines of evidence

Palsbøll *et al.* (1997) described the genetic population structure of narwhals based on mtDNA and suggested that the three aggregations of narwhals in West Greenland (i.e. Inglefield Bredning, Melville Bay and Uummannaq) were genetically distinct. However, Palsbøll *et al.* (1997) also suggested that Disko Bay, the fourth aggregation, was a mixing area where narwhal pods from northern Baffin Bay and Melville Bay were wintering. A study of stable isotope ratios of $\delta^{15}N$ showed significant differences for narwhals in Inglefield Bredning and Uummannaq, and it was suggested this was due to a difference in short-term reflections of the trophic levels between the two areas (Dietz *et al.*, 2004). The reflection of trophic level through stable isotope examination in muscle tissue likely result from short-term feeding and it is unknown exactly what time period these proxies are

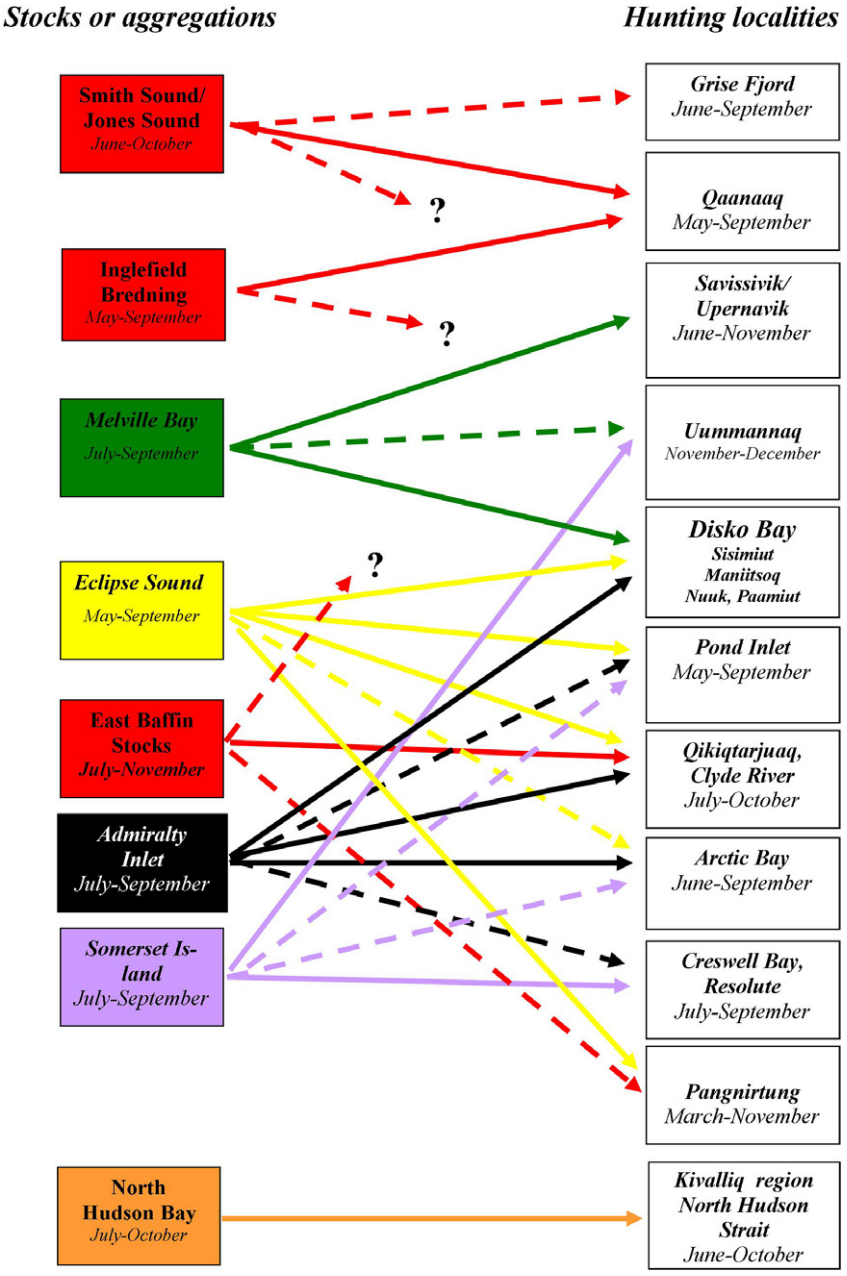

Figure 10 Hypothesized contribution to community catches in Canada and Greenland (right side) by stocks of narwhals *Monodon monoceros* (left side). Solid lines indicate catches by local communities adjacent to the stock's summering area. Broken lines indicate contribution of a stock to non-summer catches. Community names are given in italics to the right including Disko Bay that is a combination of several towns and the Kivallig region that includes Repulse Bay, Coral Harbour, Chesterfield Inlet, Rankin Inlet, and Arviat, and North Hudson Strait that includes Cape Dorset and Kimmirut. The month indicates the approximate time when the whales are present at their summering or aggregation areas and when they are available to the hunting communities. Question marks indicate unknown occurrence at other seasons.

Table 3 Approximate sizes of summering stocks of narwhals *Monodon monoceros* in Canada and West Greenland (Innes *et al.*, 2002; Heide-Jørgensen *et al.*, 2010; Richard, 1991; Westdal, 2008; Richard *et al.*, 2010). Confidence intervals (95%) are given in parenthesis

	Stock	Year	Stock size
Canada	Eclipse Sound stock	2004	20 225 (9471–37 096)
	Admiralty Inlet stock	2003	5362 (1920–12 199)
	Somerset Island stock	1996	45 358 (23 397–87 932)
	East Baffin Fiords stocks	2003	10 073 (5333–17 474)
	Northern Hudson Bay	2000	5627 (3543–8 935)
West Greenland	Inglefield Bredning stock	2007	8368 (5209–13 442)
	Melville Bay stock	2007	6024 (1403–25 860)

integrated over. Narwhals are thought to feed most heavily during winter and samples from stocks in summer do not necessarily reflect the prey choice and magnitude of feeding that occurs in winter (Laidre & Heide-Jørgensen, 2005).

Factors that may lead to demographic independence of subpopulations

Demographic independence between subpopulations of narwhals both on summering areas and, to a lesser extent, on the wintering areas is probably maintained through a combination of life-history traits and migratory routes. The mechanisms that lead to demographic independence of summering aggregations are probably related to nurturing and learning in mammals. Migratory and gregarious mammalian species, including odontocetes, tend to learn from one another and particularly from older experienced animals in their migrating group. Like other long-lived mammals, narwhal calves are believed to spend more than a year with their mother (Hay & Mansfield, 1989) and, consequently, learn from their migratory behavior. Although narwhals do not exhibit 'natal philopatry' in terms of calving and mating at the same locality, it is still conceivable that they learn their migration routes and the location of their summer and winter aggregation areas by following their mother and siblings, and, later on, other conspecifics from the same subpopulation.

While the extent of the mating season is not well known, it has been estimated that the average mating date is in the latter part of May (95% confidence interval: 1 May–12 June (Heide-Jørgensen & Garde 2011). Although some of the subpopulations utilize the same wintering areas and may be mating early in the season, other subpopulations are separated from April onward, when they are following migration routes to their summering areas and unlikely to encounter whales from other stocks. Some levels of cross-mating between stocks likely occur in late winter and low levels of cross-breeding are sufficient to dampen genetic differences between stocks, but animals composing a subpopulation (stock) are more related than in a perfect panmixia.

The degree of migratory divergence may vary between stocks, but evidently, some stocks are less likely to encounter whales from other stocks at that time of year. Mating is therefore likely to take place more between migrating whales and, consequently, with narwhals going to the same summering area (e.g. the three stocks that passes through Lancaster Sound in spring). This would contribute to maintain behavioral affinity for the same migration routes, probably a learned response, and philopatry to the same summering area.

The exception to the above seems to be the northern Hudson Bay narwhals, which segregate genetically from Baffin Bay narwhals (de March, Tenkula & Postma, 2003), probably because their seasonal distributions are separate year-round (Westdal *et al.*, 2010). These whales are also distinguished through contaminant analyses from other Canadian stocks (de March & Stern, 2003) and are therefore likely a population in the biological sense.

Three males were observed during winter to make incursions into other areas and they seem to be more likely to visit wintering areas of other stocks than the females. Satellite tracking provides insight into the coarse metapopulation structure, but estimation of the magnitude of exchange rates clearly would require substantially larger sample sizes to estimate exchange rates.

Management implications

This study proposes a metapopulation structure of narwhals in Baffin Bay and Hudson Bay, where discrete stocks are maintained through behavioral segregation. Panmixia is not supported by the data presented here on the relative stationary behavior in summer, and a return spring migration of individuals between years. The migratory destinations of narwhals from Inglefield Bredning and the East Baffin Stocks remain unknown and the association between the Uummannaq aggregation and the Somerset Island stock is based on limited information. However, for narwhal stocks, it is obvious that several stocks are hunted at many coastal locations in both Canada and Greenland, and that management action must take that into account (Fig. 8). From a management perspective, it is conservative to assume that stocks are demographically independent and therefore differentially exploited. Assuming that the Baffin Bay population is panmictic could lead to unsustainable catch levels at some localities or by some communities, which would severely affect these local narwhal stocks and the Canadian Inuit and Greenlandic populations that rely seasonally on those predictable aggregations.

Acknowledgments

We thank the many hunters of Greenland and Canada who shared their knowledge of narwhal distribution and behavior and for their field assistance in narwhal tagging projects. We are particularly grateful to Jack Orr who led several of those tagging field studies in the Canadian Arctic and whose field and organizational skills made them very successful. Stefan Romberg is acknowledged for the database on Canadian narwhal catches. This study was funded by the Greenland Institute of Natural Resources, National Environmental Research Institute, Department of Fisheries and Oceans, Nunavut Wildlife Management Board, Polar Continental Shelf Project, US National Science Foundation, NOAA Ocean Exploration, The Danish Natural Research Council and The Danish Cooperation for the Environment in the Arctic (DANCEA).

ABSTRACT

There is great interest in exploring and exploiting hydrocarbon resources in the Arctic, and one of the main methods of locating and assessing such resources is seismic survey. Marine seismic surveys involve the use of airguns that introduce high-energy noise to the Arctic's largely pristine underwater acoustic environment. Narwhals may be particularly sensitive to this noise but so far no studies have addressed the question of direct effects of high-energy airgun pulses on these animals. We are concerned about the possibility that three large recent ice entrapments were causally linked to seismic survey activities. On these occasions narwhals remained in coastal summering areas until well into the fall and early winter season, delaying their annual offshore migration and becoming lethally entrapped by rapidly forming fast ice. About 1000 narwhals died in an ice entrapment in Canada in 2008 and about 100 in two entrapments in Northwest Greenland in 2009–10. We conclude that studies of the direct effects of seismic surveys on narwhals are urgently needed and should ideally precede further seismic surveys in narwhal habitats.

Some of the largest unexplored geological basins for hydrocarbon development are located in offshore seasonally ice-covered shelf-areas of the Arctic (Gautier et al., 2009; Schenk, 2010). With the prospects for a continued reduction in extent and thickness of sea ice (Perovich and Richter-Menge, 2009), these areas are of increasing interest to the oil and gas industry. On the shelf areas of East and West Greenland alone, it has been estimated that >20 million barrels of undiscovered oil might exist and would be potentially recoverable (Gautier et al., 2009). The prospect of large-scale untapped but accessible hydrocarbon resources in a country with a stable political system has fueled interest in oil and gas exploration in Greenland. Both offshore seismic surveys and exploratory drilling have taken place in West Greenland since 2007 and licensing for areas of East Greenland is expected to take place in 2012 (http://www.bmp.gl/petroleum/).

The underwater environment in the Arctic often has high background sound levels from activity of icebergs, sea ice, wind, waves, and wildlife, but there has been, until recently, relatively little noise of anthropogenic origin (Carey and Evans, 2011; Moore et al., 2012). Despite opening of the Northwest and Northeast Passages (Arctic Marine Shipping Assessment, 2009), the level of shipping activity remains low and is largely limited to the open-water season. Therefore the underwater acoustic environment in much of the Arctic is still nearly pristine, without the chronic noise from shipping, drilling, seismic exploration and sonar. In Baffin Bay large-scale industrial seismic surveys were only recently initiated.

Arctic marine mammals use underwater sounds to locate prey, detect and avoid predators, find openings in sea ice for breathing, and to communicate and maintain contact (Richardson et al.,

1995). Historically, cetaceans and pinnipeds that live year-round in the Arctic have been exposed to very limited amounts of anthropogenic sound and there is no reason to believe that these animals have become desensitized or habituated to such noise. In fact, there is published evidence of dramatic responses to ship noise by belugas (*Delphinapterus leucas*) and narwhals (*Monodon monoceros*) (Finley et al., 1990; Cosens and Dueck, 1993; Lesage et al., 1999) and to airgun pulses by bowhead whales (*Balaena mysticetus*) (Richardson et al., 1995; Blackwell et al., 2010). The effects of anthropogenic noise on several temperate-region species have been studied (Wright et al., 2007; Rolland et al., 2012) but few studies have addressed this issue for Arctic marine mammals. Depending on the type and level of the sound as well as its spatial and temporal character, the impacts on marine mammals may include short- or long-term changes in behavior (i.e. disruption of feeding activity, avoidance, shifts in habitat-use patterns), physical damage to hearing abilities, and masking of important signals. Change in calling behavior is a commonly detected effect of noise exposure.

The narwhal, primarily found in the Atlantic sector of the Arctic with the largest numbers centered in Baffin Bay and adjoining waters (Richard et al., 2010; Heide-Jørgensen et al., 2010), is of particular concern. Narwhals are skittish, highly sensitive to human activities and easily disturbed by approaching boats, even in areas without hunting. Hunting of narwhals in several areas of West Greenland continues to be conducted from kayaks because the whales react with long submergence times and often simply disappear when pursued by boats with noisy outboard engines. No direct studies have been conducted of the effects of seismic airgun noise on narwhals but they are known to react at long distances to underwater noise from vessels, with and without ice-breaking (Finley et al., 1990). The reactions of narwhals to approaching vessels include long-distance displacement, even at relatively low received sound levels (94–105 dB re 1 μPa; 20–1000 Hz). This responsiveness at such long distances is exceptional in the literature on marine mammal disturbance (see Richardson et al., 1995). It should be noted however that recent studies indicate that some other species also react to noise at long distances (e.g. Risch et al., 2012). The responsiveness of narwhals confirmed by the paucity of sightings obtained from vessels passing through areas known (from hunting returns and aerial surveys) to have high densities of narwhals (Heide-Jørgensen et al., 2010; GINR unpublished data). In particular, observers on active seismic survey vessels rarely if ever encounter narwhals, even when surveying areas where narwhals are known to occur (Lang and Mactavish, 2011). It is likely that the animals disappear before the survey vessels are within the observers' range of visual detection.

The sounds produced by narwhals span a wide range of frequencies, from <300 Hz to >150 kHz (Miller et al., 1995), and the low-frequency sounds of seismic surveys are likely to overlap in frequency with at least a portion of the narwhal's vocal repertoire. It is uncertain at what distance from an operating seismic airgun array the sound pressure received by the narwhals would elicit a behavioral or physiological response. The received level would depend not only on distance but, perhaps more critically, on the size of the array and other factors. It is a combination of distance (to the airguns) and received level (at the whale) that is likely to elicit a response.

Although narwhals dive to depths exceeding 1000 m (maximum recorded depth was 1900 m; Laidre et al., 2003), they are not considered fast swimmers. Based on contraction times, dominance of slow-twitch muscle fibers and exceptionally high myoglobin concentrations, narwhals have been characterized as slow, aerobic swimmers (Williams et al., 2010). Observations of narwhals instrumented with satellite-linked time-depth recorders showed that horizontal speeds averaged 1.4 m s^{-1} (range = 0.81–2.36 m s^{-1}) and vertical speeds were within approximately 10% of this range (Dietz and Heide-Jørgensen, 1995; Heide-Jørgensen and Dietz, 1995). These values are among the slowest reported for any marine mammal (Williams, 2009).

The usual escape response of narwhals exposed to killer whales (*Orcinus orca*) or Inuit hunters involves prolonged submergence and entry into dense pack ice, if this is available (Williams et al., 2010; Laidre et al., 2006). In other words, they tend to hide or flee slowly and cryptically to avoid predators. Their observed response to an icebreaker was similar (Finley et al., 1990) and this is in contrast to the responses of other cetaceans with locomotor muscles divided equally into slow-twitch and fast-twitch fiber types, allowing for high-speed movement away from a disturbance (Ponganis and Pierce, 1978). Narwhals make long-distance migrations in the spring and autumn (>3000 km per year), moving between coastal summering grounds (Heide-Jørgensen et al., 2003) and winter feeding areas in the pack ice (Laidre et al., 2004). Such migrations across areas with few predators require endurance swimming (Williams et al., 2010). In summary, narwhals adhere to strict migratory schedules and routes with a high degree of site fidelity to specific localities (Heide-Jørgensen et al., in press). They live in an environment with strong seasonal variability in habitat conditions, have few predators, and are rarely exposed to human disturbances except during the short periods when they are hunted along the edges of fast ice and in open water.

Narwhals remain in the Arctic or sub-Arctic throughout the year. Although they spend approximately half of the year in dense pack ice and have done so for centuries (and presumably for millennia), they are still susceptible to ice entrapment. At intervals, large numbers succumb in this way during the winter (February through April). Ice entrapments are caused by a sudden freeze-up during periods of stable but high atmospheric pressure (Egede, 1788; Porsild, 1918; Siegstad and Heide-Jørgensen, 1994). Ice entrapments are well documented in West Greenland and to some extent also in Canada as these are major events in the lives of people living in Arctic communities. The Disko Bay area of West Greenland has long been the area with the highest incidence of narwhal ice entrapment, and it was the site of the largest such event on record: more than 1000 whales died in a February 1915 ice entrapment in Disko Bay (Porsild, 1918). This bay typically provides excellent feeding conditions for narwhals, and sea ice coverage is highly variable according to the changing strength of the warm Atlantic water and the cold polar currents that meet there. During certain weather conditions in winter, hunters are "on the lookout" for ice-entrapped whales at sites where entrapments are to some extent predictable based on local experience and knowledge. This situation, specifically the high level of local interest and consequent vigilance by people, gives us confidence in asserting that ice entrapments of narwhals occur mainly between February and March and most often in the Disko Bay region of West Greenland. There are few historical records of entrapments north of Disko Bay, none from Qaanaaq (Northwest Greenland) and few from winter in the Canadian high Arctic (Fig. 1).

Three recent ice entrapments of narwhals occurred in summering areas outside the normal range of ice-entrapment events. Two of these took place in the autumn in locations where entrapments of narwhals had not been reported previously. In November 2008 thousands of narwhals were seen moving quickly through the freezing seas near the community of Pond Inlet (northern Baffin Island, Canada) a few days before being entrapped (Watt and Ferguson, 2011). Some of the whales apparently avoided entrapment. However, after the ice had frozen solid, local residents discovered about 1000 narwhals at breathing holes about 50 km from open water. During late September and early October 2008, 2D seismic surveys (m/v Geolog Dmitriy Nalivkin) were underway

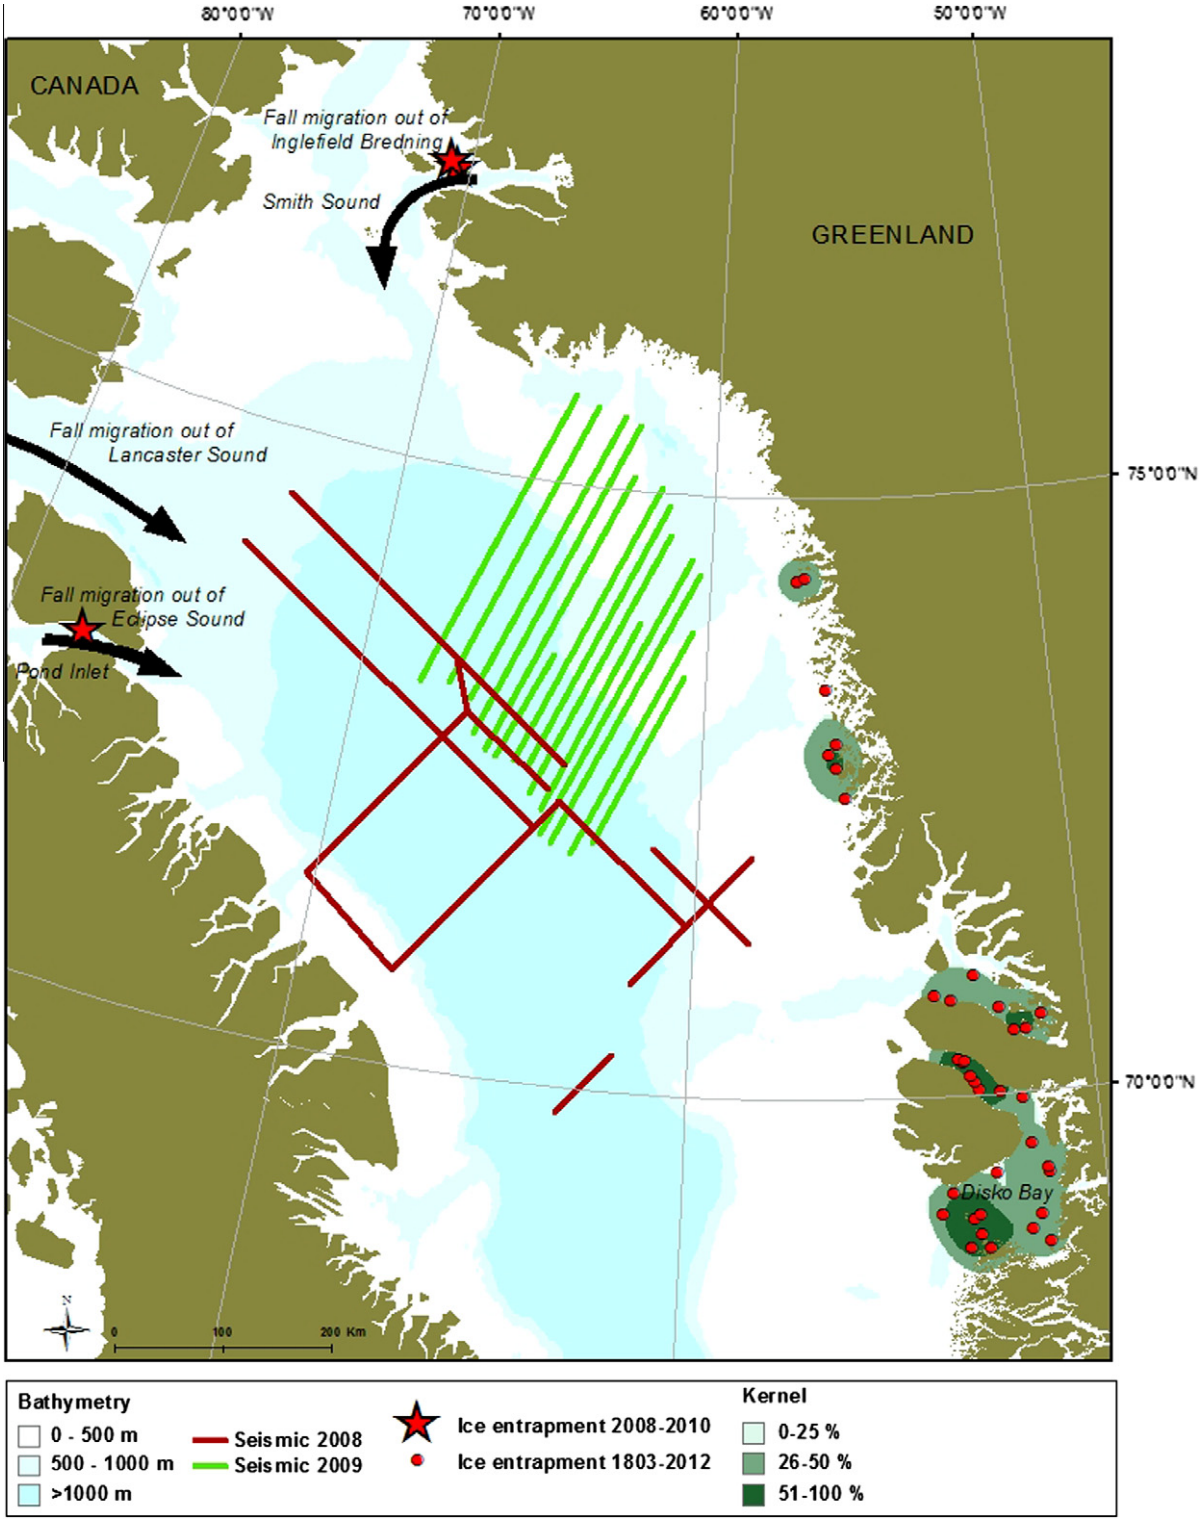

Fig. 1. Tracks of seismic survey operations in northern Baffin Bay during September–October 2008 and 2009. Historical ice entrapments in West Greenland are indicated with red dots and shown with kernel home ranges in green. Three recent entrapments are shown with red stars in Canada (November 2008) and Northwest Greenland (November 2009, February 2010). Major fall migration routes of narwhals exiting Lancaster and Eclipse sounds in Canada and Inglefield Bredning in Northwest Greenland are shown with black arrows. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

in Baffin Bay at the time when narwhals would normally be moving out of Pond Inlet and Lancaster Sound and starting their southward migration in Baffin Bay (Fig. 1). This seismic vessel normally operates with four arrays of up to 37 airguns with a combined maximum volume of 4200 inch^3 and a pressure of 2000 psi.

Two other unusual, and similarly lethal, incidents occurred in November 2009 and February 2010 in Inglefield Bredning, involving 30–100 and 50–100 narwhals, respectively (Laidre et al., 2011). Similar to 2008, seismic activity (m/v Bergen Surveyor) was taking place in northern Baffin Bay in September–October 2009, i.e. at the

Author's personal copy

time when narwhals would normally be moving out of their summering area in Inglefield Bredning. This vessel operates with an airgun arrangement (4 arrays with 12 two-gun clusters and source energy of 3460–4210 inch^3) similar to that used by m/v Geolog Dmitriy Nalivkin and both vessels deploy airgun arrays with more than enough power to produce pulses that would be audible in the entire Baffin Bay. We have no records of previous seismic surveys as late in the year as late September–October in northern Baffin Bay.

Narwhals that have spent the summer in and near Pond Inlet usually depart the fjord system around the 25th of September and head towards their wintering grounds in central Baffin Bay (Heide-Jørgensen et al., 2002; Fig. 2). The large number that remained in Pond Inlet during freeze-up in November 2008 was exceptional. Inglefield Bredning is an important summering ground for narwhals (Heide-Jørgensen et al., 2010) but the whales always leave the area in late September-early October (Born, 1986). Although the migratory destination of this population of narwhals is still not known with certainty, the narwhals traditionally move south and abandon Smith Sound for the winter (Finley and Renaud, 1980; Richard et al., 1998).

The areas where ice entrapments of narwhals usually occur along West Greenland (shown as kernel ranges in Fig. 1) are characterized by mobile pack ice where leads and cracks in most winters provide open spaces for air-breathing mammals. However, the coastal areas in northern Baffin Bay where the narwhals were entrapped in 2008 and 2009–10 are usually covered with fast ice in late November, thus it remains a mystery why the whales remained in these areas during freeze-up. Narwhals inhabit areas where climate imposes strong forcing on the habitat conditions, meaning the conditions can change from suitable (ice-free or unconsolidated pack ice) to unsuitable (solid and continuous ice cover) over short timescales. It has been speculated that, with climate change, later freeze-up on the summering grounds will delay the departure of narwhals from these areas and make them increasingly vulnerable to rapid freeze-up and ice-entrapment late in the fall (Laidre et al., 2011). This suggestion is inconsistent with the tight schedule of narwhal fall migrations; for decades, the whales have been observed to depart their summering grounds well ahead of the formation of fast-ice (Dietz and Heide-Jørgensen, 1995; Dietz et al., 2008; Heide-Jørgensen et al., 2003).

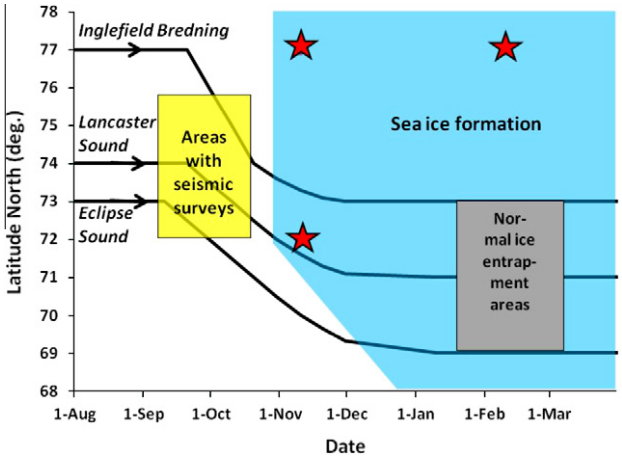

Fig. 2. Generalized model of autumn sea ice development with latitude (*y*-axis) and date (*x*-axis) in Baffin Bay. The fall migration of narwhals from three summering areas (Inglefield Bredning, Lancaster Sound and Eclipse Sound, see Fig. 1) from high latitudes towards lower latitudes is shown with black lines, and the normal latitude and season for ice entrapments of narwhals are shown as the gray box, with the three unusual entrapment events in 2008 and 2009–10 indicated with red stars in areas and seasons where entrapments have generally not been reported before. The seismic surveys (yellow square) happened just after the narwhals normally would have begun to depart from their summering grounds and while they would have been heading towards wintering areas in central Baffin Bay. For background data see Dietz et al. (2008) and Heide-Jørgensen et al. (in press). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

Low-frequency sounds from airguns can be transmitted over long distances. For example, Nieukirk et al. (2012) monitored seismic activity from moored stations along the mid-North Atlantic and documented sounds from seismic survey vessels located >3000 km away. Airgun sounds were recorded in Fram Strait, off northeastern Greenland, year-round, even during the winter when the area was ice covered and no seismic exploration was being conducted locally (Moore et al., 2012). The seismic surveys conducted in Baffin Bay in 2008 and 2009 were in a relatively deep basin (500–2000 m). The airgun pulses from the >3000 inch^3 industrial seismic arrays would have ensonified the underwater environment of most of the northern part of Baffin Bay during the early part of the narwhal fall migration, and there is little doubt that the pulses were audible to narwhals, which would have been within 200 km of the seismic vessels at least during parts of the period.

The general proximity in space and time of the seismic survey activity and the 2008 and 2009–10 ice entrapments leads us to propose as a possibility that there was a causal connection, with the seismic surveys in 2008 and 2009 interrupting the outmigration of narwhals and prompting them to return to the summering grounds which would eventually be covered with fast ice. Although direct proof of such a connection is not possible in retrospect and would be difficult even in a "real-time" situation, we believe a very cautious approach to seismic surveys in narwhal habitats is warranted. This remains true even if, as an alternative hypothesis, the recent entrapments are considered stochastic events, possibly more related to climate change than to the disruptive effects of industrial activity within the Baffin Bay region.

Persistent disturbance of narwhals (and other acoustically sensitive Arctic species) could disrupt important behavior, cause the animals to abandon important summering areas, and change their migration patterns. As they leave the summering grounds, narwhals are generally heading towards winter feeding grounds, and disturbance could cause them either to return and risk ice entrapment or to move to wintering areas that are sub-optimal for feeding. Considering that narwhals already appear to be approaching their physiological capacity and may have little flexibility to adjust their swimming and diving behavior (Williams et al., 2010), it seems critical that the whales are not disturbed to such an extent that their basic annual cycle is disrupted.

We conclude that extreme caution should be taken by companies and agencies involved in planning and conducting marine seismic surveys in or in close proximity to narwhal summering grounds and migratory routes. We also identify as an urgent research priority specific studies on the effects of seismic airgun noise on narwhals (and belugas). Such studies should include assessment of the effects of airgun noise on escape movements (dosis response experiments), migratory movements, diving activity, vocalizations and, if possible, heart rate changes during long dives. Given the uncertainty in relation to potential population effects of seismic noise, it is also recommended to monitor the population trends of exposed narwhal populations carefully.

Impacts of Anthropogenic Sound on Cetaceans

John Hildebrand
Scripps Institution of Oceanography
University of California San Diego
La Jolla, CA 92093-0205

ABSTRACT

Anthropogenic sound is created in the ocean both purposefully and unintentionally. The result is noise pollution that is high-intensity and acute, as well as lower-level and chronic. The locations of noise pollution are along well-traveled paths in the sea and particularly encompass coastal and continental shelf waters, areas that represent critical marine mammal habitat. The problem is one of isolation and a lack of awareness between humans who use the sea and marine mammals that inhabit the sea. Increased use of the sea for commercial shipping, geophysical exploration, and advanced warfare has resulted in a higher level of noise pollution over the past few decades. Informed estimates suggest that noise levels are at least 10 times higher today than they were a few decades ago. Without some effort to reduce or at least cap these noise levels, future ocean noise levels are likely to increase and further degrade the acoustic environment.

A long-term monitoring program is needed to track future changes in ocean noise. Acoustic data should be included in global ocean observing systems now being planned by U.S. and international research foundations. Data from these monitoring systems should be openly available, and accessible to decision makers in industry, in the military, and in regulatory agencies. In tandem, a database should be developed to collect, organize and standardize data on ocean noise measurements and related anthropogenic activities. Currently, data regarding shipping, seismic exploration, oil and gas production, and other marine activities are either not collected or are difficult to obtain and analyze because they are maintained by separate organizations. Marine noise measurements and anthropogenic source data should be used to develop a global model of ocean noise. An important component of model development is better understanding of the characteristics for anthropogenic noise sources such as commercial shipping, arigun arrays, and military sonar. Research should be conducted relating the overall levels of anthropogenic activity (such as the types and numbers of vessels) with the resulting noise.

Review of the evidence suggests that noise pollution is an important factor in the health of marine mammal habitats. There is sufficient evidence to conclude that high-intensity sounds are harmful and, on occasion, fatal to marine mammals. Behavioral data on marine mammal reaction to sound is complex, partially because of our meager abilities to observe marine mammal behavior in the wild. Evidence suggests that given the opportunity, marine mammals avoid high-intensity sound. Damage to marine mammal hearing due to anthropogenic sound exposure has been documented in the most extreme cases. Multiple mass-stranding events of beaked whales following high-intensity sound exposure demonstrate a repeated pattern of events. Following exposure to high-intensity sonar or airguns, beaked whales rapidly swim to the beach, and the animals die if not returned to the sea by human intervention. Those that are returned to the sea have an unknown fate. Understanding the causes and consequences of beaked whale mass stranding should be a high research priority. What is the mechanism for damage and/or disturbance?

An impediment to assessing the biological effects of ocean noise is a continued lack of knowledge about marine mammal behavioral response to sound. Behavioral data must be collected in the wild to reveal potential effects. Significant ocean noise effects may be confined to a few individuals exposed at high sound pressure levels, and/or from widespread exposure at a population level. Discerning population level effects is challenging since the observations must be conducted over broad distances and long time periods. Our lack of understanding marine mammal behavioral reaction to sound is vast and must be addressed in the face of raising ocean noise levels.

Research tools are needed to better observe marine mammal behavior in the wild. These are needed both to characterize normal behaviors and to detect changes in behavior associated with anthropogenic noise. Tools

also are needed to study marine mammal physiology in the wild. For instance, indicators of stress may be one way to assess the impact of anthropogenic noise on marine mammals. Anthropogenic ocean noise sources are primarily concentrated into a few well defined zones, at major commercial ports and along shipping lanes, in areas of oil exploration and development, and within military test and training sites. The marine mammal populations within these zones should be characterized and monitored for potential impact due to anthropogenic noise.

INTRODUCTION

There is growing concern that sound introduced into the sea by human activities has detrimental effects on marine mammals. Mounting evidence suggests that high-intensity anthropogenic sound from sonar and airguns leads to strandings and subsequent mortality of beaked whales. Although the mechanisms of injury in these events are unclear, the species affected and implicated sound levels follow a consistent pattern. A potentially more pervasive, yet more subtle, problem may be the effects on marine mammals due to increases in ambient noise levels from commercial shipping. Higher levels of ambient noise may interfere with marine mammals' ability to detect sounds, whether these are calls of conspecifics, echos from prey, or natural sounds that aid in navigation or foraging. Such noise may affect reproductive or immune functions and cause more generalized stress. The effects of other pollutants (e.g., chemicals) may be additive or synergistic with those of noise.

Sources of anthropogenic noise are becoming both more pervasive and more powerful, increasing both oceanic background sound levels and peak intensity levels. Ambient noise in the ocean has increased over the past 50 years at both at low (less than 1000 Hz) and mid-frequencies (1-20 KHz). Contributors to ambient noise are commercial shipping, defense-related activities, hydrocarbon exploration and development, research activities, and recreational activities.

Sound is an extremely efficient way to propagate energy through the ocean, and marine mammals have evolved to exploit its potential. Many marine mammals use sound as a primary means for underwater communication and sensing. Toothed whales have developed sophisticated echolocation systems to sense and track the presence of prey and engage in complex exchanges of vocalizations with conspecifics. Baleen whales have developed long-range acoustic communication systems to facilitate mating and social interaction. Some produce intricately patterned songs that continue for hours or days. Marine mammals may use sound from natural sources as a guide for navigation, prey detection, and avoidance of predation. The sound environment of the ocean is an important aspect of marine mammal habitat and we can expect marine mammals to choose their locations and modify their behavior based, in part, on natural and anthropogenic sounds.

Human presence at sea is normally on the surface, and the sounds that we produce within the water are rarely given much consideration. The air-sea interface creates a substantial sound barrier. Sounds waves in the water are reduced in intensity by more than a factor of a thousand when crossing the air-sea boundary. This means that we are effectively insulated from the noise produced by rotating propellers that drive our ships or by high-intensity sonars used to measure the depth or probe the interior of the sea. The conflict between human and marine mammal use of the sea is fundamentally a consequence of the fact that we do not inhabit the same sound environment. Marine mammals live with their ears in the water, and we live, even at sea, with our ears in the air.

A notable exception is when the military uses submarines, and stealth is required. Minimization of sound production then becomes crucial to survival. Reduction in noise has been achieved by placing rotating machinery on isolating mounts and by designing efficient propellers that thrust without unnecessary accompanying vibrations and cavitations. Thus, when it has seemed important to keep the sea quiet, the necessary technology has been developed and made available. .

NOISE LEVELS IN THE OCEAN

Sound is a vibration or acoustic wave that travels through some medium, such as air or water. Acoustic waves can be described either by the speed at which a small piece of the medium vibrates, called the particle velocity, or by the corresponding pressure associated with the vibration. Frequency is the rate of vibration, given in Hertz (Hz) or cycles per second; we perceive frequency as the pitch of the sound. A tone is a sound of a constant frequency that continues for a substantial time. A pulse is a sound of short duration, and it may include a broad range of frequencies.

In water, sound waves are typically measured by their pressure using a device called a hydrophone. When discussing ambient noise, the implicit assumption is that sound pressure fluctuations are being described, although it is not clear whether a particular marine organism is able to sense particle velocity or acceleration. Sound pressure is measured in Pascals (Pa) in the international system of units (SI), although it is expressed in bars by the geophysical community ($1\ Pa = 10^{-5}$ bar). Since mammalian hearing and sound production cover a large range of pressure values, sound pressure level (SPL) is usually measured on a logarithmic scale called the decibel (dB), and compared against a 1 µPa reference (P_o) for underwater sound as follows:

$$\text{SPL dB re: 1 µPa} = 10 \log_{10} (P / P_o)^2$$

$$\text{SPL dB re: 1 µPa} = 20 \log_{10} (P / P_o)$$

Pressure is squared in the above expression as a proxy for acoustic intensity, that is, the power flow per unit area in the sound wave, with units of watts/m^2. Sound intensity is the product of pressure (P) and particle velocity (v). Acousticians working in one medium (water or air) use the fact that for plane waves the pressure and particle velocity are related by the characteristic impedance (Z) of the medium as follows:

$$Z = P / v$$

This allows the acoustic intensity (I) to be related to the pressure squared, divided by the impedance:

$$I = 10 \log_{10} (P^2 / (Z * I_o))$$

Acoustic power is obtained by integrating intensity over some area, and acoustic energy is obtained by integrating the power over some time period. The same acoustic energy can be obtained from a high-intensity source over a short time (impulse) and a low-intensity source over a long time (continuous wave).

When sound propagates from water into air, there is a 30 dB (1000 x) decrease in acoustic intensity because the characteristic impedance of water is much greater than that of air. This means that sounds made by a high-intensity underwater source (such as a sonar) are not transmitted into the air with the same intensity. In essence, sailors and passengers on ships are protected from the sounds that they generate. Without the air-sea boundary for protection, there would be a strong incentive to protect human hearing from the noise of sonars and cavitating propellers on ships. (Note that for sound in air a different reference level is used, P_o = 20 µPa, and this is a source of much confusion when comparing underwater and in-air sounds.)

Underwater sounds are classified according to whether they are transient or continuous. Transient sounds are of short duration, often called pulses, and they may occur singly, irregularly, or as part of a repeating pattern. For instance, an explosion represents a single transient, whereas the periodic pulses from a ship's sonar are patterned transients. Underwater sounds also can be classified as continuous, that is, they occur without a pause or hiatus. Continuous sounds are further classified as periodic, such as the sound from rotating machinery or pumps, or aperiodic, such as the sound of a ship breaking ice.

Pulsed sounds are measured in terms of their total energy, rather than just their pressure or intensity. Pressure and power measures are difficult to interpret for a brief pulse since they depend on the averaging

time. Energy is proportional to the time integral of the squared pressure, described in the units μPa^2-s. For brief pulses, energy in dB re: μPa^2-s is less than peak squared pressure values in dB μPa^2. As others have warned, better standardization of measurement methods for pulsed underwater sounds is urgently needed to permit meaningful comparisons (Greene 1995).

Ambient noise in the ocean is the background sound that incorporates the broad range of individual sources, some identified and others not. Ocean noise may come both from distant sources, such as ships, or from nearby sources, such as the waves breaking directly above the listener. Although ambient noise is always present, the individual sources that contribute to it do not necessarily create sound continuously.

Natural ocean acoustic environment

The ambient acoustic environment of the ocean is highly variable. At a given time and place, a broad range of sources may be combined. In addition, conditions at a particular location may affect how well ambient sounds are received (e.g., sound propagation, water depth, bathymetry, and depth). Natural phenomena known to contribute to oceanic ambient noise include: (a) wind, sea state and swell patterns, (b) bubble distributions, (c) currents and turbulence, (d) seismic activity, (e) precipitation, (f) ice cover and activity, and (g) marine life.

Wind, Waves and Ice

Ocean surface motions due to wind, sea state and swell patterns are the dominant physical mechanisms for natural sound in the ocean. Noise is primarily associated with wind acting on the surface, causing wave activity. In the absence of anthropogenic and biological sound, ambient noise is wind dependent over an extremely broad frequency band from below 1 Hz to at least 100 kHz. At frequencies below 10 Hz, interactions of surface gravity waves are the dominant mechanisms for sound generation. Across the remainder of the band from 10 Hz – 100 kHz, oscillating bubbles in the water column are the primary noise source, both as individual bubbles and as bubble clouds.

In early descriptions, ocean noise was related to sea state (Knudsen et al. 1948). By this theory, noise levels increase with increasing sea state by the same amount across the entire frequency band from 1 kHz to 100 kHz. More recent work has suggested that noise is better correlated with wind speed than with sea state or wave height. The correlation between noise and wind speed allows for more accurate prediction, as sea states are more difficult to estimate than wind speeds. In the open ocean, the noise of breaking waves is correlated with wind speed. Spilling and plunging breakers raise underwater sound levels by more than 20 dB across the band from 10 Hz to 10 kHz (Wilson et al. 1985). Precipitation is another factor that can increase ambient noise levels by up to 35 dB across a broad band of frequencies from 100 Hz to more than 20 kHz (Nystuen and Farmer 1987). Ice cover alters the ocean noise field depending on its type and degree, for instance, whether it is shore-fast pack ice, moving pack ice, or at the marginal ice zone (Milne 1967). Shore-fast pack ice isolates the water column from the effects of wind, and results in a decrease in ambient noise of 10-20 dB. Sounds from ice cracking, however, may increase noise levels by as much as 30 dB. Ice cracking can generate broadband pulses up to 1 kHz lasting for a second or longer. Interaction of ocean waves with the marginal ice zone may raise noise levels by 4-12 dB (Diachok and Winokur 1974).

Earthquakes

Earthquakes and thunder are examples of transient natural sound sources. Underwater recordings of thunder from storms 5 to10 km distant show peak energy between 50 and 250 Hz, up to 15 dB above background levels (Dubrovsky and Kosterin 1993). Seismic energy from undersea earthquakes couples into the ocean and is called T-phase (tertiary) in addition to the usual P-phase (primary) and S-phase (secondary) seismic waves that are observed on land. At ranges of less than 100 km, T-phase energy can have frequencies greater than 100 Hz, with peak energy at 5-20 Hz. It can be as much as 30-40 dB above background noise, with a sharp onset, and can last from a few seconds to several minutes (Schreiner et al. 1995).

Anthropogenic Sound

Human activity in the marine environment is an important component of the total oceanic acoustic background. Sound is used both as a tool for probing the ocean and as a byproduct of other activities. Anthropogenic noise sources vary in space and time, but may be grouped into general categories: (a) large commercial ships, (b) airguns and other seismic exploration devices, (c) military sonars, (d) ship-mounted sonars, (e) pingers, (f) acoustic harassment devices (AHDs), (g) polar ice-breakers, (h) offshore drilling implements, (i) research sound sources, and (j) small ships.

Commercial Shipping

At low frequencies (5 to 500 Hz), commercial shipping is the major contributor to noise in the world's oceans. Distant ships contribute to the background noise over large geographic areas. The sounds of individual vessels are often spatially and temporally indistinguishable in distant vessel traffic noise. Noise from vessel traffic at high latitudes is particularly efficient at propagating over large distances because in these regions the oceanic sound channel (zone of most efficient sound propagation) reaches the ocean surface.

Ships generate noise primarily by (a) propeller action, (b) propulsion machinery, and (c) hydraulic flow over the hull. Propeller noise is associated with cavitation (Ross 1987, 1993), the creation of voids from zones of pressure above the ambient. The collapse of these voids generates sound. Cavitation creates both broadband noise and tonal sounds, as it may be modulated by blade-passage frequencies and their harmonics (the blade lines). The broadband and tonal components produced by cavitation account for 80-85 percent of ship-radiated noise power (Ross 1987). Propeller noise may be also generated by unsteady propeller blade-passage forces. Additional ship noise results from propulsion machinery such as diesel engines, gears, and major auxiliaries such as diesel generators.

Particular vessels produce unique acoustic signatures associated with noise source levels and frequency bands. Sharp tonal peaks produced by rotating and reciprocating machinery such as diesel engines, diesel generators, pumps, fans, blowers, hydraulic power plants, and other auxiliaries often are seen in these acoustic signatures. Hydrodynamic flow over the ship's hull and hull appendages is an important broadband noise-generating mechanism, especially with increased ship speed. At relatively short ranges and in isolated environments, the spectral characteristics of individual ships can be discerned. At distant ranges in the open ocean, multiple ships contribute to the background, and the sum of many distant sources creates broad spectral peaks of noise in the 5 to 500-Hz band.

Models for representative noise spectra for different classes of ships have been developed by the U.S. Navy. The Research Ambient Noise Directionality (RANDI) model (Wagstaff 1973; Schreiner 1990; Breeding 1993) uses ship length and speed as well as an empirically derived power law to determine the broadband (5-500 Hz) spectral level for various classes of vessels. Peak spectral densities for individual ships range from 195 dB re μPa^2/Hz @ 1 m for fast moving supertankers, to 140 dB re μPa^2/Hz @ 1 m for small fishing vessels. Source-level models have been also developed for the propeller tonal blade lines, occurring at 6-10 Hz for most of the world's large merchant fleet (Gray and Greeley 1980). Small vessels do not contribute significantly to the global ocean acoustic environment, but may be important local sound sources. Examples of noise levels for whale-watching boats are presented by (Au and Green 2000) and (Erbe 2002). A recent study of noise levels from small powerboats suggests peak spectral density levels in the 350-1200 Hz band of 145-150 dB re $1\mu Pa^2$/Hz @ 1 m (Bartlett and Wilson 2002).

Vessel traffic is not uniformly distributed. The major commercial shipping lanes follow great circle routes, or follow coast lines to minimize the distance traveled. Dozens of major ports and "megaports" handle the majority of the traffic, but in addition hundreds of small harbors and ports host smaller volumes of traffic. The U.S. Navy defines 521 ports and 3,762 traffic lanes in its catalog of commercial and transportation marine traffic (Emery et al. 2001). Vessels found in areas outside major shipping lanes include fishing vessels, military ships, scientific research ships, and recreational craft – the last typically found near shore.

Lloyd's Register of the world's commercial fleet for the year 2001 listed 92,817 vessels (NRC 2003). The principal types (their numbers in parentheses) are cargo/passenger transport (34,704), fishing (23,841),

towing/dredging (13,835), oil tankers (10,941), bulk dry transport (6,357), and offshore supply (3,139). Gross tonnage may be a more important index of noise production than vessel numbers. From that perspective, oil tankers and bulk dry transport vessels represent nearly 50 percent of the total tonnage, but less than 8 percent of the total number of vessels.

The numbers of recreational craft are poorly documented. Some information on the number of U.S. boat registrations, by state and category, is available from the National Marine Manufacturer's Association (2003). The vessel categories are outboard, inboard, sterndrive, personal watercraft, sailboats, and miscellaneous.

Vessel operation statistics indicate steady growth in vessel traffic over the past few decades (Mazzuca 2001). There has been an increase both in the number of vessels and in the tonnage of goods shipped. For example, a 30 percent increase has occurred in the volume of goods shipped by the U.S. fleet (by flag and ownership) over the past 20 years (U.S. Maritime Administration, 2003). Oceanic shipping is an efficient means of transporting large quantities of goods and materials globally. The globalization of economic infrastructure means that more raw materials, as well as finished goods, require long-distance transport. The economic incentives for oceanic shipping are strong, and in the near term, there is no viable alternative for transporting large-tonnage materials to distant global locations.

The bulk of U.S. waterborne trade is conducted through a few ports (Table 1). For instance, the combined ports of Los Angeles and Long Beach carry 37 percent of the total (U.S. Maritime Administration 2003). Within the U.S. Exclusive Economic Zone, this concentrates the noise from shipping into the regions adjacent to these ports and their approaches. Since the Southern California Bight is a particularly productive habitat for marine mammals, the concentration of shipping noise within this region is a cause for concern. Significant concentrations of shipping traffic also occur in New York (13 percent) and the Puget Sound area (8 percent).

Table 1: U.S. Foreign Waterborne Trade, Calendar Year 2002
Units are thousands of Twenty-Foot-Equivalent (TEU) containers.
Source: U.S. Maritime Administration (2003)

Rank	U.S. Port	Total	Export	Import
1	Los Angeles	4,060	866	3,194
2	Long Beach	3,184	717	2,467
3	New York	2,627	747	1,879
4	Charleston	1,197	521	676
5	Savannah	1,014	453	561
6	Norfolk	982	431	551
7	Oakland	979	469	482
8	Houston	851	430	420
9	Seattle	850	338	512
10	Tacoma	769	278	491
TOTAL		19,729	6,814	12,916

Plans exist for a new generation of container ship that is significantly faster (36 knots) and has a larger carrying capacity (1,400 Twenty-Foot-Equivalent containers) (Morrison 2000). These plans involve cross-over ship designs from the fast-ferry industry and appear technically feasible. The economic viability of fast shipping depends on the balance between the additional fuel and other expense for shipping the goods, and the value of the goods being shipped. When the cost of greater ship speed is offset by the value gained from diminished time spent in shipping, then faster container ships will become economically competitive. With respect to noise, these vessels will generate more low-frequency noise than current vessel designs owing to their greater speed and propulsive power.

Seismic Exploration

Seismic reflection profiling uses high-intensity sound to image the earth's crust. It is the primary technique for finding and monitoring reserves of oil and natural gas. Seismic reflection profiling is used by academic and government groups to gather information on crustal structure, for the purpose of understanding the origin and tectonic history of the earth's crust.

Arrays of airguns are the sound-producing elements in seismic reflection profiling (Dragoset 1984, 2000). Airguns release a specified volume of air under high pressure, creating a sound pressure wave from the expansion and contraction of the released air bubble. To yield high intensities, multiple airguns are fired with precise timing to produce a coherent pulse of sound. Oil industry airgun arrays typically involve 12 to 48 individual guns, operate at pressures of 2000 psi, and are dispersed over a 20 m by 20 m region, typically towed about 200 m behind a vessel. The pressure output of an airgun array is proportional to (1) its operating pressure, (2) the number of airguns, and (3) the cube root of the total gun volume. For consistency with the underwater acoustic literature, airgun-array source levels are back-calculated to an equivalent source concentrated into a one-meter-radius volume, yielding source levels as high as 256 dB re 1µPa @ 1 m for the Root-Mean-Square (RMS) output pressure (Greene and Moore 1995). This source level predicts pressures in the far-field of the array, but in the near-field the maximum pressure levels encountered are limited to 235-240 dB re 1µPa. The far field pressure from an airgun array is focused vertically, being about 6 dB stronger in the vertical direction than in the horizontal direction for typical arrays. The peak pressure levels for industry arrays are in the 5-300 Hz range. The guns are towed at speeds of about 5 knots and are typically fired about every 10 seconds. A seagoing seismic-reflection operation includes a series of parallel passes through an area by a vessel towing an airgun array as well as 6-10 seismic receiving streamers. A recent practice is the use of repeated seismic reflection surveys for "time-lapse" monitoring of producing oil fields.

Offshore oil and gas exploration and construction activities occur along continental margins. Currently active areas include northern Alaska and northwestern Canada, eastern Canada, the U.S. and Mexican Gulf of Mexico, Venezuela, Brazil, West Africa, South Africa, North Sea, Middle East, northwestern Australia, New Zealand, southern China, Vietnam, Malaysia, and Indonesia. New areas of exploration include the deepwater U.S. Gulf of Mexico and deepwater West Africa, both of which have seen activity in the past 5 to10 years.

Sonar

Sonar systems intentionally create acoustic energy to probe the ocean. They seek information about objects within the water column, at the sea bottom, or within the sediment. Active sonar emits high-intensity acoustic energy and receives reflected and/or scattered energy. A wide range of sonar systems are in use for both civilian and military applications. For purposes of discussion, sonar systems can be categorized as low-frequency (< 1000 Hz), mid-frequency (1 – 20 kHz), and high-frequency (> 20 kHz).

Military sonars are used for target detection, localization, and classification. They generally cover a broader frequency range with higher source levels than civilian sonars. They are operated during both training exercises and combat operations. Because far more time is spent in training than in combat, training exercises may be the primary context in which marine mammals are exposed to military sonar. Low Frequency Active (LFA) sonars are used for broad-scale surveillance; they are designed to allow submarine tracking over scales of many hundreds to thousands of kilometers. Specialized support ships are used to deploy LFA sonars, which consist of arrays of source elements suspended vertically below the ship. The U.S. Navy's Surveillance Towed Array Sensor System (SURTASS) LFA sonar uses an array of 18 projectors operating in the frequency range of 100 to 500 Hz, with 215 dB re 1µPa @ 1 m source level for each projector (Johnson 2002). These systems are designed to project beams of energy in a horizontal direction. The effective source level of an LFA array, when viewed in the horizontal direction, can be 235 dB re 1µPa @ 1 m or higher. The signal includes both continuous-wave (CW) and frequency-modulated (FM) components with a bandwidth of approximately 30 Hz. A ping sequence can last 6 to 100 seconds, with a time between pings of 6 to 15 minutes and a typical duty cycle of 10 to 15 percent. Signal transmissions are emitted in patterned sequences that may last for days or weeks.

Mid-frequency tactical Anti-Submarine Warfare (ASW) sonars are designed to detect submarines over several tens of kilometers. They are incorporated into the hulls of submarine-hunting surface vessels such as destroyers, cruisers, and frigates (see Table 2). There are 117 of these sonars on U.S. Navy ships currently in active service, and equivalent systems in allied navies (e.g., British, Canadian, French). The AN/SQS-53 is the most advanced surface ship ASW sonar used by the U.S. Navy. The AN/SQS-53C sonar generates frequency-modulated pulses of 1-2 second duration in the 1-5 kHz band, at source levels of 235 dB re 1µPa @ 1 m or higher (Evans and England 2001). These sonars emit beams of sound in the horizontal direction. The AN/SQS-53C is designed to perform direct-path ASW search, detection, localization, and tracking from a hull mounted transducer array of 576 elements housed in a bulbous dome located below the waterline of the ship's bow. These systems are used to track both surface and submerged vessels, often picking up surface ships at greater range than most radar systems.

Table 2. US Navy surface ships with Anti-Submarine Warefare active sonars.

Type of Ship	Class	Type of Sonar	Number in use
Cruiser	Ticonderoga	SQS-53	27
Destroyer	Spruance	SQS-53	11
Destroyer	Arleigh Burke	SQS-53	49
Frigate	Oliver Hazard Perry	SQS-56	30
Total			117

Other mid-frequency military sonars in use by the Navy include depth sounders and communication sonars for interplatform information exchange or device activation.
High-frequency sonars are incorporated either into weapons (torpedoes and mines) or weapon countermeasures (mine countermeasures or anti-torpedo devices). They are designed to operate over ranges of a few hundred meters to a few kilometers. Mine-hunting sonars operate at tens of kHz for mine detection and above 100 kHz for mine localization. These sonars are highly directional and use pulsed signals. Other high-frequency military sonars include sidescan sonar for seafloor mapping, generally operated at frequencies near 100 kHz.

Over the past decade, there has been a trend in the U.S. Navy to emphasize training operations in coastal and shallow-water settings. There are currently plans to construct shallow-water training ranges on both the U.S. West and East Coasts. The use of active sonar in these settings means that large numbers of marine mammals may be exposed to high-intensity sonar.

Commercial sonars are designed for fish finding, depth sounding, and sub-bottom profiling. They typically generate sound at frequencies of 3 to 200 kHz, with only a narrow frequency band generated by an individual sonar system. Source levels range from 150-235 dB re 1µPa @ 1 m. Commercial depth sounders and fishfinders are typically designed to focus sound into a downward beam. Depth sounders and sub-bottom profilers are operated primarily in nearshore and shallow environments, however, fish finders are operated in both deep and shallow areas.

The acoustic characteristics of small-scale commercial sonars are unlikely to change significantly in the future since they are limited by several key physical properties. At the low-frequency end (about 3 kHz), they are limited by the physical dimensions of the transducers. At the high-frequency end (200 kHz) they are limited by severe attenuation of sound. Likewise, the maximum power level that can be emitted by a single transducer (200 dB re 1µPa @ 1 m) is limited by cavitation at shallow depths of operation. Higher power levels can be achieved by constructing arrays of sensors on the hull of the vessel. For example, multibeam echosounding systems (e.g., SeaBEAM or Hydrosweep) form narrow directional beams of sound and are used for precise depth sounding. Using hull-mounted arrays of transducers, these systems can achieve 235 dB re 1µPa @ 1 m source levels and are typically operated at 12-15 kHz in deep water, and at higher frequencies (up to 100 kHz) in shallow water.

A significant fraction of the 80,000 vessels in the world's commercial fleet and the 17 million small boats owned in the US are equipped with some form of commercial sonar. Sonar is an extremely efficient means for fish finding and depth sounding/sub-bottom profiling, and new applications may lead to even greater proliferation of these systems.

Research in underwater acoustic propagation and acoustical oceanography often involves use of sound sources. Almost all of these programs are sponsored by the Office of Naval Research, and the information obtained is of value for improving military sonar systems. The sound sources used for these studies are either commercially available transducers or systems specially designed to meet specific research requirements. A wide variety of signals, bandwidths, source levels, and duty cycles are transmitted during these projects. The spatial extent of most experiments is tens of kilometers, but basin-scale projects such as the Acoustic Thermometry of Ocean Climate (ATOC) program have also been undertaken.

The ATOC (later the North Pacific Acoustic Laboratory [NPAL]) project was initiated in the early 1990s to study ocean warming, and received much attention from regulatory agencies, the public, and the scientific community due to concerns regarding the potential impact of its sound source on marine mammals (Baggeroer et al. 1998). This program was extensively discussed in two National Research Council reports (NRC 1994, 2000). The ATOC source has a 195 dB re 1µPa @ 1 m level and is deployed at 939 m, near the axis of the deep sound channel (Howe 1996). It is designed to study the entire North Pacific basin, with the sounds being received by the U.S. Navy's fixed hydrophone arrays. The transmitted signal is centered at 75 Hz with a bandwidth of 37.5 Hz. It broadcasts on 4-hour intervals with a "ramp-up" period of 5 minutes and a full power signal duration of 20 minutes. The long time frame for operation of this experiment was a key aspect that led to questions regarding its potential impacts on marine mammals (Potter 1994).

Another basin-scale sonar research project uses drifting sources (Rossby et al. 1986), called SOFAR or RAFOS floats. These devices drift at depth and periodically emit a high-intensity tone (195 dB re 1µPa @ 1 m) that is frequency swept at 200-300Hz or a CW signal at 185-310 Hz with durations of 120 sec or more. The sounds are detected at distant receivers and their timing is used to determine the float location and therefore its drift, as a proxy for deep currents.

Acoustic Deterrent Devices

Acoustic deterrent devices (ADD) use sound in an effort to repel marine mammals from fisheries activities. The idea behind these devices is that they keep marine mammals away by introducing a local acoustic annoyance. Pingers are used in some fisheries to reduce the bycatch of marine mammals. These are typically low-power ADDs with source levels of 130 – 150 dB re 1µPa @ 1 m. Acoustic harassment devices (AHD) are used to reduce depredation by marine mammals on caught or cultured fish. These are high-powered devices with source levels of 185 – 195 dB re 1µPa @ 1 m. Both pingers and AHDs have frequencies in the 5 – 160 kHz band, and generate pulses lasting from 2 – 2000 msec. To reduce habituation, a single device may transmit a variety of waveforms and have pseudo-random time intervals between transmissions.

Pingers have been shown to be effective in reducing bycatch, at least for some marine mammal species in some settings (Kraus et al. 1997; Culik et al. 2001; Bordino et al. 2002). A trial of pinger use in the California drift gillnet fishery for swordfish and sharks showed that for both cetaceans and pinnipeds, the entanglement rate in nets with pingers was only one third of what it was in nets without these devices (Barlow and Cameron 2003). Likewise, a large-scale trial of pingers in Danish gillnet fisheries showed a reduction in bycatch of harbor porpoises (Larsen 1997; Vinther 1999).

Concerns have arisen that use of AHDs in aquaculture facilities leads to unintended displacement of marine mammals in the cases of killer whales (Morton and Symonds 2002) and harbor porpoises (Olesiuk et al. 2002) in the vicinity of salmon farms off British Columbia. Likewise, there are concerns that widespread use of AHDs may lead to the exclusion of porpoises from important feeding habitat (Johnston 2002). AHDs have sufficiently high source levels that they could result in hearing damage to marine mammals exposed at close range.

Explosions

There are two classes of man-made explosions in or over the ocean: nuclear and chemical. Until the advent of the Comprehensive Test Ban Treaty, nuclear devices were tested regularly in the ocean, in the atmosphere above the ocean, or on oceanic islands. The most recent series of oceanic tests was conducted by France in 1995-1996 on the islands of Fangataufa and Mururoa in the South Pacific. There is currently a low probability of continued ocean testing of nuclear devices although this situation could change with geopolitical developments over the coming years or decades.

Nuclear explosion are extremely strong sources of underwater sound. It is likely that past tests had significant impacts on marine mammals in the vicinity of the test sites. No monitoring data are available, however, to document impacts of nuclear tests on marine mammals. To ensure compliance with the test ban treaty, an international monitoring system is being implemented, including a series of hydrophone- and island-based seismic stations to detect high-intensity sounds (www.ctbto.org). This information is transmitted, in real time, to the International Data Centre where analysts evaluate the data for indications of nuclear explosions. Physical characteristics of the oceans allow the sounds of such explosions to travel for extremely long distances with little energy loss, and monitoring is conducted over a large fraction of the world's oceans with a small number of stations. The network designed for ocean monitoring contains 11 stations located primarily in the Southern Hemisphere.

Clemical explosions are more portable and more easily conducted in an ocean setting. They have been used for oceanic research, for construction, and for military testing. A surprisingly large number (300-4000 per month) of underwater explosions were reported in the North Pacific during the 1960's (Spiess et al. 1968). In the past, chemical explosions were commonly used for marine seismic exploration, but they have been replaced by airgun arrays that provide a more reliable source signature. Chemical explosions continue to be used in the construction and removal of undersea structures, primarily by the oil industry, but the frequency of shot detonation presumably has decreased over the past few decades.

New classes of military vessels undergo tests, called ship-shock trials, to determine their ability to withstand explosions (Commander_Naval_Air_Warfare_Center 1994). During a ship-shock trial, a large chemical explosion (e.g. 10,000 lb) is detonated near the vessel's hull, while measurements of hull stress are conducted. Ocean explosions are also conducted by other Navy programs, such as the "Sinkex" program that sinks retired ships using torpedos or other chemical explosions. Weapons are tested during development, and operational stores are test-fired to monitor their military readiness. During the recent Iraq war, Navy SEA LS disposed of a dozen 500 pound sea mines confiscated from the Iraqi Navy by simultaneously detonating them in the Persian Gulf, a blast that could be heard 50 miles away in Kuwait (Dao 2003).

The spectral and amplitude characteristics of chemical explosions vary with the weight of the charge and the depth of the detonation. The RMS source level of the initial shock wave, a large component of the energy, is given by

$$SL\,(\text{dB re } 1\mu\text{Pa @ 1 m}) = 269\ \text{dB} + 7.53 * \log(w),$$

where w is the charge weight in pounds (Urick 1975). For instance, 100 lb of TNT would produce a shockwave SL of 284 dB re 1µPa @ 1 m with almost constant frequency content from 10 to 1000 Hz. The energy from the bubble pulse oscillations will contribute approximately 5 additional dB of source level, yielding a total SL of 274 dB re 1µPa @ 1 m. Research on blast damage to animals suggests that the mechanical impact of a short duration pressure pulse (positive acoustic impulse) is best correlated with organ damage (Greene and Moore 1995).

Industrial Activities and Construction

Industrial activities and construction both in the ocean and along the shoreline can contribute to underwater noise. Examples include coastal power plants, pile driving, dredging, tunnel boring, power-generating wind

mills, and canal lock operations (Greene and Moore 1995). The coupling of these sounds into the marine environment is poorly understood, but it is generally more efficient at low frequencies.

Marine dredging is commonly conducted in coastal waters to deepen channels and harbors, reclaim land, and mine seabed resources. Reported source levels for dredging operations range from 160 to 180 dB re 1µPa @ 1 m for 1/3 octave bands with peak intensity between 50 and 500 Hz (Greene and Moore 1995).

Oil and gas activities that generate marine noise include drilling, offshore structure emplacement and removal, and production. The associated noise levels from drilling, structures, and production are typically lower than those from seismic surveying. Sound pressure levels associated with drilling are the highest with maximum broadband (10 Hz to 10 kHz) energy of about 190 dB re 1µPa @ 1 m. Drill-ship noise comes from both the drilling machinery and the propellers and thrusters for station-keeping. Jack-ups are the most commonly used offshore drilling devices, followed by platform drill rigs. Drilling generates ancillary noise from the movements of supply boats and support helicopters. Emplacement of offshore structures creates localized noise for brief time periods. Powerful support vessels are used to transport these large structures from the point of fabrication to the point of emplacement. This activity may last for a few weeks and may occur 8 to 10 times a year worldwide. Additional noise is generated during oil production activities, which include borehole casing, cementing, perforating, pumping, pipe laying, pile driving, and ship and helicopter support. Production activities can generate source levels as high as 135 dB re 1µPa at 1 km from the source (Greene and Moore 1995) which suggests as much as 195 dB re 1µPa @ 1 m with peak levels at 40 to 100 Hz.

Oil and gas production is moving from shallow-water settings into water depths of up to 3000 m. Deep-water drilling and production have the potential to generate greater noise than shallow-water production, owing to the use of drill ships and floating production facilities. This noise may be more easily coupled into the deep sound channel for long-range propagation. The worldwide count of offshore mobile drill rigs in use fluctuates with business conditions, but there are an increasing number of drill rigs available, with an approximate 10 percent increase over the past five years.

Comparison and summary of anthropogenic sound sources

The anthropogenic sound sources discussed above are summarized by source level and other parameters in Table 3, ordered by their relative potential for large-scale exposure of marine mammals to high-intensity sound. Underwater nuclear tests and ship-shock trials produce the highest overall sound pressure levels, sufficient to cause physical damage, yet these are rare events and so may be assumed to have limited population-level impacts. Military SURTASS-LFA sonars and large-volume airgun arrays both have high SPLs. The long ping lengths and nearly continuous duty cycle of LFA sonars increase their likelihood of exposing marine mammal populations on a basin-scale. Both the SURTASS-LFA and airgun arrays have dominant energy at low frequencies, where long-range propagation is likely. Tactical military sonars (such as the 53C) have shorter ping durations and more moderate duty cycles than LFA sonars; they also operate at mid-frequencies, where propagation effects limit their range. Concern for the impact of these sonars is for local settings, particularly where deep-diving animals may be present (as discussed later in this paper). Commercial supertankers are arguably the most ubiquitous high-intensity sound source, with more than 10,000 vessels operating worldwide. Concern with these noise sources will be concentrated near major ports and along the most heavily utilized shipping lanes. The moored research sound source for the ATOC project is an equivalent source level to a supertanker although it operates on a much lower duty cycle. Acoustic harassment devices have source levels of concern for long-term hearing damage, and may displace marine mammals from important habitat. Multibeam hull-mounted echo-sounders have a high source level, but their narrow beam widths and mid-frequency character limit their range and the ensonified area. Research acoustic floats (RAFOS) produce a moderately high source level but are operated at a very low duty cycle. Fishing vessels and acoustic deterrent devices have moderate source levels but may represent at least local acoustic annoyances, although in the case of ADDs there is a significant benefit from the reduction of marine mammal bycatch.

TABLE 3. Comparison of anthropogenic underwater sound sources ordered by their potential for marine mammal high-intensity sound exposure.

Sound Source	**SPL** dBre 1µPa @1m	**Ping Energy** (dB re 1µPa^2*s)	**Ping Duration**	**Duty Cycle** (%)	**Peak Frequency** (Hz)	**Band Width** (Hz)	**Direct-ionality**
Underwater Nuclear Device (30 kilo-ton)	328	?	1000 s	Inter-mittant	Low	Broad	Omni
Ship Shock Trial (10,000 lb TNT)	299	?	100 s	Inter-mittent	Low	Broad	Omni
Military Sonar (SURTASS/LFA)	235	243	6 – 100 s	10	250	30	Horizontal
Airgun Array 2000 psi and 8000 in^3	256	241	30 ms	0.3	50	150	Vertical
Military Sonar (53C)	235	232	0.5 – 2 s	6	2,600-3,300	Narrow	Horizontal
Super Tanker 270 m long	198		CW	100	23	5-100	Omni

Acoustic Deterrent Device (AquaMark300)	132	127	300 ms	8	10,000	2000	Omni

Long Term Trends in Ocean Noise

What is the long-term trend for ocean noise? Overall trends of the level of sounds in the sea can be broken down into anthropogenic and non-anthropogenic components. For instance, there is evidence that global climate change may have resulted in higher sea states (Bacon and Carter 1993; Graham and Diaz 2001), which would increase ambient noise levels. Over the past few decades, however, it is likely that increases in anthropogenic noise have been more prominent. In order of importance, the anthropogenic sources most likely to have contributed to increased noise are: commercial shipping, offshore oil and gas exploration and drilling, and naval and other uses of sonar.

To isolate the effects of anthropogenic and non-anthropogenic noise, waters surrounding Australia, which are remote from commercial shipping, have been examined. At low frequency (100 Hz), Australian data suggest that ocean noise levels may be as low as 50 dB re $1\mu Pa^2$/Hz, which is about 30 to 40 dB below levels in North American and European waters ((Cato and McCauley 2002)). These data further suggest that wind/wave noise increases at low frequencies, in contrast to the predictions of the deepwater curves developed from northern hemisphere data (Wenz 1962). Cato (2001, from NRC2003) points to the difficulty of separating wind/wave-generated noise from shipping noise in North American datasets.

Trends in ambient noise over the past few decades suggest that sound levels have increased by 10 dB or more between 1950 and 1975 (Ross 1987, 1993). These trends are most apparent in the eastern Pacific and eastern and western Atlantic, where they are attributed to increases in commercial shipping. A doubling of the number of ships explains 3 to 5 dB, and greater average ship speeds, propulsion power, and propeller tip speeds explain an additional 6 dB.

Other data on long-term noise trends come from comparison of historical U.S. Navy acoustic array data (Wenz 1969) with modern recordings along the west coast of North America (Andrew et al. 2002). A low-frequency noise increase of 10 dB over 33 years is observed at a site off the central California coast. The explanation for a noise increase in this band is the growth in commercial shipping, in terms of both number of ships and gross tonnage. From 1972 to 1999 the total number of ships in the world's fleet increased from approximately 57,000 to 87,000, and the total gross tonnage increased from 268 to 543 million gross tons.

Mazzuca (2001) compared the results of Wenz (1969), Ross (1987), and Andrew (2002) to derive an overall increase of 16 dB in low-frequency noise from 1950 to 2000. This corresponds to a doubling of noise power (3 dB) every decade for the past five decades, equivalent to a 7 percent annual increase in noise. During this period the number of ships in the world fleet tripled (from 30,000 to 87,000) and the gross tonnage increased by a factor of 6.5 (from 85 to 550 million gross tons) (NRC 2003; from (McCarthy and Miller 2002).

Ocean Noise Research Priorities

Ocean noise is an important component of the marine habitat. Data on ocean noise trends are scarce, however, despite substantial investment by the U.S. government in underwater sound data collection for military purposes (e.g. SOSUS and other ASW monitoring systems). Informed estimates suggest noise has increased significantly during the past few decades. Expanding use of the sea for commercial shipping and advanced warfare has resulted in noise levels are at least 10 times higher today than they were a few decades ago. Without some effort to monitor, reduce or at least cap these noise levels, they are likely to increase and further degrade the acoustic environment of marine mammals. A summary of recommendations for tracking and improving our understanding of ocean noise sources are presented in Table 4.

Table 4. Research Priorities for Understanding and Tracking Ocean Noise.

Priority	Research Topic
1	Initiate long-term ocean noise monitoring programs
2	Collect, organize, and analyze historic marine anthropogenic noise data
3	Develop global models for ocean noise
4	Report signal characteristics for anthropogenic noise sources
5	Determine the relationship between anthropogenic activity level and noise level

Priority 1: Initiate long-term ocean noise monitoring

A long-term monitoring program is needed to track future changes in ocean noise (NRC 2003:90). Acoustic data should be included in global ocean observing systems now being developed by U.S. and international research foundations. Data from these monitoring systems should be openly available, and presented in a manner accessible to decision makers in industry, in the military, and in regulatory agencies.

Priority 2: analyze historic marine anthropogenic noise data

In tandem with the effort to collect and monitor present-day ocean noise, a database should be developed to collect, organize and standardize data on ocean noise measurements and related anthropogenic activities (NRC 2003:89). Infrastructure already is in place that is appropriate for maintaining an archive of these data (e.g. the National Oceanographic Data Center, www.nodc.noaa.gov). Currently, data regarding shipping, seismic exploration, oil and gas production, and other marine activities are either not collected or are difficult to obtain and analyze because they are maintained by separate organizations. International cooperation in this effort should be encouraged.

Priority 3: Develop global models for ocean noise

Marine noise measurements and anthropogenic source data should be used to develop a global model of ocean noise (NRC 2003:92). This model should incorporate both transient events, and continuous noise sources. The development an accurate global model depends on access to ocean noise data and anthropogenic activity data, as described for the database research priority above.

Priority 4: Report signal characteristics for anthropogenic noise sources

An important component of model development is better understanding of the signal characteristics for representative anthropogenic noise sources. The description of these signals should include enough information to allow reconstruction of its character (e.g. frequency content, pressure and/or particle-velocity time series, duration, repetition rate).

Priority 5: Determine the relationship between anthropogenic activity level and noise level

Research should be conducted relating the overall levels of anthropogenic activity (such as the types and numbers of vessels) with the resulting noise (NRC 2003:90). These relations will help to extend noise modeling to areas without direct long-term monitoring, but where anthropogenic noise sources are present.

HOW NOISE AFFECTS MARINE MAMMALS

The response of marine mammals to sound depends upon a range of factors including: (1) the sound pressure level and other properties (e.g., frequency, duration, novelty), (2) the physical and behavioral state of the animals, and (3) the ambient acoustic and ecological features of the environment (see Richardson et al. 1995 for a review of marine mammal responses to specific noise sources). No comprehensive understanding of marine mammal responses to noise is available, either to predict how marine mammals respond behaviorally to intense sounds, or to long-term increases in ambient noise.

In humans, the perceived loudness level of a sound involves not only hearing sensitivity but also psychological/physiological factors (Beranek and Ver 1992). A loudness-level scale has been developed

from detailed testing where the human subject judges the relative loudness of two sounds. For instance, the phon (in dB) compares the loudness level of a 1 kHz tone to tones of varying frequency. In practice the annoyance level of a sound depends upon a range of factors in addition to loudness, such as the sound's fluctuation. Intermittent sounds are more annoying than continuous ones. How reliably human noise studies can be extrapolated to marine mammals is problematic, of course, in view of the vast differences in the role of sound in sensing the marine and terrestrial environments.

Marine mammal sound production

The frequency band of noise that may be important to marine mammals should approximately match the range of the sounds that they produce. For large mysticetes, sound production is in the low-frequency range of 10 to 1,000 Hz, whereas for small odontocetes, sound production is in the mid- and high-frequency range of 1 to 200 kHz. Marine mammal call frequencies show an inverse correlation with body size (Watkins and Wartzok 1985), Richardson et al. 1995, Wartzok and Ketten 1999).

Odontocetes produce (a) broadband clicks with peak energy between 5 and 150 kHz, varying by species, (b) burst-pulse click trains, and (c) tonal or frequency-modulated whistles that range from 1 to 25 kHz. Mysticetes generally produce low-frequency sounds in the range 10 Hz to 2 kHz. Mysticete sounds can be broadly characterized as (a) tonal calls, (b) frequency-modulated sweeps, and (c) pulsed tonals. These sounds can be generated either as individual calls or combined into patterned sequences or songs. Pinnipeds that breed on land produce a limited range of barks and clicks ranging from <1 to 4 kHz. Those that mate in the water produce complex vocalizations during the breeding season. All pinnipeds, the sea otter, and manatees use sound to establish and maintain the mother-young bond, especially when attempting to reunite after separation (Sandegren et al. 1973; Hartman 1979).

The ability to use self-generated sounds to obtain information about objects and features of the environment — echolocation — has been demonstrated for at least 13 odontocete species (Richardson et al. 1995). No odontocete has been shown to be incapable of echolocation. Based on their echolocation signals, odontocetes have been divided into two acoustic groups: (a) type I species produce clicks with peak spectra above 100 kHz and few whistles, and (b) type II species produce clicks with peak spectra below 80 kHz and use whistles regularly (Ketten and Wartzok 1990). Type I odontocetes are inshore and riverine delphinids that operate in acoustically complex environments. Examples are Amazon river dolphins (*Inia geoffrensis)* that sometimes hunt small fish in the flooded forest (Norris et al. 1972) and harbor porpoises (*Phocoena phocoena)* that live primarily in shallow, near-shore waters (Kamminga 1988).

Type II odontocetes include nearshore and offshore species that inhabit environments with low object densities and that engage in conspecific communication. Examples are bottlenose dolphins (*Tursiops truncates*), which are coastal, and pantropical spotted dolphins (*Stenella* spp.), which often occur in offshore waters. There is some suggestion of a negative correlation between body size and the maximum frequency of whistles (Ding et al. 1995). Odontocete whistles have been described as "signature" calls which identify individuals (Caldwell and Caldwell 1965). Likewise burst-pulse sounds produced by killer whales are group-specific (Tyack 2000) and click train codas in sperm whales show geographic variation (Rendell and Whitehead 2003).

Source levels for odontocete clicks have been reported to be as high as 228 dB re 1µPa @ 1 m for false killer whales (*Pseudorca crassidens)* (Thomas and Turl 1990) and for bottlenose dolphins echolocating in the presence of noise (Au 1993) and 232 dB re 1µPa @ 1 m for male sperm whale (*Physeter macrocephalus*) clicks (Mohl et al. 2000). The short duration of these echolocation clicks (50 to 200 µs) means that their total energy is low (197 dB re 1µPa^2-sec) although their source levels are high. Odontocete whistles have lower source levels than their clicks, ranging from less than 110 dB re 1µPa @ 1 m for the spinner dolphin (*Stenella longirostris*) (Watkins and Schevill 1974) to 169 dB re 1µPa @ 1 m for bottlenose dolphins (Janik 2000) and 180 dB re 1µPa @ 1 m for short-finned pilot whales (*Globicephala macrorhychus*) (Fish and Turl 1976). The detection range for odontocete clicks and whistles may be 1 km or less, although much greater detection ranges also have been reported (Leaper et al. 1992; Barlow and Taylor 1998; Gordon et al. 2000).

Mysticete calls can be detected over long ranges (Payne and Webb 1971). For instance, blue whales (*Balaenoptera musculus*) produce low-frequency (10 to100 Hz) calls with estimated source levels of 185 dB re 1µPa @ 1 m (McDonald et al. 2001). Most large mysticetes (blue, fin, bowhead, right, humpback, Bryde's, and gray whale) are known to vocalize at frequencies below 1 kHz, with estimated source levels as high as 180 dB re 1µPa @ 1 m (Richardson et al. 1995).

Source levels and frequencies have been estimated for the underwater calls of several species of pinnipeds. Examples are the Weddell seal (*Leptonychotes weddellii*), which produces calls from 148 to 193 dB re 1µPa @ 1 m at frequencies of 0.2 to 12.8 kHz (Thomas and Kuechle 1982), and the Ross seal (*Ommatophoca rossi*), which produces calls at 1 to 4 kHz (Watkins and Ray 1985). These calls may be detected at ranges of several kilometers both in the open ocean and under ice (Wartzok et al. 1992).

Marine mammal hearing

Sound propagates efficiently underwater, and one reflection of its importance to marine mammals is their development of broader hearing frequency ranges than is typical for land mammals. Audiograms have been produced for 10 species of odontocetes and 11 species of pinnipeds, out of a total of approximately 119 marine mammal species (data are summarized by Wartzok and Ketten 1999). All hearing data are from species that are small enough to be held in captivity. Direct hearing data are not available for the species that are not readily tested by conventional audiometric methods. For these species, audiograms must be estimated from mathematical models based on ear anatomy or inferred from the sounds they produce and from field exposure experiments.

Most odontocetes have functional hearing from 200 Hz to 100 kHz, and some species may hear frequencies as high as 200 kHz. Odontocete hearing has peak sensitivity between 20 and 80 kHz, along with moderate sensitivity in the 1–20 kHz range. Because ambient noise decreases at high frequencies, odontocetes may find an advantage in having their hearing and echolocation at high a frequency to filter out as much of the low-frequency noise as possible.

Based on modeling but with no measured audiograms, mysticete hearing ranges between 20 Hz and 20-30 kHz. Several of the larger species, such as blue and fin whales, are predicted to hear at infrasonic (10 Hz) frequencies. Pinnipeds have their best hearing between 1 and 20 kHz, with the exception of the northern elephant seal, which has good hearing below 1 kHz (Kastak and Schusterman 1998). Some pinnipeds hear moderately well in both water and air, while others are better adapted for underwater than for in-air hearing.

Marine mammal hearing is adapted to an aquatic environment, yet their inner ears resemble those of land mammals. The divergence in hearing physiology between land and marine mammals is most pronounced in the external ears, which are absent in most marine mammal species, and in the middle ears, which are extensively modified in marine mammals. Because hearing loss in land mammals is often related to physical damage to the inner ear, hearing loss in marine mammals may involve similar mechanisms. Because ambient noise in the sea can vary by many orders of magnitude due to storms and other natural phenomena, marine mammals may have developed resilient inner ears to guard against hearing loss. Existing studies do not allow for prediction of the impacts of high-intensity sounds on marine mammal hearing except in general terms.

Hearing Losses

Hearing thresholds for hearing may be degraded by exposure to high-intensity sound. Hearing losses are classified as either temporary threshold shifts (TTS) or permanent threshold shifts (PTS), where repeated TTS may lead to PTS. The extent of hearing loss is related to the sound power spectrum, the hearing sensitivity, and the duration of exposure. High-intensity, impulsive blasts can damage cetacean ears (Ketten et al. 1993). Hearing losses may result in poor conspecific communication, lessened abilities for echolocation and foraging, and erratic behavior with respect to migration, mating, stranding, and

vulnerability to predators. For cetaceans, which are highly dependent on their acoustic sense, both TTS and PTS must be considered serious.

There are relatively few data on hearing loss in marine mammals. Experiments on captive bottlenose dolphins (Ridgway et al. 1997) suggest that TTS is observed at levels of 193 to 196 dB re 1µPa for exposure to 1-second tones at 20 kHz. Recent work by (Finneran et al. 2002) with impulsive sources (seismic waterguns) suggest that exposure to sound pressure levels of 217 dB dB re 1µPa and total energy fluxes of 186 dB dB re 1µPa^{2}s produces TTS in beluga whales (*Delphinaptera leucas*). One assumption is that animals are most vulnerable to TTS at the frequencies of their greatest hearing sensitivity. For baleen whales, this suggests low-frequency sensitivity and for smaller cetaceans, mid- and high-frequency sensitivity. It also raises the question of why marine mammals (apparently) do not damage their hearing by their own sound production, as both the tonal and impulsive sounds that they produce can be comparable in SPL to those found to induce TTS in the controlled experiments mentioned above. It appears that there are internal mechanisms that protect an animal from its own vocalisations. For instance, the pterygoid sinus cavities of odontocetes may be positioned to shield their inner ears from their own sound production.

Noise Masking

Acoustic signals are detected against a background of ambient noise. When background noise increases, it may reduce an animal's ability to detect relevant sound, called noise masking. Noise is effective for masking when it is within a critical band (CB) of frequency around the desired signal. The amount by which a pure tone must exceed the noise spectral level to be audible is called the critical ratio (CR). The CR is related to the bandwidth within which background noise affects the animal's ability to detect a sound. Estimates of marine mammal CBs and CRs come from captive odontocetes and pinnipeds (Richardson et al. 1995). For all species, when CB is plotted as a function of frequency, there is a steep rise at low frequencies (25 – 75 percent at 100 Hz), and a much lower level (1 – 10 percent) at mid and high frequencies (1 – 100 kHz). This suggests that narrow-band noise is more effective at masking low frequencies than mid and high frequencies. An animal's directional hearing capabilities may aid in avoiding masking by resolving the different directions of propagation between the signal and the noise. A directivity index of as much as 20 dB has been measured for bottlenose dolphins (Au and Moore 1984), whereas directional hearing is less acute in pinnipeds.

Masking of beluga whale sounds by icebreaker noise has been studied (Erbe and Farmer 1998; Erbe 2000; Erbe and Farmer 2000), including construction of software to model this process (Erbe et al. 1999). Icebreaker noise from ramming, ice cracking, and bubbler systems were shown to produce masking at noise-to-signal ratios of 30 to 800 (15 to 29 dB). The predicted zone of masking for beluga calls from ramming noise was 40 km (Erbe and Farmer 2000). Beluga whales' vocal output changes when they are moved to locations with higher background noise. With noise at low frequencies, an animal increases both the sound pressure level and the frequency of its vocalizations, perhaps in an attempt to avoid masking. Beluga whales also have been observed to increase call rates and shift to higher call frequencies in response to boat noise (Lesage et al. 1999).

Hearing Development

Is increased noise in the oceans causing developmental problems for young animals? High-noise environments affect speech and language development in very young rats (Chang and Merzenich 2003). Brain circuits that receive and interpret sound did not develop at the same rate in animals living in an environment of continuous background noise as in animals that were raised in a quiet environment. It took three to four times as long for rats raised in a noisy environment to reach the basic benchmarks of auditory development. For marine mammals, these data may be difficult to obtain but should be an important consideration of the potential impact of ocean noise.

Effects of Noise on Marine Mammal Behavior

The behavioral responses of marine mammals to noise are complex and poorly understood (Richardson et al. 1995). They may depend upon hearing sensitivity, behavioral state, habituation or desensitization, age,

sex, presence of offspring, location of exposure, and proximity to a shoreline. Behavioral responses may range from subtle changes in surfacing and breathing patterns to cessation of vocalization to active avoidance or escape from the region of highest sound levels. For instance, several studies suggest that bowhead whales (*Balaena mysticetus*) follow a pattern of shorter surfacings, shorter dives, fewer blows per surfacing, and longer intervals between blows when exposed to anthropogenic noise, even at moderate received levels (114 dB re 1µPa). Another common response pattern is a reduction or cessation of vocalization, such as for right whales (*Eubalaena* spp.) in response to boat noise (Watkins 1986), bowheads in response to playback of industrial sounds (Wartzok et al. 1989), sperm whales in response to pulses from acoustic pingers (Watkins and Schevill 1975) and in the presence of military sonar (Watkins et al. 1985), and sperm and pilot whales in response to the Heard Island test acoustic source (Bowles et al. 1994). Moreover, humpback whales (*Megaptera novaeangliae*) lengthen their song cycles when exposed to the LFA source (Miller et al. 2000), move away from mid-frequency sonar (Maybaum 1993), and tend to cease vocalizations when near boats (Watkins 1986). Beluga whales adjust their echolocation clicks to higher frequencies and higher source levels in the presence of increased background noise (Au et al. 1985). Gray whales (*Eschrichtius robustus*) exhibited an avoidance response when exposed to airgun noise, and their response became more as the source level increased from 164 to 180 dB re 1µPa (Malme et al. 1984). They also preferentially avoided LFA transmissions conducted in a landward direction (Tyack and Clark 1998).

Marine mammals have also been observed to have little or no reaction to some anthropogenic sounds. For example, sperm whales continued calling when they encountered echosounders (Watkins 1977) and when they were exposed to received sound levels of 180 dB re 1µPa from a detonator (Madsen and Mohl 2000). A fin whale (*Balaenoptera physalus*) continued to call with no change in rate, level, or frequency in the presence of noise from a container ship (Edds 1988).

Age and sex are important factors in marine mammal noise sensitivity. For instance, juvenile and pregnant northern sea lions (*Eumetopias jubatus*) are more likely to leave a haul-out site in response to aircraft overflights than are territory-holding males and females with young (Calkins 1979). Walruses (*Odobenus rosmarus*) may stampede and crush calves (Loughrey 1959) or temporarily abandon calves (Fay et al. 1984) when exposed to sounds from aircraft or vessels. Likewise, in gray whales cow-calf pairs are more sensitive than other age or sex classes to disturbance by whale-watching boats (Tilt 1985), and humpback groups containing at least one calf are more sensitive to vessel traffic than are groups without calves (Bauer et al. 1993).

Marine mammal responses also appear to be affected by the location, motion, and type of onset of a sound source. California sea lions (*Zalophus californianus*) and harbor seals (*Phoca vitulina*) react at greater range from a ship when they are hauled out, and this is also true of walruses (Fay et al. 1984). Bowheads are more responsive to overflights of aircraft when they are in shallow water (Richardson and Malme 1993). Fin whales are more tolerant of a stationary than a moving source (Watkins 1986). Humpback whales are less likely to react to a continuous source than to one with a sudden onset (Malme et al. 1985). In the St. Lawrence River, beluga whales are less likely to change their swimming and diving patterns in the presence of vessels moving at low speed than in the presence of fast-moving boats (Blane and Jaakson 1994). In Alaska, beluga whales feeding on river salmon may stop and move downstream in response to noise from small boats, whereas they are relatively unresponsive to noise from fishing boats (Stewart et al. 1982). In Bristol Bay beluga whales continue to feed even when surrounded by fishing vessels, and they may resist dispersal even when purposely harassed (Fish and Vania 1971).

Few studies document long-term responses to anthropogenic noise by marine mammals. At Guerrero Negro Lagoon in Baja California, shipping and dredging noise associated with a salt works may have induced gray whales to abandon the area through most of the 1960s (Bryant et al. 1984). After ship traffic declined, the lagoon was reoccupied, first by single whales and later by cow-calf pairs. Killer whales (*Orcinus orca*) in the British Columbia region were displaced from Broughton Archipelago during 1993-1999, a period when acoustic harassment devices were in use at existing salmon farms (Morton and Symonds 2002).

Habituation and tolerance of noise

Habituation is the loss of sensitivity to noise over time. The best evidence for habituation of marine mammals to intense sound comes from attempts to use acoustic harassment devices (AHDs) to keep marine mammals away from aquaculture facilities or fishing equipment (Jefferson and Curry 1994). For instance, there is some evidence that harbor seals habituate to AHDs, partly because they modify their swimming behavior to keep their heads out of the water when they are in high-intensity sound fields (Mate and Harvey 1987). Likewise, harbor porpoises have been shown to habituate to gillnet pingers over a span of 10 or 11 days (Cox et al. 2002).

Observations of responses to whale-watching and other vessels also suggest some level of habituation to noise. Near Cape Cod, minke whales (*Balaenoptera acutorostrata)* changed from being attracted to vessels to appearing generally uninterested; fin whales from flight reactions to disinterest, and humpback whales from mixed but usually strongly negative to strongly positive reactions (Watkins 1986). At San Ignacio Lagoon, gray whales become less likely to flee from whale-watching boats as the season progresses (Jones and Swartz 1984).

Habituation does not signify that hearing loss or injury from high-intensity sounds has not occurred. Humpback whales found in Newfoundland remained in a feeding area near where seafloor blasting was being conducted (Todd et al. 1996). Received sound pressure levels at 1 mile from the explosions were typically 145-150 dB re 1µPa at 240-450 Hz, with presumed source levels of 295-300 dB re 1µPa at 1 m. The whales showed no clear reaction to the blasting in terms of behavior, movement, or residence time. However, increased entrapment in nets followed the blast exposure (Todd et al. 1996). In addition, two whales were found dead after a 5000-kg explosion, and examination of the temporal bones of their inner ears revealed significant blast trauma (Ketten et al. 1993). This incident highlights the difficulty of using overt behavioral reactions to monitor marine mammal harassment by noise or high intensity sound.

Incidents of Mass Stranding Associated with High-Intensity Sound

On several occasions multiple-animal strandings have been associated with the use of high-intensity sonar during naval operations and airguns during seismic reflection profiling. Most of these incidents involved Cuvier's beaked whales (*Ziphius cavirostris)*. At many of these sites, Cuvier's beaked whale is not thought to be the most abundant cetacean species present.

Only odontocetes are known to mass strand, that is, to come ashore in groups of two or more animals (Walsh et al. 2001). Mass strandings of beaked whales are relatively rare events. The National Museum of Natural History, Smithsonian Institution (James Mead, pers. comm.) has compiled a global list of *Ziphius cavirostris* strandings involving two or more animals (Table 5). Except for a stranding of two individuals in 1914, there are no records of multiple-animal strandings until 1963. However, from 1960 to 2000, 3 to 10 multi-animal strandings have been recorded per decade.

The first published suggestion of a connection between beaked whale strandings and naval activity was by (Simmonds and Lopez-Jurado 1991). They described a set of three multi-animal strandings associated with naval activity in the Canary Islands in 1985, 1988, and 1989. Additional incidents of beaked whale mass strandings in the Canary Islands were noted in 1986 and 1987. Simmonds and Lopez-Jurado (1991) did not draw a connection between beaked whale mass strandings and the use of ASW sonar, but rather to the nearby presence of naval operations.

The increased incidence of multi-animal beaked whale stranding events indeed may be correlated with the advent of high-intensity sonar. Prototypes of hull-mounted ASW sonars (e.g., SQS-23 and 26) were first tested in 1957 (Gerken 1986) and were deployed on a broad range of naval ships (frigates, cruisers, and destroyers) operated by the United States and other nations beginning in the early 1960s. This timing coincides with increased reports of mass strandings of Cuvier's beaked whales (Table 5). A third (11 of 32) of the documented strandings of *Ziphius cavirostris* strandings are associated with concurrent naval activities.

An examination of the circumstances surrounding mass strandings of beaked whales may help to define their relationship with the use of high-intensity sound. Two such strandings have been documented by investigative reports: the Kryparissiakos Gulf, Greece, incident of May 1996 (D'Amico and Verboom 1998), and the Bahamas incident of March 2000 (Evans and England 2001). Examination of other beaked whale mass strandings provides additional perspective on the diversity of sound sources, environment, and conditions associated with these events.

Table 5. Strandings involving at least two *Ziphius cavirostris* (Zc) from Smithsonian records (James Mead, pers. comm., with author updates). These represent the only known multiple stranding events for *Mesoplodon europaeus* (Me) and *Mesoplodon densirostris* (Md).

Kryparissiakos Gulf, Greece, May 1996

Frantzis (1998) first brought attention to a mass stranding of Cuvier's beaked whales in the Ionian Sea, which coincided with tests of an ASW sonar (LFAS) by the North Atlantic Treaty Organization (NATO). Along 56 km of coastline, 14 *Ziphius cavirostris* stranded during 12–13 May 1996. Twelve of 14 animals stranded alive, with no apparent disease or pathogenic cause. These strandings corresponded with a four-day period (12–16 May) when the vessel *NRV Alliance* was towing an acoustic source in the vicinity. The acoustic source generated both low-frequency and mid-frequency sound at source levels of 226 dB re 1µPa @ 1m. The transmitted low-frequency signal included a 2 sec upsweep at 450-650 Hz, and a 2 sec cw tone at 700 Hz. The mid-frequency signal included a 2 sec upsweep at 2.8-3.2 kHz and a 2 sec tone at 3.3 kHz. Both sources projected horizontally directed beams of sound with vertical beamwidths of about 23 degrees. Three source tows of about 2 hours duration were conducted each day; and the strandings occurred most closely in time with the first two source runs of 12 May (runs 9 and 10, D'Amico and Verboom [1998]) and the last two source runs of 13 May (runs 13 and 14, D'Amico and Verboom [1998]).

The association of stranding locations and acoustic source tracks in space and time is compelling evidence that these animals were affected by the ASW sonar (D'Amico and Verboom 1998). Figure 1 shows the acoustic source tracks and stranding locations for 12 and 13 May. There is a general correlation between the offshore source track locations and the inshore stranding locations. The 13 May source tow track is shifted northward from the 12 May track, and likewise some of the 13 May stranding locations are farther north. Correlation of stranding times and source track locations for 12 May suggests that at least three of the six animals with known stranding times were affected by the 0600-0800 source tow (run 9) as their stranding times precede the 1100-1300 source tow (run 10). Assuming that they were near the source when they were exposed to a high sound level, their swimming distances were approximately 30 nm to reach the shore, covered at speeds of approximately 10 knots. The two strandings in the afternoon of 12 May with known times likewise required swimming distances of 20-30 nm.

Bahamas, March 15 -16, 2000

Sixteen cetaceans were found stranded along the Providence Channel in the Bahamas Islands during a two-day period in March 2000. This mass stranding correlated with a U.S. Navy training exercise using ASW sonar (Evans and England 2001). The stranded animals were predominantly beaked whales (*Z. cavirostris* [9], *Mesoplodon densirostris* [3]), and *Ziphiid* sp. [2]). At least two minke whales (*Balaenoptera acutorostrata)* were also found stranded. One dolphin *(Stenella frontalis)* stranded at a somewhat distant location and may have died of unrelated causes. Eight of the beaked whales died, and the remaining animals were refloated and their fate is unknown. None of these animals has been recognized as restranded or resighted (Balcomb and Claridge 2001). Tissue samples were collected from five of the dead beaked whales. Gross necropsy results suggested that all five were in good body condition; none showed evidence of debilitating disease. Some kind of auditory damage was found in four of the beaked whales examined. Hemorrhages were found in the acoustic fats of the head, the inner ears, and some spaces around the brain, with no evidence of external blunt force trauma. The pattern of injury in the freshest specimens suggested that the ears were structurally intact and the animals were alive at the time of injury (Evans and England 2001).

Four U.S. Navy ships were operating hull-mounted ASW sonars in the area, two SQS-53C and two SQS-56. The SQS-53C sonars were operated at 2.6 and 3.3 kHz with a source level of 235 dB re 1µPa @ 1 m or higher, and 0.5 - 2 sec ping lengths alternating between tones and frequency-modulated sweeps. The SQS-56 sonars were operated at 6.8, 7.5, and 8.2 KHz at 223 dB re 1µPa @ 1 m. Integrated sound exposure levels >160 dB for 10-30 sec were found throughout much of the Providence Channel during 15 March 2000 (Evans and England 2001).

The association of stranding locations and acoustic source tracks in space and time is compelling evidence that these animals were affected by the high-intensity sound sources (Evans and England 2001). The acoustic source tracks and stranding locations are shown in Figure 2, divided into the morning (0700-1100) and afternoon (1200-1430). During the morning two source ships were in the Providence Channel off the southwest end of Abaco Island and moving toward the west, and the other two source ships were entering the channel from the east. A cluster of strandings occurred at the south end of Abaco Island during this

time, at minimum ranges of 10-30 nm from the ships' closest points of approach. During the afternoon, the source ships moved northwestward, approaching Grand Bahama Island. A cluster of noon and afternoon strandings occurred on the south coast of Grand Bahama Island, again with minimum source-to-shore ranges of 20-30 nm. Assuming that these animals received peak sound exposures at locations near the source tracks, then immediately following exposure they would have swum toward the stranding sites at high speed (~ 10 kts). Alternatively, lower exposure levels more distant from the source tracks and closer to the stranding sites would imply slower swim speeds.

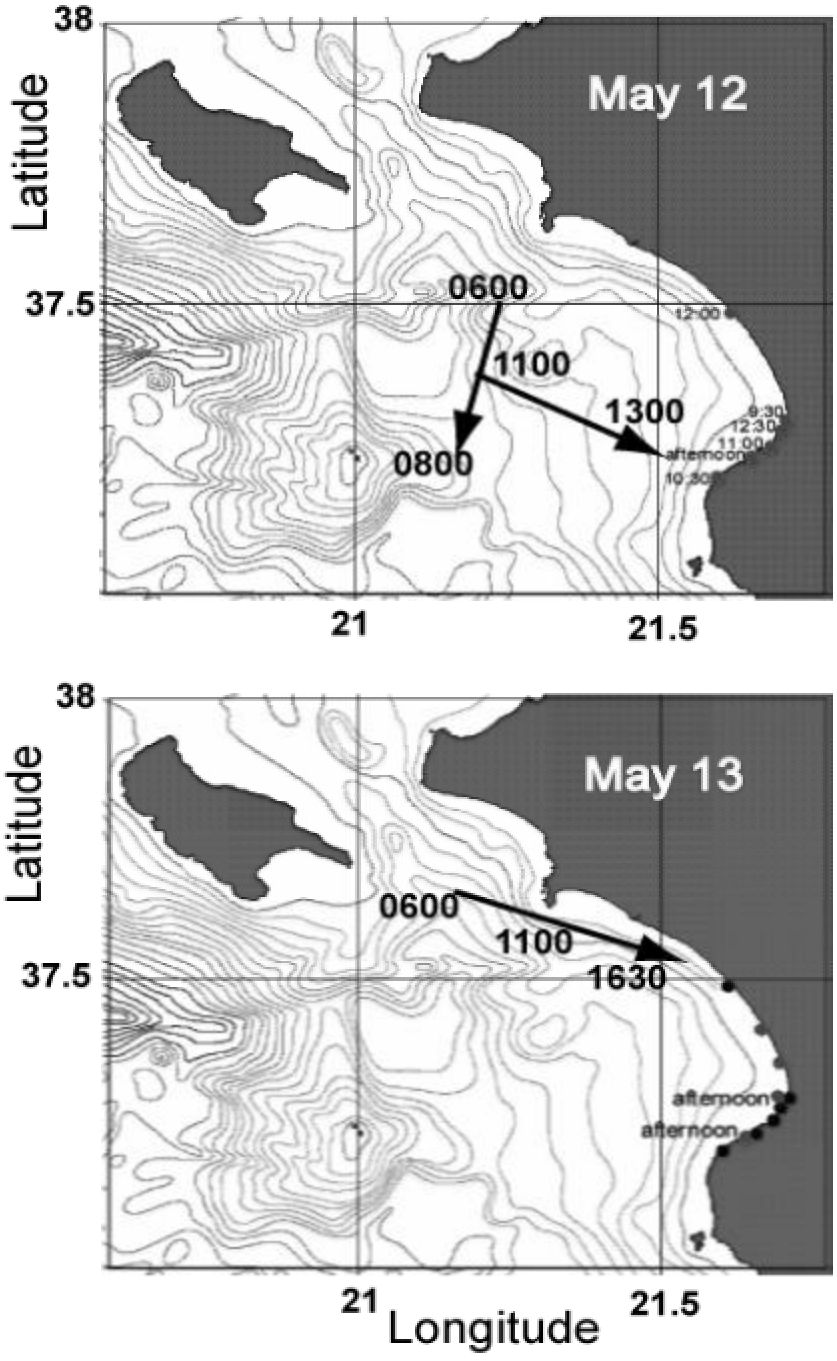

Figure 1. Kyparissiakos Gulf, Greece, *Ziphius cavirostris* stranding locations and acoustic source tracks for 12 May (upper) and 13 May (lower) 1996. Known times are indicated in GMT.

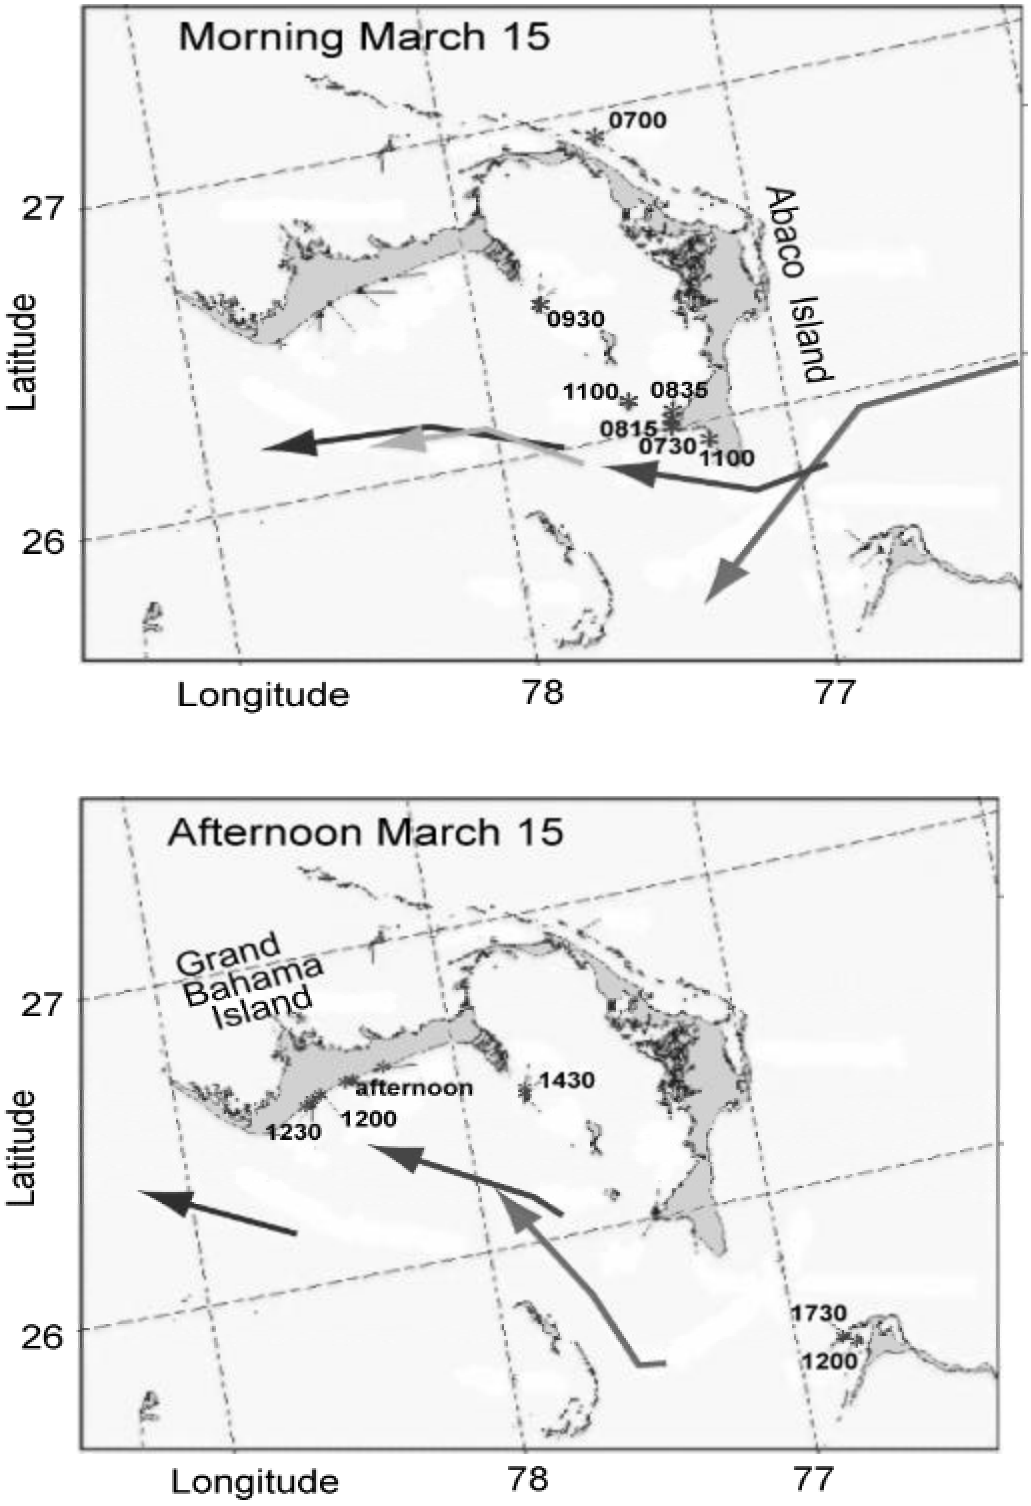

Figure 2. Bahamas strandings locations and acoustic source tracks for 15 March 2000, morning (upper) and afternoon (lower). Known times are indicated in GMT.

Madeira, May 2000

A stranding of three *Ziphius cavirostris* occurred in May 2000 on the Madeira Archipelago, in the northeastern Atlantic (Luis Freitas, Madeira Whale Museum, pers. comm.). The deep-water channel between islands has been the site of repeated observations of live *Z. cavirostris*. The animals that stranded in May 2000 consisted of two subadults (one male, one female) and a female of unknown age. The two subadults were examined and found to have hematomas, eye hemorrhages, pleural hemorrhages, and lesions of the lungs (Luis Freitas, pers. comm.). The third animal was found in an advanced state of decomposition and did not receive a detailed examination. The presence of a NATO exercise was signaled by naval vessels and aircraft in the deep-water channel, coincident with the stranding events. Details of the acoustic sources in use during this exercise are lacking at this time.

Canary Islands, 24 September 2002

A mass stranding of as many as 19 beaked whales occurred on the Canary Islands of Fuerteventura and Lanzarote, associated with naval maneuvers by Spain and other NATO countries on 24–25 September 2002. The stranded animals were predominantly *Ziphius cavirostris* (7), but also included *Mesoplodon europaeus* (2) and *Mesoplodon densirostris* (1). On 24 September a total of 14 animals were found stranded; five were dead, three were alive and subsequently died, and six were pushed back to sea. Five more animals were found dead and in a state of decomposition between 25 and 28 September. It is possible that these included animals that had been pushed out to sea and subsequently stranded . Preliminary necropsy results for six of the beaked whales suggest that they were healthy. The strandings occurred at dawn or in the early morning, and the animals that were found alive all appeared disoriented. Those that were found dead had been feeding recently (Vidal Martín and Antonella Servidio, pers. comm.).

Necropsies and dissections revealed no visible signs of trauma (Antonio Fernández, Universidad de Las Palmas de Gran Canaria). Hemorrhages were observed along acoustic paths and in the brain and spinal cord. All animals were bleeding profusely in the eyes. Multifocal petechial (pinpoint) hemorrhages were observed, similar to decompression sickness. Fat embolism was observed, which could have been responsible for hemorrhages in the macrovascular system. Degeneration (in vivo) of vestibucochlear portions of the ear were noted, specifically, degeneration and resorption of some hair cell bundles and associated nerve fibers. This may suggest a chronic condition, and that some damage to the cochlea had occurred prior to this stranding event.

The strandings occurred along the southeastern coast of the islands of Fuerteventura and Lanzarote. At the time of the 24–25 September strandings, 10 NATO countries — Germany, Belgium, Canada, France, Greece, Norway, Portugal, Britain, Turkey, and the United States — were conducting a multinational naval exercise; however, the acoustic sources employed during the exercise are not known at this time. There have been seven mass strandings of *Z. cavirostris* in the Canary Islands since 1985, and naval exercises have been recorded as associated with five of them (Table 5).

Gulf of California, 24 September 2002

A stranding of two *Ziphius cavirostris* occurred on 24 September 2002 on Isla San Jose in the Gulf of California, Mexico, coincident with seismic reflection profiling by the *R/V Maurice Ewing* operated by Columbia University, Lamont-Doherty Earth Observatory (Malakoff 2002). On 24 September at about 2 to 4 PM local time (2100–2300 GMT), fishermen discovered two live stranded whales and unsuccessfully attempted to push them back out to sea (Jorge Urbán, pers. comm.). A group of marine biologists found the whales dead on 25 September (Barbara Taylor, pers. comm.). By 27 September, when one carcass was necropsied, the advanced state of decomposition did not allow the cause of death to be determined.

On 24September the *R/V Ewing* had been firing an array of 20 airguns with a total volume of 8500 cubic inches. These airguns have an equivalent broadband source level of 256 dB re 1µPa @ 1m, with peak energy frequencies at 40-100 Hz. Source levels at mid-frequencies (1-5 kHz) may be diminished by 20 to 40 dB (Goold and Fish 1998). The airguns were fired with an approximately 20 sec repetition rate (50 m distance between shots). Figure 3 indicates the ship track for 24–25 September; the *R/V Ewing* was on a transect line directed toward the stranding site and reached the closest point-of-approach (within 22 km) at 1400 local time (2100 GMT) range.

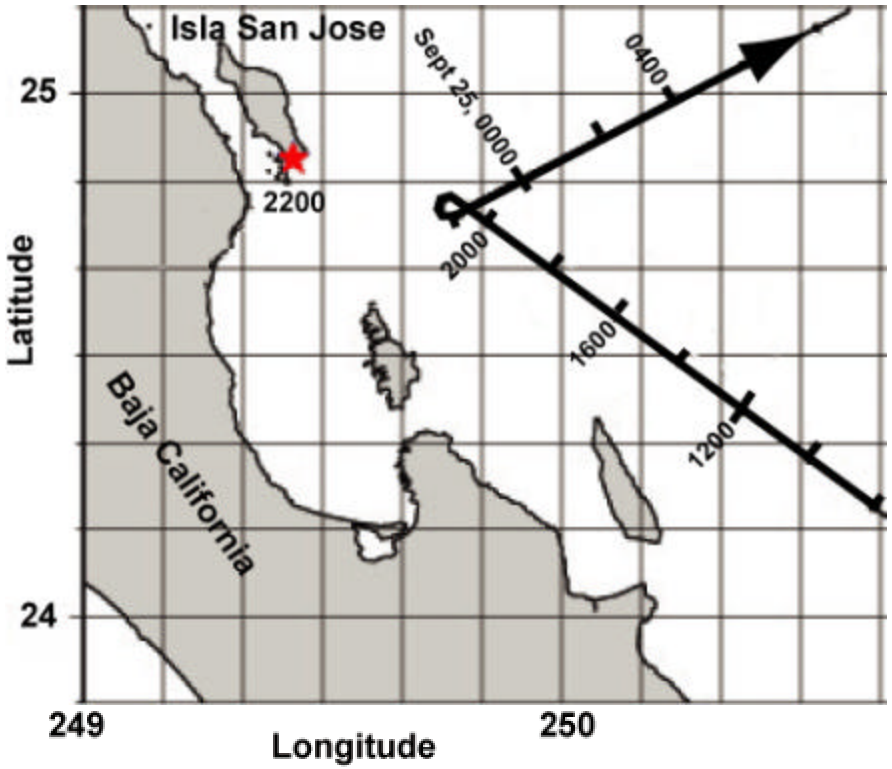

Figure 3. Gulf of California standings location and acoustic source tracks for 24–25 September 2002. Times are indicated in GMT.

Summary of Beaked Whale Stranding Events

Repeated mass strandings of beaked whales following high-intensity sound exposure demonstrate a pattern of events. Cuvier's beaked whales are, by far, the most common species involved in these stranding events; they make up 81 percent of the total number of stranded animals. Other beaked whales (including *Mesoplodon europaeus*, *Mesoplodon densirostris*, and *Hyperoodon ampullatus)* comprise 14 percent of the total, and other species (*Stenella coeruleoalba*, *Kogia breviceps*, and *Balaenoptera acutorostrata*) are sparsely represented. It is not clear whether (a) *Ziphius cavirostris* is more prone to injury from high-intensity sound than other species, (b) its behavioral response to sound makes it more likely to strand, or (c) it is substantially more abundant than the other affected species in the areas and times of the exposures leading to the mass strandings. One, two, or three of these possibilities could apply. In any event, *Ziphius cavirostris* has proven to be the "miner's canary" for high-intensity sound impacts. The simultaneous deployment of naval ASW sonars in the 1960s and the coincident increase in *Ziphius cavirostris* mass strandings suggest that lethal impacts of anthropogenic sound on cetaceans have been occurring for at least several decades.

The settings for these incidents are strikingly consistent: an island or archipelago with deep water nearby, appropriate for beaked whale foraging habitat. The conditions for mass stranding may be optimized when the sound source transits a deep channel between two islands, such as in the Bahamas incident. When exposed to high sound levels, beaked whales rapidly swim to the nearest beach. The animals appear on the beach not as one tight cluster of individuals but rather distributed over miles of coastline. Hypothermia ensues, and the animals die if they are not returned to the sea by human intervention. The fates of those animals that are returned to the sea are unknown. Necropsies of stranded animals suggest internal bleeding in the eyes, ears, and brain, as well as fat embolisms.

The implicated sound levels involve long-duration (~ 1 sec) and high-intensity (235 dB re 1µPa @ 1 m) sonar pings or equivalent airgun blasts. Mid-frequency (1-6 kHz) sound is clearly implicated in the sonar-

induced stranding incidents. It is unclear whether low-frequency sound also causes injury to beaked whales. Although airguns create predominantly low-frequency energy, they also have ample mid-frequency energy, which may be related to the associated injuries.

Research Priorities for Marine Mammal Noise Effects

Almost a decade has passed since the NRC (1994) outlined a set of research priorities for understanding the effect of noise on marine mammals. In most of the areas outlined for study by the NRC (1994) report, we still lack basic understanding. Many of the same research priorities were reiterated by two subsequent NRC (2000, 2003) reports directed at understanding marine mammal noise impacts. The need to conduct most of these noise impact studies in the field, rather than in captive settings, means that it may be many years before a clear understanding of these issues becomes available. There is an additional need to differentiate those effects that are significant to individual animals from those that are significant on a population level. This distinction points to the need for observations that are distributed in space and time, and involve large numbers of cases to create strong statistics. With these issues in mind, Table 6 summarizes key research priorities needed to diminish the uncertainties associated with anthropogenic noise production and the protection of marine mammals.

Table 6. Summary of Research Priorities for the Effect of Noise on Marine Mammals.

Priority	Research Issue
1	Understand the detailed causes of beaked whale mass stranding events
2	Determine behavioral responses to anthropogenic sound
3	Improve tools for marine mammal behavioral observation including acoustic recording tags and passive acoustic methods
4	Develop tools to study marine mammal physiology in the wild including stress indicators and hearing capabilities
5	Characterization of marine mammal populations within areas of high intensity sound generation

Priority 1: Understand the causes of beaked whale mass stranding events

When exposed to high intensity sound levels, beaked whales strand and die in mass. Understanding the causes and consequences of beaked whale mass stranding represents the highest research priority for our community. The sound levels implicated in these events is probably not sufficient to cause permanent hearing threshold shifts. What is the mechanism for damage and/or disturbance? The behavioral reaction is swift, and vigorous on an individual level. The lack of close animal clustering on the beach suggests little or no social component to these stranding, yet the potential for large numbers of stranded animals suggests significance at a population level. What are the source parameters that lead to damage? Is low frequency sound (the primary energy component of airguns) as damaging as mid frequency sound (used by SQS-53 ASW tactical sonars)? What sound pressure exposure level creates damage and/or disturbance? Beaked whale mass stranding events make it abundantly clear that high intensity anthropogenic sound is a threat to marine mammals, yet there are key parameters that we must understand about beaked whale strandings before we can predict the impact of high intensity sound on other species in other settings.

Priority 2: Determine behavioral responses to anthropogenic sound

A key impediment to assessing the biological effects of ocean noise is a continued lack of knowledge about marine mammal behavior in general, and lack of understanding their behavioral response to anthropogenic sound in particular. Behavioral data must be collected in the wild to provide a full picture of the potential

effects. Significant ocean noise effects may be confined to a few individuals exposed at high sound pressure levels, and/or from widespread exposure at a population level. Controlled exposure experiments may be helpful in defining obvious and/or short term impacts to individuals, but may not reveal long term impacts. Discerning population level effects is challenging since the observations must be conducted over broad distances and long time periods. Relating migration and movement to noise level is one potential approach. Do marine mammals systematically avoid habitat areas with high noise levels? More subtle behavioral changes may be associated with exposure to high ambient ocean noise. Is natural sound (e.g. snapping of shrimp) useful for prey location? A better understanding of how and why marine mammals make and use sound would greatly aid or ability to predict how ocean noise might be disruptive to marine mammal behavior. The sound avoidance reaction of marine mammals has been exploited to exclude them from fisheries interactions by acoustic harassment devices, but does their behavioral reaction occur before losses to their hearing? Our lack of understanding marine mammal behavioral reaction to sound is vast and must be addressed in the face of raising ocean noise levels.

Priority 3: Improve tools for marine mammal behavioral observation

Research tools are needed to better observe marine mammal behavior in the wild. These are needed both to characterize normal behaviors and to detect changes in behavior associated with anthropogenic noise. Marine mammal acoustic recording tags are an important technology for detailed behavioral studies in the presence of noise. Technical improvements are needed over current tags to increase their duration of attachment, to expand the volume of stored data and to enhance the suite of available sensors. Tag attachment system improvements are particularly needed for large cetaceans than cannot be captured for tag emplacement. Current non-invasive attachments have limited duration, whereas invasive attachments involve both damage and disturbance to the animal. Technology for passive acoustic tracking of animals is another important component of behavioral study with the potential for future improvement.

Priority 4: Develop tools to study marine mammal physiology in the wild

For many species of marine mammal it is unlikely that large number of individual animals will be kept in captivity for study of their physiology. Tools are needed to study marine mammal physiology in the wild. For instance, indicators of stress may be one way to assess the impact of anthropogenic noise on marine mammals. If stress factors can be measured fromblubber or blood samples, perhaps biopsy of other tissue samples collected in the wild could reveal regional or population-wide stress levels associated with noise. Likewise, without a rapidly deployed field method for determination of hearing capabilities, it will be difficult to collect audiometric data on the full range of marine mammal species and under conditions were chronic noise may have degraded hearing capabilities. The ability to collect audiometric data on beached or ensnared animals would be a first step, particularly useful when high intensity sound may be suspected in the animals' stranding.

Priority 5: Marine mammal populations within areas of high intensity sound generation

Anthropogenic ocean noise sources are primarily concentrated into a few well defined zones: (1) at major commercial ports and along shipping lanes, and (2) within military test and training sites. The marine mammal populations within these zones should be characterized and monitored for potential impact due to anthropogenic noise. A combination of both visual and acoustic monitoring may provide an efficient means for monitoring both marine mammal distributions and ambient noise. These data will further aid efforts to determine if ocean noise is a factor in discouraging habitat use by marine mammals.

Introduction

Multi Klient Invest AS (MKI) contracted NEXUS Coastal Resource Management (NEXUS) to complete an assessment of the interaction of several marine mammals and MKIs proposed 2D seismic survey in Baffin Bay and Davis Strait. This assessment will be used to inform MKIs acquisition plan for the proposed seismic survey. This assessment includes the following 'species of interest': narwhal, beluga whale, bowhead whale, walrus, bearded seal, ringed seal and harp seal.

This report is limited to a general discussion of migration trends to inform the planning of MKIs proposed Baffin Bay and Davis Strait seismic program. It is not meant to be a definitive assessment of the migration routes of the species of interest. As well, the Proponent cannot guarantee that a species will or will not be found in the survey area outside of the times discussed in this report.

Information to inform the preparation of this report was obtained from government, research and organizational studies and reports. The studies and reports were published from 1980 to 2013 and include a range of methodologies (satellite tracking, workshops, aerial surveys, etc). Due to the lack of documented information on whale, seal and walrus migration routes, the interaction maps include only documented summer and winter habitat ranges near the survey area.

Methodology

Interaction maps of the proposed survey lines (total plan, year 1, year 2 and year 3) in relation to marine mammal habitat ranges (interaction maps) in the survey area were produced. MKI provided maps of their proposed survey plan which served as base-map to create the interaction maps.

Narwhal, beluga and bowhead whales, walrus and bearded, ringed and harp seal habitat ranges were discerned and digitized from sources. NEXUS contacted the lead authors in each report that was included in the analysis and requested a higher quality image to be used in creating the maps. The images were digitized using Arc GIS to create digital layers that were placed over the base-map. As a result of the varying amount of geographic detail in the PDFs used to prepare the interaction maps, the margin of error is between 375m to 5km.

Supplementary Report II (TGS/PGS/MKI, 2013) and the Environmental Assessment (LaPierre et al., 2011) provide a complete description of the papers and reports used in preparing the interaction maps and analysis. Twenty interaction maps were created. Interaction maps were created for each species of interest (5) for the proposed survey lines (4).

Results

The following papers and reports were used to prepare the interaction maps and accompanied summaries:

Narwhal

- Dietz, R., Heide-Jørgensen, M.P., Richard, P.R. and M. Acquarone. (2001). Summer and fall movements of narwhals (Monodon monoceros) from Northeastern Baffin Island towards Northern Davis Strait. Arctic, 54(3): 244-261.

Migration Routes

The following summarizes the known migration routes (if applicable) for the species of interest from the articles and reports listed in the methodology. When applicable, discussion focused on individual stocks of the population.

- **Narwhal**: All three narwhal stocks leave their summering grounds located around Lancaster Sound from the middle of September to the middle of October to migrate to their wintering grounds.
    - Somerset Island stock: Narwhal begin their migration in early October east through Lancaster Sound directly offshore to their wintering grounds in Northern Baffin Bay in early November. Some narwhal continue their migration to the west coast of Greenland.
    - Eclipse Sound stock: Narwhal migrate east through Lancaster Sound continuing south along the coast of Baffin Island, arriving near Qikiqtarjuaq and Pangnirtung in October/November. Narwhal from this stock remain close to the coast stopping in fjords and bays on their fall migration. The whales then head offshore to Baffin Bay to their wintering ground in Southern Baffin Bay.
    - Admiralty Inlet stock: Narwhal migrate east through Lancaster Sound, then south along the eastern coast of Baffin Island within 100km of the land. Once narwhal reach Clyde River and Qikiqtarjuaq in October, they migrate offshore to their wintering ground in Southern Baffin Bay.
- **Beluga whale**
    - Cumberland Sound stock: Beluga whales remain in Cumberland Sound year round. During the winter, belugas can be found in the fjords of Cumberland Sound, while in the summer, belugas are located at the mouth of Cumberland Sound.
    - Western-Northern-Southern Hudson Bay stock: Beluga whales from this stock appear to migrate east through the Hudson Strait and north along Baffin Island and are hunted in Iqaluit and Kimmirut.
- **Bowhead**
    - Davis Strait- Baffin Bay population: Bowhead whales summer in the High Arctic take one of two migration paths to their wintering grounds. Bowhead whale fall migration begins in September or October when some bowhead whales begin their migration south along the east coast of Baffin Island, while other whales cross northern Baffin Bay and arrive near Upernavik, Greenland. It is at this time that large congregations of bowhead whales may occur in Cumberland Sound.
- **Walrus**
    - Northern Hudson Bay-Hudson Strait- Southeastern Baffin Island- Northern Labrador stock: Walrus generally remain close to land or within proximity to sea ice in the summer. There is a suspected migration corridor for walrus between Qikiqtarjuaq and Greenland. We do not know what time of year walrus migrate between Qikiqtarjuaq and Greenland.

- **Bearded Seal**
    - Bearded seals spend a large portion of the summer in coastal areas and in the many fjords and bays within and around Baffin Island and Ellesmere Island. They have been known to spend time in deeper waters.
- **Ringed Seal**
    - During the summer months, ringed seals can either be found near the coast of Baffin Island or offshore in northern Baffin Bay and the North Water. There may be two populations of ringed seals with one group preferring coastal fast ice, while the other prefers offshore pack ice.
- **Harp Seal**
    - Harp seals are located throughout Baffin Bay.

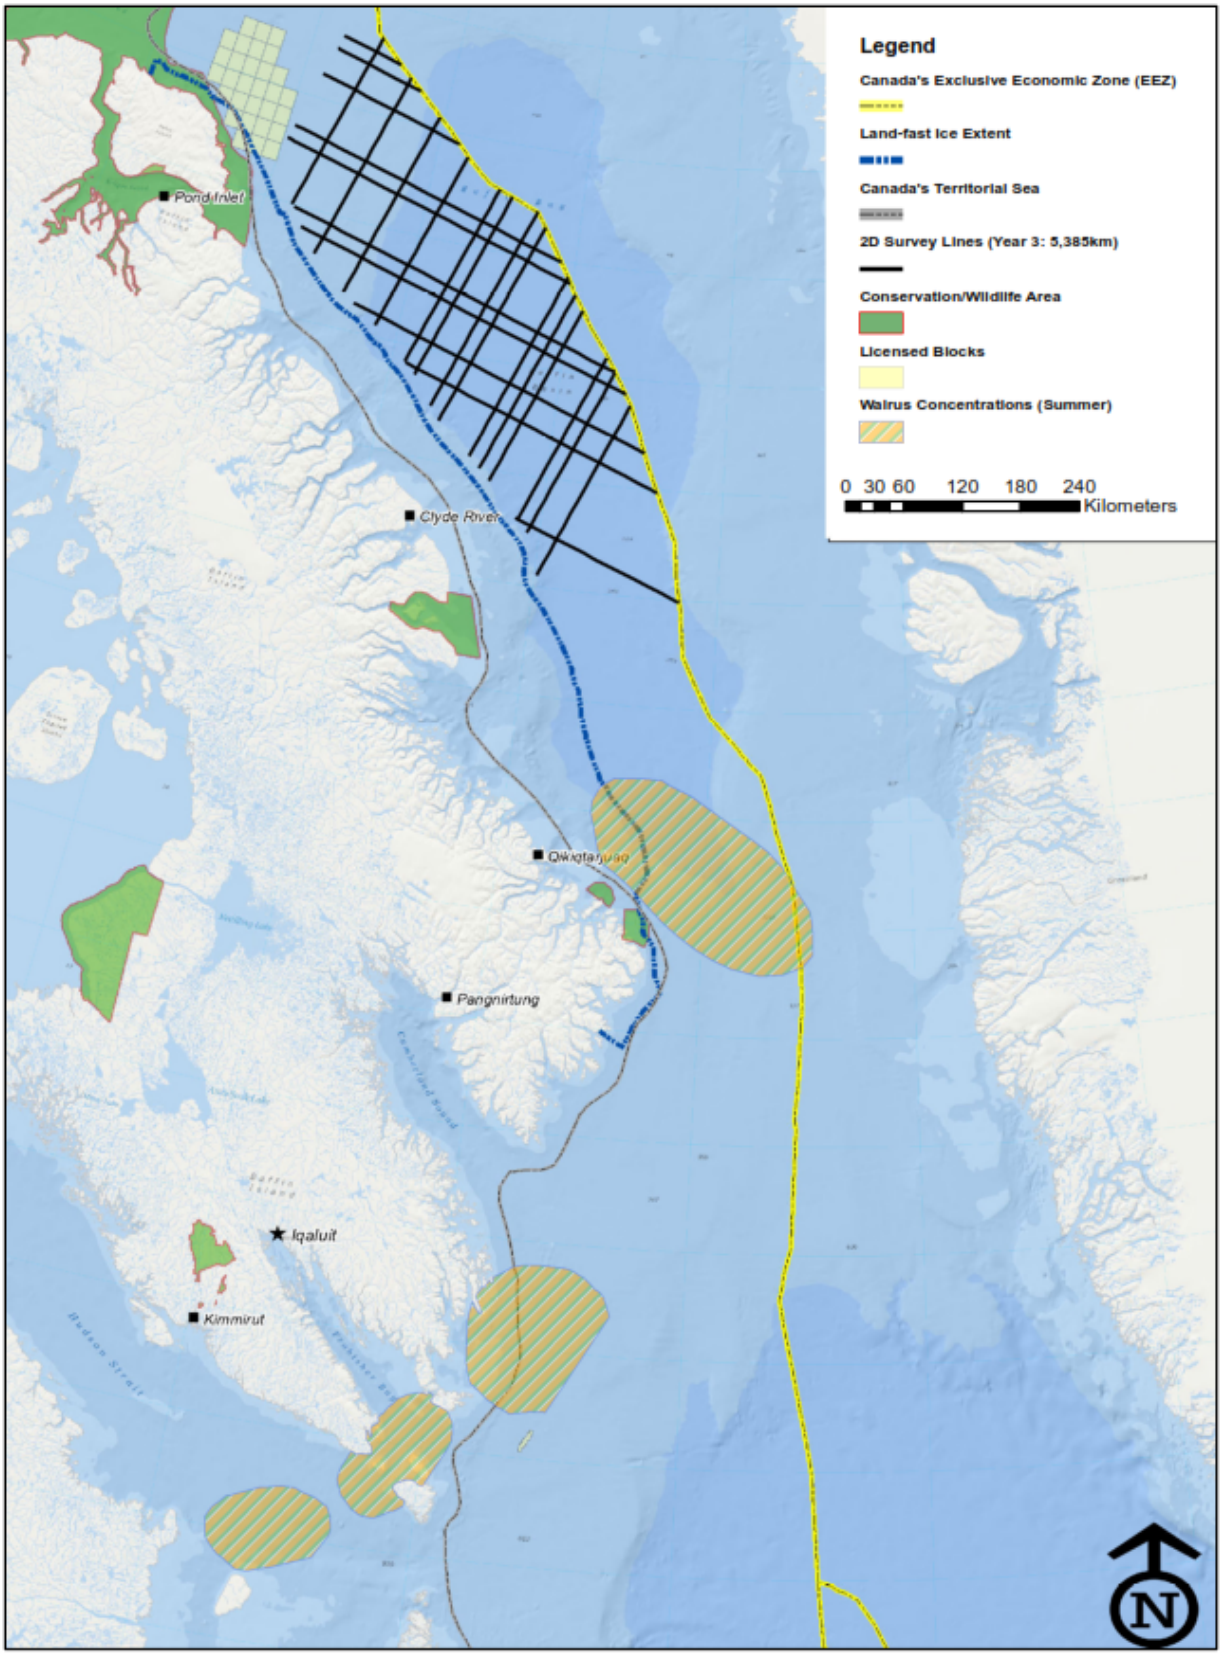
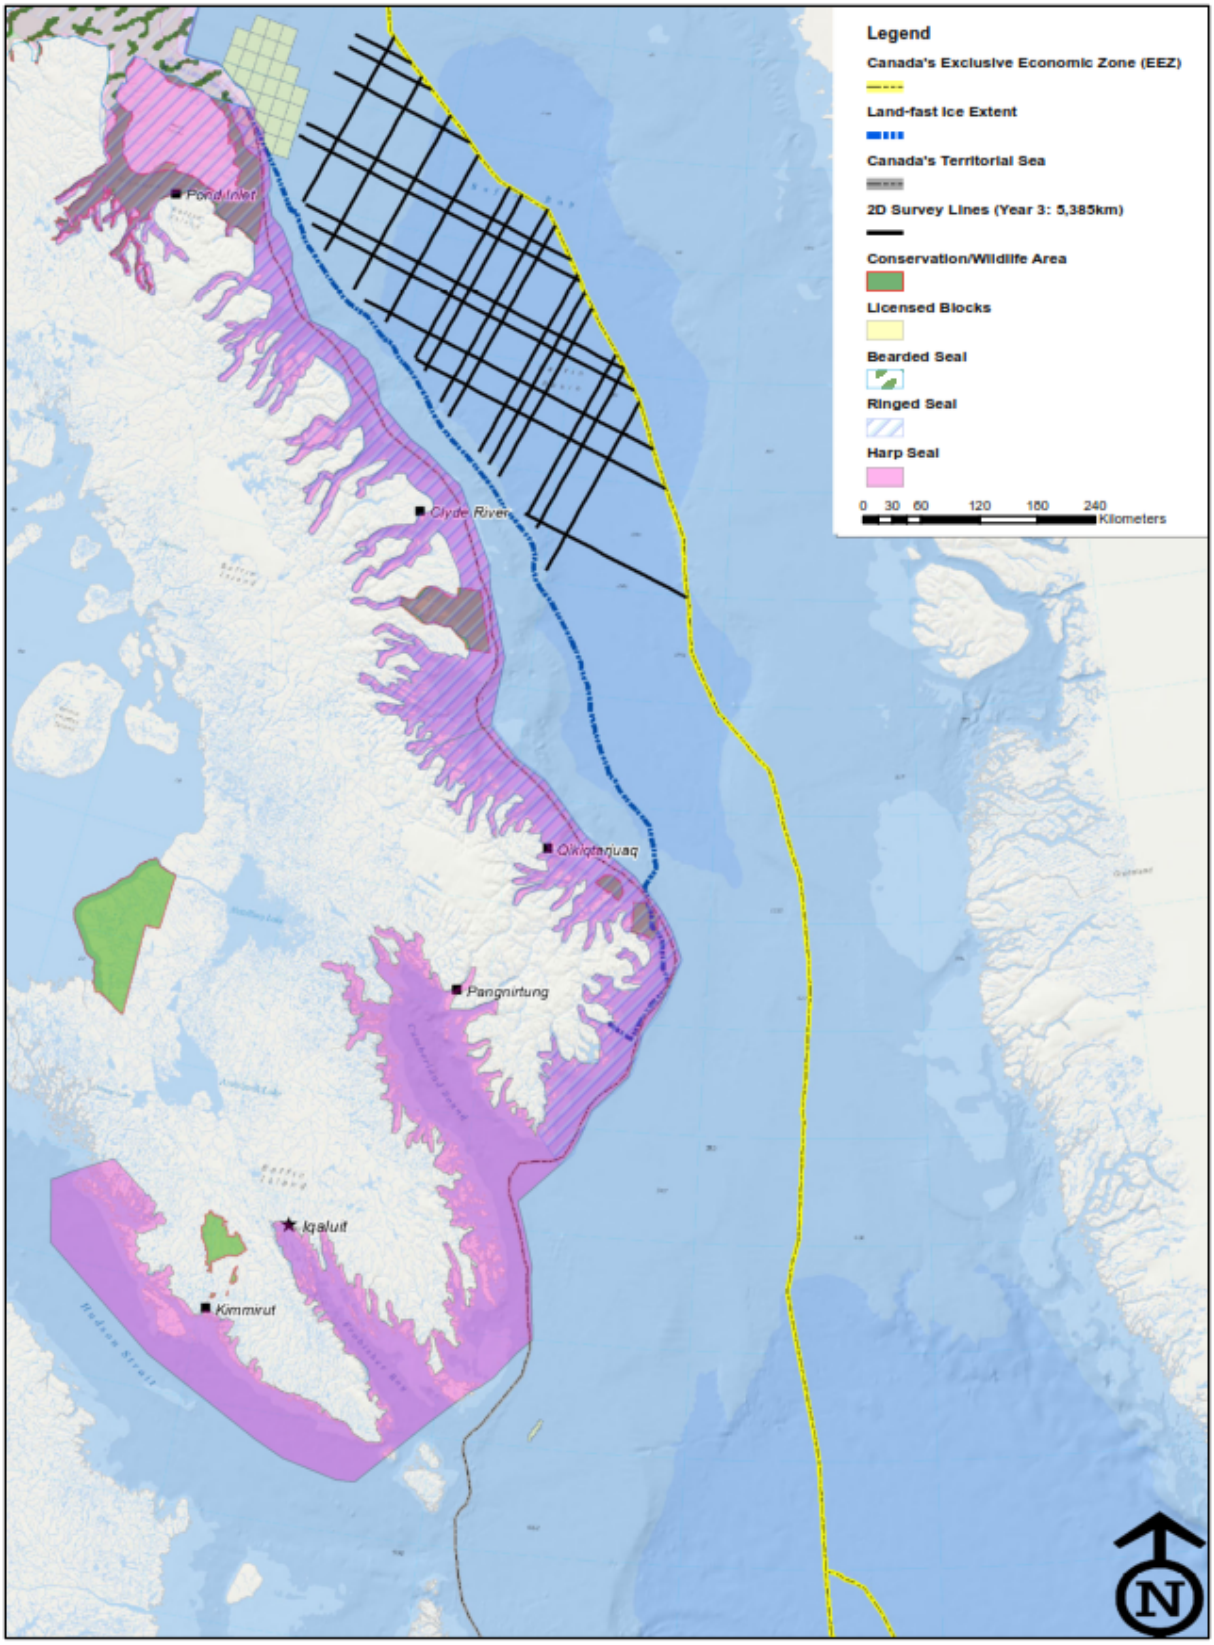
Walrus Concentrations near Survey Area (Year 3: 5,385km)



Areas of High Seal Concentration near Survey Area (Year 3: 5,385km)



Analysis

All three narwhal stocks will follow their fall migration routes into the survey area. Papers discussing satellite tracking of the Somerset Island mention that this stock is thought to begin their migration the middle of October. Therefore, they may begin to enter the location of the proposed survey toward the end of October. Peer reviewed papers discussing the results of satellite tracking of narwhal from the Admiralty Inlet and Eclipse Sound stocks suggest that these stocks begin their migrations around the middle of September. Unlike the Somerset Island stock, these stocks migrate south along the eastern coast of Baffin Island remaining within close proximity to the coast. Satellite tracking demonstrated that whales from these stocks begin their offshore migration from Clyde River to Pangnirtung from mid to late October.

Beluga whales from the Cumberland Sound stock are unlikely to be in the survey area as reports indicate that they remain in Cumberland Sound throughout the year. It is unlikely that belugas from the Western-Northern-Southern Hudson Bay stock migrating east through Hudson Strait towards Iqaluit would be located in the survey area.

The Davis Strait- Baffin Bay bowhead whale population undertakes a coastal migration route beginning in September into October from the North Water south towards Cumberland Sound and Davis Strait. Bowhead whales already in Cumberland Sound move south to Hudson Strait in early September to late October. Information obtained from bowhead whales tracked using satellite telemetry suggests that bowhead whales fall migration occurs near the coast of Baffin Island. Therefore, it is unlikely that coastal migrating bowhead whales will interact with the proposed offshore project.

Walrus from the Northern Hudson Bay-Hudson Strait- Southeastern Baffin Island- Northern Labrador stock may occur in the survey area. The limited survey lines within proximity to Qikiqtarjuaq reduce the likelihood of encountering a walrus migrating between Qikiqtarjuaq and Greenland.

Identified areas of high concentration of bearded, ringed and harp seals are outside of the survey area.

In summary, narwhal are likely to be in the survey area north of Cumberland Sound beginning in mid to late October. It is unlikely that beluga whales from the Cumberland Sound stock will be found within the survey area. Despite available reports and studies which suggest that the Western-Northern-Southern Hudson Bay beluga stock and the Davis Strait- Baffin Bay bowhead whale population migration routes occur outside of the survey area, individual whales may move offshore into the survey area. Walrus may be found within the survey area as a result of the suspected walrus migration corridor between Qikiqtarjuaq and Greenland. However, it is not known how many walrus use this route or when they complete this migration. Areas of high seal concentration are outside of the survey area. However, it is likely that seals will be in the survey area.

Foreword

The collection of Inuit Traditional Knowledge in this report has been implemented by the current Southeast Baffin Beluga Management Committee (SEBBMC) which was a recommendation of the former SEBB Management Plan. The study was carried out in the three communities of Pangnirtung, Iqaluit and Kimmirut for which the SEBBMC is responsible. The information contained herein is from the knowledge and experiences of the people living in these communities.

Acknowledgments

I would like to thank the following people for their hard work in helping to complete this final report.

First, I'd like to thank the three community HTOs for their involvement, and especially the chairpersons for their guidance. I'd also like to thank the three cameramen for assisting me in the three communities: Mark Kilabuk in Iqaluit, Ricky Kilabuk in Pangnirtung and Eezeedsiak Padluq in Kimmirut. I'd also like to thank Daisy Sowdluapik, Eena Alivaktuk, Rosie Kilabuk and Mary Kilabuk for writing the transcripts, and finally, thanks to Jonah and Bill Kilabuk for their translation and transcribing services.

Again, thanks to everyone for all your help, dedication and encouragement.

Introduction

This study has resulted in an abundance of Traditional Knowledge being obtained. It is through the sharing of Traditional Knowledge by the elders/hunters interviewed that I am able to submit this report on the Southeast Baffin Beluga and hunting.

Historically, fewer people have lived in the occupied areas of the Southeast Baffin. Most of the inhabitants were scattered along the coastal areas permanently residing in camps. By sharing what they had and conserving their catches even when game was abundant, the people were able to live in harmony with the wildlife and the surrounding environment and survived many hardships.

Today, many people in the bigger communities no longer live in harmony with the wildlife and the surroundings. Regrettably, a lot of Traditional Knowledge concerning the Southeast Baffin Beluga and its habitat has been lost over the past five decades. As Elder Nooveeya Ipeelee of Iqaluit said during the workshop, “I am glad I was given this opportunity at my age to pass along this information as I am no longer able to instruct out on the land.” Nooveeya is of a past generation that used kayaks to hunt Beluga whales.

Methodology

In planning and carrying out the study, the Nunavut Wildlife Management Board (NWMB), Department of Fisheries & Oceans (DFO), and the three communities were involved in the planning and collection of topics and questions for the three-day workshops. The study was carried out in three phases:

In Phase 1, Study Coordinator Peter Kilabuk visited each of the HTO boards to collect the topics for discussion and questions concerning the Southeast Baffin Beluga and methods of hunting Beluga whales.

In Phase 2, three-day workshops were carried out in the communities to collect the Traditional Knowledge of the Southeast Baffin Beluga as per the topics, issues and questions collected from Phase 1. The collection of information was done with eight Hunters/Elders who had been selected in Phase 1. The information was collected on videos which were then transcribed and translated into Inuktitut and English. Maps were also used to record ecological information.

Phase 3 involved the Study Coordinator who wrote the final report with the information provided by each of the communities.

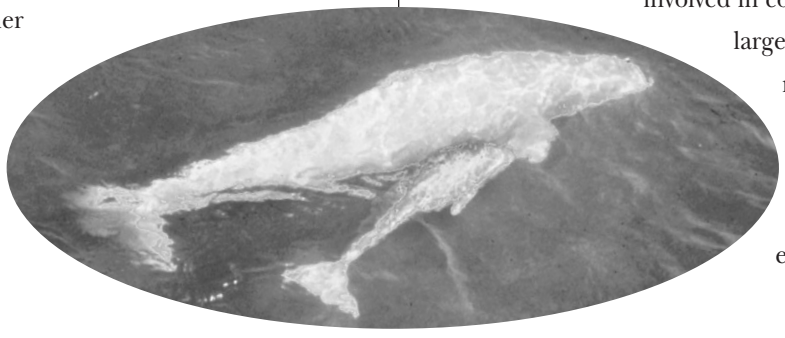
Overview of Southeast Baffin Beluga

Migration of whales

When Beluga whales leave the three communities in the fall, hunters are not certain where they go to winter.

Many believe some of the whales congregate in winter near the mouth of Frobisher Bay. This area is known by hunters from Iqaluit who hunt there when conditions permit. Beginning in April, whales are often seen from the floe-edge at all three communities. It appears that Iqaluit hunters can hunt both Pangnirtung and Kimmirut whale populations during this spring migration. In the summer very few whales are sighted around Frobisher Bay. Although an undetermined number of whales do summer around the bay, no permanent numbers are known to reside in the area.

Kimmirut hunters, with no whales summering in their area, instead hunt whales migrating towards Cape Dorset and beyond. It is in the fall migration that these whales return to the mouth of Frobisher Bay. The whales that migrate to the Clearwater Fiord reside there until fall or sometime in August after they have given birth to their young and have shed their skins or moulted. When they leave, they head towards the mouth of Frobisher Bay. However, due to high winds in the fall around the mouth of Frobisher Bay, minimal hunting for Beluga whales takes place. From this information, it appears that because of the extremely transient nature of the various whale populations – especially during the summer season – only a minimal number are being hunted by each community as per the allowable quotas.



Interestingly, hunters in each of the communities are able to identify individual whales sighted at different times of the year and belonging to different populations. These whales are identified by their physical characteristics and behaviour.

Different Stocks

It is certain that different whale populations or stocks migrate through the Kimmirut area, as opposed to those whales that go up to Clearwater to give birth and shed. The populations – though similar in body size and behaviour – travel in opposite directions at the same time of year. It is not clear, however, which stock Iqaluit hunters are hunting in the summer and, in fact, this could be a separate, smaller population from the two mentioned.

Changes in the behaviour, abundance and population of whales

All three communities agree that behavioural changes have occurred due to the noise of motorized boats and snowmobiles. Since the 1960s when motorized boats were first introduced to the North and hunters started using them to hunt whales, many changes have happened, both when and in the way the whales are hunted. Today, the whales are scattered in areas where they were once densely concentrated. Initially, the alien noise motorized boats brought was not feared. In fact, most whales were curious when they first heard them. Today, however, it is the last thing a whale wants to hear. Whales can hear from great distances and, as a result, avoid areas where motorized boats are heard. This has contributed to the thinning of whale concentrations and their population sizes.

Though Kimmirut and Iqaluit hunters have never been involved in commercial hunts to any large degree, still they have noticed a definite decrease in the numbers of whales available today compared to the numbers they hunted five decades ago.

In Pangnirtung, the commercial hunts carried out by whalers from the late 1800s into the early 1900s have had a great impact that has resulted in a significant decrease in the whale population. The Hudson's Bay Company was also active in the commercial hunts of Beluga whales in the early 1900s. Great numbers were taken and as a result, elders recall that the size of the population continued to shrink even years after the commercial hunts were stopped.

Despite the quota given to each of the three communities, an emphasis for more commercial hunting was not a consideration of those interviewed, instead they see a need to implement better methods of conservation and hunting as a primary concern.

Traditional ways, modern ways and equipment

Today, there is a high degree of competition among the hunters. This is the result of a decline in Traditional Knowledge and the introduction of modern hunting equipment. Quotas are the most cited reasons given for the increase in competition among hunters. It is apparent that irreversible changes have occurred since the mass introduction of modern equipment that hunters avail themselves to today. The elders interviewed are still optimistic that there is a chance for compromise – by adopting and abiding by the practices of Traditional Knowledge, the elders feel that once again hunters can re-establish a harmonious relationship with the Beluga whales.

As hunter Jooeelee Papatsie of Pangnirtung stated during the study: "We, the younger group of hunters, have taken you away from your traditional ways and replaced them with our modern ways of rushing into everything." This is a strong statement advocating the use of Traditional Knowledge to help close the extensive gap in the use of Traditional Knowledge that today exists in each of the communities.

Educational needs a priority

This study has introduced new views and understanding about the need to restore Traditional Knowledge as part of our school systems' curriculum. Currently, students learn about whales from other sources. There is no involvement from community elders on the subject. The three communities favour the creation and introduction of videos on selected topics. The videos could be produced in the communities and made available to the schools. There is also an identified need for written material in Inuktitut and English for teachers and students. Both videos and written material would promote Traditional Knowledge and skills.

There is also a desire to produce local or regional hunters' guidelines for hunting Beluga whales. These guidelines would ensure that hunters use the right equipment, that they use nets properly, butcher the whales properly, make safety a priority, use the proper calibre rifles, use proper harpoons and floats, practice proper hunting techniques and other related matters. An established set of guidelines would help ensure that there is minimal loss and wastage and keep the safety of hunters a priority. These guidelines would also be made available to the public in written form in Inuktitut and English.

Sampling program carried out by DFO

The Beluga Sampling Program has been conducted in the southeast Baffin communities since 1989. The Department of Fisheries and Oceans has led the program. Hunters are supplied with sampling kits through the community HTO, and hunters are paid for the samples they return. The purpose of the program is to collect important information on Beluga hunting and tissue samples and measurements from Belugas that are harvested. This information is used primarily to answer questions about stock identity through genetic and contaminant studies, and to monitor the reproductive rate and general health of Belugas.

It is unfortunate that the three communities have very little or no knowledge of the sampling program. Most participants at these workshops had not been consulted on the intentions and goals of the program. Because there has been no proper community consultation, only a few active HTO board members have any knowledge on the program. All participants expressed a sense of urgency for proper

community consultations. This could be done with written material on the program and the ensuing results. The participants felt that hunters would be more willing to assist if they were made to understand more about the sampling program. They also feel that NWMB should be more proactive in making the program better known to hunters and people involved in the program. There is, at this time, a lot of mixed feelings towards the program and its progress as those who have contributed information feel that they are getting little, if any, feedback, on the study results. Consequently, some hunters are avoiding using the kits. This needs to be addressed by the NWMB and DFO.

Conclusion

Because this has been the most in-depth study to ever take place on the collection of Traditional Knowledge on the Southeast Baffin Beluga, the study has brought a better understanding to all the community participants. New opportunities and ways of hunting are being created with the information that has been collected, and new perspectives and views are being expressed. One would hope that this is how the study will be used – to improve the understanding and undertakings of all those involved.

I have enjoyed working with the people in the three communities and their hospitality was more than welcomed. I'd like to thank all those who gave me their advice, guidance and support in helping me to complete the study.

Inuit Ecological Knowledge Study of the S/E Baffin Beluga

KIMMIRUT NT
APRIL 8, 9 & 10, 1997

INTRODUCTION

As part of the S/E Baffin Beluga Management Committee goals, an Inuit Ecological Traditional Knowledge Study was done in Kimmirut. Peter Kilabuk of Pangnirtung, with the involvement of the three communities, NWMB and DFO, planned out the study.

The Inuit knowledge and recommendations have been collected and are included in this report. The collection of the material was done with the involvement and support of eight hunters/elders in each of the three communities. This included the general knowledge, health, population, and hunting of the S/E Baffin Beluga. All the working material and final documents are the property of the NWMB and are available only through them.

The study was conducted at the Kimmirut HTO office with the group of eight hunters/elders listed below:

Newyaliak Qimirpik	Hunter
Sandy Akavak	Hunter/Elder
Josephee Padluq	Hunter
Paulosie Lyta	Hunter/Elder
Simeonie Aqpik	Hunter/Elder
Joanasie Lyta	Hunter/Elder
Eliyah Michael	Hunter Elder
Eeyeevadloo Josephee	Hunter
Mikidjuk Kolola	Hunter S/E Baffin Beluga Committee Member
Peter Kilabuk	Interviewer
Eezeedsiak Padluq	Assistant and Camera Man

MIGRATION

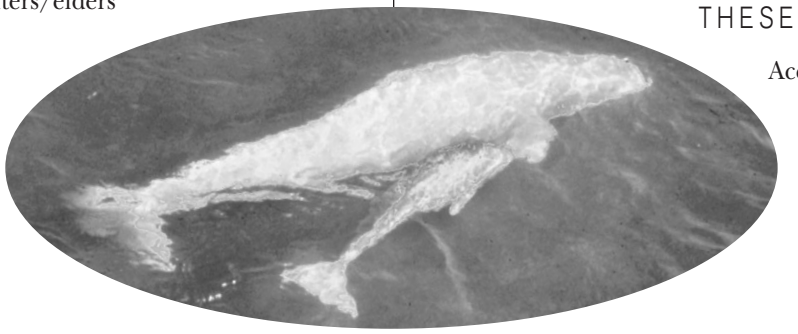
From their many years of combined Traditional Knowledge, the group of hunters and elders interviewed believe that because Beluga whales are rarely encountered during the summer months, Kimmirut hunters are hunting mostly migrating whales.

The whales that migrate through Kimmirut first arrive at the floe-edge in the spring (around April). They travel from the east to the west towards Cape Dorset (see map #97-01 enclosed) and may be found feeding in the waters near Kimmirut. There are no known areas near Kimmirut where the Beluga whales spend any length of time (during summer). Most of the whales that migrate tend to travel outside Big Island near Kimmirut (refer to map 97-01) as the current of the tide is steadier, allowing the whales to travel further.

On their return migration through Kimmirut waters in the fall, the whales tend to travel the same paths but in bigger herds. It has been noted that compared to the past, the whales are reaching Kimmirut much later in the fall, closer to freeze up.

CHANGES IN THE MIGRATION OF THESE WHALES

According to the study participants, the whales that migrate through



Kimmirut nowadays appear later in the spring and in smaller numbers. It was noted that this decrease is not due to over-hunting but rather due to some members of the population taking a different route during the migration. The decrease in numbers has been noticed since the early 1980s. Today, the whales do not return in the fall migration until much later – when the ice is forming and when it is difficult for the hunters to do any hunting by boat. The majority of the whales that migrate in these fall herds are females with young and juveniles. There are fewer male adults as there were originally in the mid 1900s.

Hunters in Kimmirut have very recently seen an increase in the number of individual whales and have noticed that the noise from motorized boats is deterring whales from reaching certain camps that were previously visited. This deterring effect changes from year to year, as does the number of returning whales.

Like Pangnirtung and Iqaluit, the main cause of this change in behaviour is attributed to the noise created by motorized boats and snowmobiles.

A more recent concern of the hunters has been an unknown source of explosive sounds that have been heard out in the open waters near Kimmirut. The sounds have been encountered by different hunters at different times in the summer. There is still no explanation for the cause of these sounds.

Feeding

Beluga whales do not stay near Kimmirut in the summer. The only time they may visit is when they are feeding off Arctic cod at the floe-edge in the spring or when following the direction of the currents when searching for cod in the summer. It is also thought that after a period of time if no more disturbances are sensed, the previously-hunted whales return to feed. This may be at the next tide or the following day. Aside from cod, there are no other food sources available near Kimmirut, although some invertebrates have been found in the stomachs of whales. See feeding area on map #97-02.

There are no calving areas known near Kimmirut.

Populations and distribution of migrating whales

When migrating west, upon reaching Kimmirut waters, the whales travel in more scattered herds than they do in the fall upon their return. The whales are often seen in small groups or individually when feeding, they then regroup later to form bigger herds. If disturbed, scattered whales will also eventually regroup to form bigger herds from the same numbers. Today it is felt that there are fewer whales than there were 40 or more years ago. No actual numbers are available on how many fewer whales there really are. Hunters suggest that motorized boats and the noise they bring may be redirecting some of the whales elsewhere. Overhunting is believed to have had little to do with this decline.

Commercial hunts by whalers or traders

According to the elders, in the early 1900s traders would trade for whale blubber. This, however, had a minimal effect on how many whales were actually hunted. Though some hunters may have traded blubber for tobacco if they couldn't make cash payments, most families only hunted what was needed for the camp. There were no organized hunts or blubber stored for the coming year or for trading which, if there had been, would have led to an increase in the numbers of whales being killed.

Health of the Beluga whales

Since the introduction of motorized boats, there is no evidence that there have been any detrimental changes in the general health of the Beluga whales. Though some individual whales have been found sick, too skinny or badly deformed, the general health of the Belugas has remained unchanged. Generally, the whales are fat when they reach Kimmirut in the spring, and skinnier in the fall when returning from their summering waters. Whales carrying young and calves tend to be fatter than the males in the same population. This is the natural annual cycle of all S/E Baffin Beluga whales.

Hunters have no reason to believe that there are any differences today in the way the muktuk and meat may appear in color or taste as compared to the earlier 1900s. The change that occurs with shedding (moulting) is an annual cycle and has no bearing on any other changes over the last decades. These whales are differentiated by age and by the color of their skin – the youngest calves being dark grey, then as they get older they turn whiter until they reach adulthood and remain white from then on. Hunters prefer the greyish whales as they are considered better eating.

Behaviour of the whales

Kimmirut hunters have seen major changes in the way these whales behave in their natural environment. Most behaviour changes started with the introduction of motorized transportation. The noise created by the motorized boats has made the whales detour by great distances. Whales will also flee any area where a motorized boat is detected. Hunters have also noticed changes in whale behaviour at the floe-edge. Where most whales used to dive close to the ice to feed, today, they either do less dive-ins or make their dive-ins from further out. During the night when all is quiet, the whales will often return to feed at the floe-edge. This is evident with the breathing holes they leave on the newly forming ice alongside the thicker ice. In general the major causes of behavioural changes are suspected to be the motorized means of transportation whether they be boats or snowmobiles.

Differences in sizes

Kimmirut hunters may very well be hunting smaller-sized whales than they would have been in the 1950s when there were bigger whales that are today notably absent from the population. The bigger whales were distinguished by being clean white in colour and having longer and bigger teeth than the present whales. They also travelled in larger pods. These larger whales can be traced back to "Numaayuuq" a scout and known whale leader who disappeared in the 1950s. This whale was particularly noted for its large physical appearance and its dominant role in the herd. The disappearance of "Numaayuuq" may be related to the ensuing absence of large whales which is still evident today in the Kimmirut area.

Sampling studies carried out by DFO

Hunters in Kimmirut, like hunters in Pangnirtung and Iqaluit, claim that they are not benefiting from the sampling studies carried out by DFO. Hunters have been very patient in waiting to hear about the results of these studies, as very little, if any, information is being passed onto them. Hunters here say the progress and process have been very slow with no consultations with the public and no written material being provided. There have also been no visits made by those running the study. Most people do not even know what the intentions of the study are.

Hunters also say that they have forwarded information to DFO and then never hear the study results. Though these studies have been carried out for a number of years, the hunters claim that there are not enough meetings or consultations being carried out on the study's progress or purpose. Although the hunters receive postcards acknowledging their input, it was suggested by the group that more information be returned to the hunters on the cards. The hunters have been given no indication on the health of the Belugas or any of the other findings from the studies. They also feel that the population group the whale is from should be noted on the cards.

Different populations reaching Baffin

Hunters in Kimmirut have noted different kinds and shapes of flukes and flippers for different whales. The ends of the fins often vary with the different populations. It is suggested that photos be made available to distinguish the different whales. The Kimmirut hunters feel that a certain population of larger Belugas that has longer teeth is no longer present. However, Sandy Akavak an elder/hunter, is not sure if this can be used accurately to determine the different populations. There was also mention of bigger whales with bent

front flippers that have been notably absent from Kimmirut since around 1982. The hunters feel that there may be different populations reaching the Kimmirut area now.

Changes at the outpost camps

There are notable changes that hunters have seen over the years concerning Beluga whales near the outpost camps. They are arriving later in the fall and they are fewer in number than in the past. The whales are also migrating farther out, probably in response to the sound of motorized boats. However, when an area has been undisturbed by motorized sounds, there are signs at the floe-edge that the whales do return. Kimmirut hunters still go out to the old outpost camps looking for whales but much less are found.

Hunters here are not able to recall if there have ever been any studies or counts done near these older outpost camps. The outpost camps are marked on map #97-03.

General hunting areas

Though Kimmirut hunters hunt at the different times of the year, they hunt in the same general areas in the spring, summer and fall. The spring and fall hunting area is marked on map #97-04. In these areas the hunters feel there has been a decrease in the population of migrating whales due to the more numerous motorized means of transportation. But in general, the hunters of Kimmirut are hunting the same general areas they would have hunted years back.

Hunting of Beluga whales

In avoiding unnecessary injury to the whales, only the injured are chased. Whales are chased closer to the land where it is shallower and where it's possible to hook dead sunken whales. This takes careful planning as the whales sink more in the fall. Kimmirut hunters insist that harpoons be used and that injured whales be hunted first to avoid unnecessary wounding of other whales. The percentage of hunters who use these practices is unknown. Other examples of knowledgeable hunting methods include: In deep waters where the whale might sink if killed outright, it is instead shot in an area that will not kill it right away – it is only shot and killed in shallower waters. Kimmirut hunters have also adopted new hunting methods. One example is that at the floe-edge harpoons are used less; big hooks (to retrieve a dead whale) are used instead which can be thrown out further and require less accuracy.

Nonetheless, hunters here have indicated that they would welcome and support the creation of local or regional hunting guidelines. Some of the topics suggested as guidelines include:

1) Distribution of catch (Traditional distribution methods)
2) Chasing of whales, including steering of whales
3) Safe hunting practices
4) Hunt leaders
5) Traditional laws i.e.: leaders to take first shot, etc.

The importance of developing guidelines was underscored by everyone in the group.

Traditional knowledge in the school programs

In Kimmirut, students learn about Beluga whales from outside sources. The reason for this is that there is no local knowledge material available to them in the schools. Hunters here feel this is a serious oversight and that material should be made available to the students. "We learned by taking part in the hunts and events," said one hunter. Hunters recognize the value of including students in the hunts and letting them witness first hand how they are correctly done. Sandy Akavak, an elder/hunter feels that this would be very beneficial for the students, and that it could be funded either through cultural inclusion programs, or activated through NWMB. It is also felt that it would be very beneficial if written materials could be made available to the students in Inuktitut and English. Some of the topics covered could include hunting methods, proper placement of shots, names and parts of whales, edible parts, sinew threads, drying of meat, and class visits by elders.

Beluga studies or counts

This was not discussed as hunters and elders said there had never been a study or count conducted near Kimmirut.

Beluga hunting with nets

Nets have been used near Kimmirut since the 1920s. They were used successfully even in the past when net material was hard to obtain. Seal nets were often used to catch whales. Today most nets are used in the fall when the whales are on their return migration. This occurs starting around September and usually lasts until freeze up.

The hunters in Kimmirut today use larger mesh sizes to avoid catching seals. The differences in a whale that is shot and killed and a whale caught in a net are quite noticeable. A whale that was caught in a net tends to be more salty, there is more blood in the blubber, the muktuk texture may be different and most noticeably the whale may be bloated. Bloated whale remains may not be suitable for consumption. Netted whales often yield products of lower quality than those from shot whales. To avoid this, hunters need to check their nets frequently.

Whales in Kimmirut Inlet

It was expressed that Beluga whales used to enter the inlet of Kimmirut more frequently and in larger numbers in the past. Today this is rarely the case. Numerous motorized boats and vibrations from the power plant are suspected to be the reasons why whales are not seen at Kimmirut anymore. The Beluga whales do not like foreign noises, and if they hear a foreign noise they will avoid the area. There are also natural cycles in certain years where whales will not show in a particular area.

Hunts and distribution of catch

Though there are no significant changes in the way whales are hunted today compared to the past, the introduction of motorized boats and snowmobiles have changed how a whale is hunted.

Today, unlike in the past, the whales are met at the floe-edge by snowmobiles or from lookout spots by boats. Before, people didn't hunt whales unless the whales were in the vicinity of the camp, thus the hunters didn't need to travel. Besides, there were no motorized means of transportation anyway.

At the conclusion of a successful hunt, the distribution of the catch is still an important part of the hunt in Kimmirut. Some traditional means of distribution are still practiced and are important to the community. Today in Kimmirut, hunters cut up the whale differently. Certain parts are not harvested anymore. In the past, the hunter who caught the whale would be allowed to take his share first, and have it cut up in a certain way. Not today. Now the skin is cut up in forms that have no traditional use. They used to make rope from the top part of the whale only. This was equally distributed among the hunters. Meat and tendons were cut in a certain way to make sinew. But this is not considered necessary anymore and as a result, the practice has disappeared. Today the flippers and vertebrae are still taken back for all the women to eat. However, because today there are more women, muktuk is added to make up for the insufficient number of flippers and vertebrae. This allows those less fortunate the opportunity to taste traditional country food within the community. One of the biggest changes has been in the way everything used to be divided equally for distribution. This is rarely practiced anymore.

Behavioural changes at the floe-edge

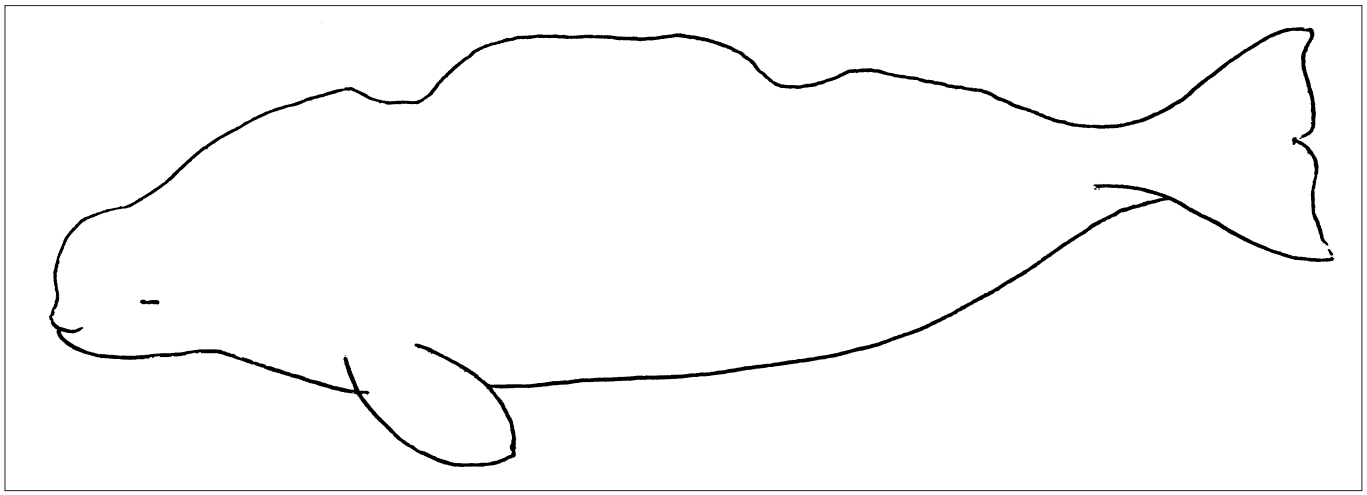
Like the other communities, Kimmirut hunters hunt whales at the floe-edge towards the spring. Some elders recall that there used to be more whales diving under the ice to feed. This was when hunters still used dogteams. As a result the whales were more vulnerable at the floe-edge. To minimize noise the hunters used to walk out to the floe-edge when they came across whales. Today there are less whales and the hunters use snowmobiles to arrive at the floe-edge before the whales arrive. Once again, foreign noise is suspected to be a problem for their shrinking numbers. The whales do not appear to be as playful anymore, but this could be due to the fact that they are just passing through during migration. There is no known area of mainstay (summering) for the whales or for shedding. Whales do not float still by the ice anymore; now they first move away from the ice and then float still. Some suspect this could be because they are

waiting for other whales who are still feeding. Whales are known to make noises of distress and playful whistling noises. When the leaders sense danger they give the distress call and all move away. But playful noise is hardly ever encountered by hunters here.

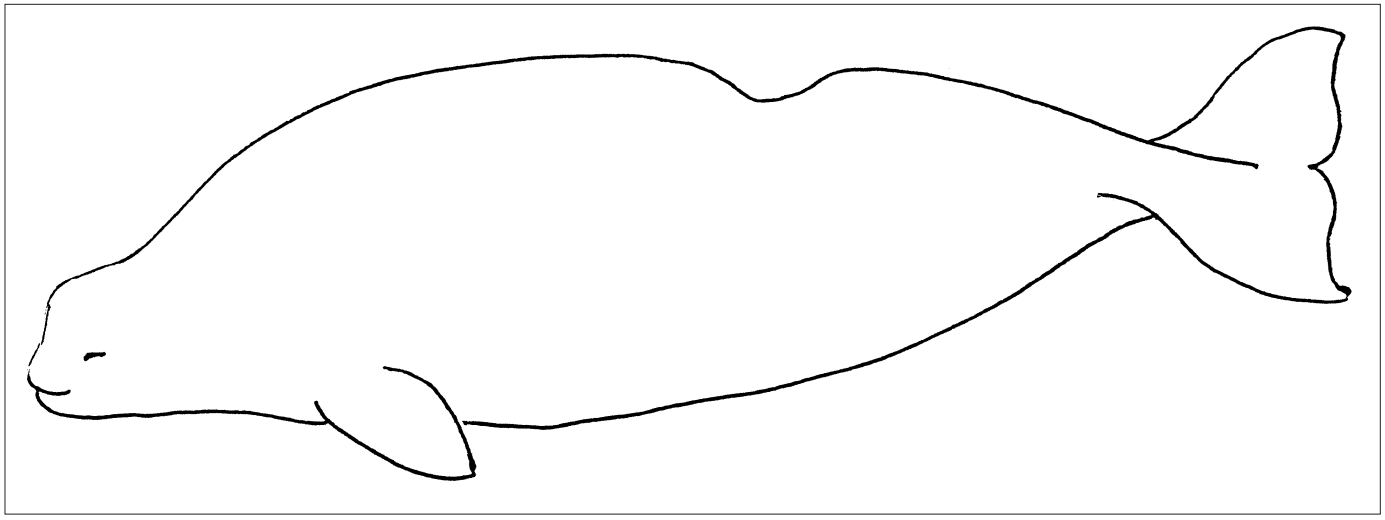
Some hunters think that less cod in the area, or because the cod have moved to another area, may be a factor in the decrease. There are many more harp seals feeding in the area now than before. When whales have fed, or if they sense danger, they move out to open water. They return to the floe-edge later. It was also noted that more dive-ins occur when there are more whales in the vicinity.

Badly scarred whales

There is a small group of three or four individual whales that Kimmirut hunters recognize at the floe-edge or near Kimmirut. They seem to act as scouts patrolling an area before the larger groups appear. The others may appear the same day or the next day after the scouts. These scarred whales tend to travel away from the ice and travel alone, but one is usually seen before the others. One whale has been known to appear almost annually since 1977. The others could not be dated. See diagram below of the badly scarred whales seen near Kimmirut.



A) 2 notches from side view (still seen today).



B) Notch in the lower back (still seen today).

EXPECTATIONS FROM THE WORKSHOP

A strong sense of finally having a say in the gathering and distribution of Inuit Traditional Knowledge to the public, and especially to younger age groups, was expressed by all hunters/elders involved. It was felt that the younger age groups will have a lot of new information to absorb and learn from, providing the information is made accessible to them. The people of Kimmirut expect that with the Final Report out, the information can also be used by Inuit to deal with Government Departments on various issues. Those interviewed felt that the other communities would share similar views and as a result, the report findings would make the three communities more united.

It was also expressed that hunters are not accustomed to note-taking but that if diary books could be made available for them to use, it could prove very beneficial (e.g. recording their sightings and catches of Belugas).

CONCLUSION

It is apparent that the hunters and elders of Kimmirut have seen changes in the behaviour, feeding, migration, and sensitivity patterns of the S/E Baffin Beluga. These changes have been caused since the 1960s, by the introduction of numerous motorized means of transportation. Beluga whales continue to be a very important part of their lives and means of diet. The changes in the whales' behaviour are not known by the younger generation. That makes this study all the more vital in preserving Traditional Knowledge and passing it on to a new audience. Kimmirut residents are strongly committed to preserving the whales which is apparent in the measures and practices being carried out by the hunters today.

SUGGESTIONS MADE TO NWMB AND DFO

The Kimmirut participants in this study would like to make the following suggestions to NWMB. This is with the understanding that they would be approached first before the guidelines are activated as other important topics may need to be addressed:

1) More Traditional Knowledge material should be made available for learning to the school systems and to the students of Kimmirut. These should include: hunting methods, places of proper fatal shots, safe hunting practices, names and parts of whales, edible parts, sinew thread making, drying of meat, and class visits by elders.
2) That a local or regional guideline be drawn up to include the following:
    1) Distribution of catch.
    2) Chasing of whales, including steering of whales.
    3) Safe hunting practices.
    4) Hunt leaders.
    5) Traditional Laws be used at hunts, i.e.: leaders to take the first shots, etc.

The nine participants would also like to suggest that the DFO sampling program be reviewed by NWMB and DFO regarding the following problems being addressed by hunters involved with the sampling program:

1) The intentions and goals of the program should be made known fully to the hunters in Kimmirut.
2) The cards being sent back to the hunters should include more information as to which populations the whales belonged to.
3) More meetings or consultations should take place with the public as to the results of the studies.

The above suggestions should be reviewed to improve the present school programs with the above noted, as there are no local materials available in Kimmirut on the Traditional Knowledge of S/E Baffin Beluga.

The sampling program as in the other two communities, can be improved to better the return of information. It has been made obvious with the participants that hunters are not clear at all as to the intentions and goals of the sampling program carried out by DFO. Nor are they getting any of the results these studies have to offer.

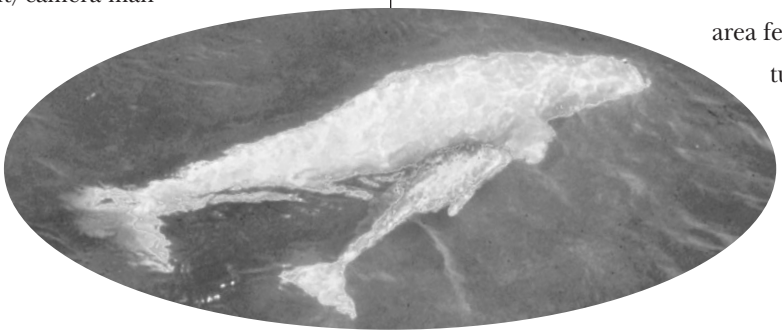
Inuit Traditional Knowledge on the S/E Baffin Beluga and Hunting Study, Report for Iqaluit

April 15 & 16, 1997, HTO Office in Iqaluit

As part of the Traditional Knowledge study on the S/E Baffin Beluga and hunting, eight hunters and/or elders from Iqaluit selected by their HTO participated in this study. The participants included:

Johnny Nowdlak	HTO chairman/hunter
Qutaiggut Lyta	Hunter
Akakaa Sataa	Elder/Hunter
Peter Itungat	Elder/Hunter
Jeetaloo Kakee	Hunter
Noshoota Jimmy	Hunter
Noveeya Ipeelee	Elder/Hunter
Simaniq Kilabuk	Hunter
Peter Kilabuk	Interviewer
Mark Kilabuk	Assistant/camera man



An introduction was given by Peter Kilabuk on the study plans for the next few days. It was also noted that the study was being done in two other communities: Pangnirtung and Kimmirut. The study was being carried out through the NWMB to collect Inuit Traditional Knowledge of the S/E Baffin Beluga and hunting.

Migratory routes

The whales that come into Frobisher Bay and the Iqaluit area do not permanently reside there. The whales spend a very short time in the area throughout the summer and in some years very few have been sighted. In the spring, however, many are found at the floe-edge out in Frobisher Bay. Many or most of these whales will migrate outside of the bay. When the whales do travel towards Iqaluit, they travel mostly on the west side of Frobisher Bay, although some have been seen travelling in the middle of the bay. (See map #97-01 Migratory Routes.) As in the other two Communities – Pangnirtung and Kimmirut – motorized boats and other means of transportation have affected where the whales travel. As one hunter said, "The whales are not given the chance to settle down." Hunters maintain lookout spots out in the bay. It was pointed out that there are probably whales throughout the winter further out in Frobisher Bay as evidenced by traces where they had surfaced through the ice at the floe-edge. When the whales are more active – in the early spring – the bigger yellowish whales tend to appear first, guiding the smaller whales. They seem to have the same travel pattern near the floe-edge each year. Overall, Iqaluit hunters have seen a decrease in the number of whales. Fewer are found today compared to the number found before on the west side of Frobisher Bay.

Feeding

The whales in Frobisher Bay or the Iqaluit area feed off Arctic cod, though turbot have also been found in the stomach contents of whales caught at both the floe-edge and the

Iqaluit area. Whales have been known to feed off char when char are returning up to the lakes. There are small size turbot on the deeper west side of Frobisher Bay which the whales also feed on at the floe-edge. Some invertebrates have also been found in some stomachs. (See map #97-02.)

Traditional hunting methods and equipment

Before the use of motorized boats towards the 1960s, the hunting of Beluga whales was quite different. Since ammunition was hard to come by, rifle shots were not used to steer the whales towards the land where hunters waited with their rifles. Kayaks were also used to steer the whales, the hunters created noise with the use of rocks and banging on their kayaks, or any other tools they could use to create noise. Harpoons were relied on much more and the "anguvigaq"* – similar to a harpoon – was sometimes the only weapon used to kill the whale.

Some families used nets, mainly in the fall. At the floe-edge the whales were only hunted if they showed up the same time that a hunter did. Hunters didn't go looking for whales at lookout spots like they do today. Also, no noise was allowed at any time before the hunters were ready to strike. The behaviour of the whales was undisturbed and as a result, methods used to hunt them were different. Whales came close to the ice and floating was part of their feeding and resting behaviour. Back then, designated hunters were chosen as sharp shooters. So accurate was their aim that some whales were killed with the use of 22 long rifles from sharp shooters perched high atop lookout spots.

Realizing that today, students and younger groups are less knowledgeable about Beluga whale hunting, the elder/hunter participants feel it would be beneficial if a video could be produced on the traditional ways of hunting whales.

** anguvigaq – killing lance or spear.*

Whalers and traders history

In Iqaluit and the Frobisher Bay area, the elders say there were no whalers and traders in the early 1900s. The elders suspect that because of the small number of whales back then, Beluga whale hunting never developed as an industry. Some elders only recall such activities near Kimmirut.

General health of the Beluga whales

In Iqaluit, the physical health of the whales has not changed according to the hunters and elders. Just a few sick individual whales have been found in the area over the years. Like the other Baffin belugas, the whales are fat from spring to summer and then lose a lot of their fat in the fall. The shedding (moulting) period is when they lose most of their fat. This is an annual change that the whales go through in the region. In the Iqaluit area, there is no evidence of any physical changes that have occurred in the whale population; not in their appearance and size, nor in the taste and texture of the muktuk and meat.

Behavioural changes of the Beluga whales

In Iqaluit, the hunters have seen changes in the whales' behaviour in feeding, migration, and in their populations and groupings. According to the Iqaluit hunters, the changes in whale behaviour can be attributed to the motorized boats and other mechanized means of travel. Whales are also feeding less at the floe-edge and in the summer due to numerous hunts in the area. They are migrating or travelling in smaller numbers and they are more scattered. Repeat disturbances in the area by hunters are also making the whales avoid areas where earlier they would have been found. Some of them are known to travel within ice packs to avoid hunters.

At the floe-edge, their behaviour has also changed in terms of feeding patterns. They no longer stay close to the ice when feeding nor do they float still after feeding. Many whales have learned to avoid hunters at the floe-edge. It is believed that noise has caused these changes. Hunting methods have also changed in the Iqaluit area with new equipment available to the hunters. Hunters no longer walk out to the ice to approach the whales. Instead they travel to the whales by snowmobile. Hunters also chase the whales

with their snowmobiles along the floe-edge. This is affecting the whales' behaviour to a great degree since most of Iqaluit's whales are found at the floe-edge.

Population and distribution of whales

In the Iqaluit area there are no summering whales. The number of Beluga whales differs from one year to the next. Some years, there have hardly been any whales due to ice packs in the bay.

Hunters and elders agree that there are not as many whales in Frobisher Bay nowadays as there used to be. The adult males travel in smaller pods unlike the juveniles and females who often travel in larger groups. It is not clear if there has really been a decrease in the number of whales with the information and knowledge forwarded, although it has been noticed that the whales are travelling in groups smaller than before. The elders and hunters are certain that motorized boats are causing the whales to be more scattered in the area. Before the introduction of motorized boats, elders recall seeing many whales that have never been seen in the area again. The noise of motorized boats is suspected to have been a big factor in the changes of the whale population and their distribution, especially when compared to past recollections prior to motorized vehicles being introduced.

As indicated earlier there are more whales found at the floe-edge than in the summer. The elders suspect the whales travel towards Pangnirtung from the Frobisher Bay floe-edge after the winter.

Sampling studies carried out by DFO

Like the hunters at Kimmirut and Pangnirtung, the hunters here have little knowledge if any on the intentions or reasons why there is even a sampling program on whales. It is apparent that a lot of the hunters are not being reached and that there is a definite lack of communication. Here again the hunters have not seen any results of studies that have been carried out. In Iqaluit the lack of communication between DFO, HTO and the public is creating problems. Some hunters are hesitant to use the sampling kits. Some of them feel that the information they forward on the questionnaire contains negative information that has no bearing on the sampling of the whales. They are also unclear on the intentions of this study. Here in Iqaluit like Pangnirtung and Kimmirut, it is felt that more hunters would be willing to assist with the program if they had a better understanding of the sampling program as a whole.

Some questions raised by the participants include:

- Why are there no consultations with the community on the results?
- What are the intentions of the sampling program?
- Is it to determine different populations?
- Is it to see if other populations are reaching Baffin Island?
- Is it to see how many males/females are being killed?
- If it's to determine contamination levels – what contaminant levels are harmful to the human body?
- What goals or purposes do biologists have in this sampling program?
- Are there any policies in place for any whales that may be found sick?
- Why are the results only discussed at the management level or board level, and not at the community level?

Regardless of the situation, Iqaluit hunters are certain that there are not enough community consultations to explain the intentions, results, and contents of the kits or questionnaires. It is strongly suggested that community consultations be done so that the hunters can have more knowledge and will be more willing to assist. "Cash payments are good," said one, "but, there are too many unanswered questions." In some instances, hunters are sampling other hunters' whales for the money. Another problem some hunters have measuring the whales is that some don't have the manpower to move the whale and as a result, they cannot complete the sampling.

Other concerns include: A follow-up on the samples that were to be studied in Winnipeg and due to a backlog were left in storage. No results are yet forthcoming. The resulting DFO study, determined it was clear that Pangnirtung and

Iqaluit do not share the same whale population. It was also pointed out that there are foreign (contaminants) material being brought into the north, and that this study would assist in finding contaminant levels in the whales. What are the results?

As cited by the other communities, more community consultations are needed on the goals and intentions of the study here in Iqaluit.

Different populations of whales

There are different populations of whales reaching Frobisher Bay according to the participants of the study. They are distinguished by their flippers and flukes, as well as the whales' size, behaviour, and their colours at different times of year. These differences may not be apparent to the younger hunters – which is why experience is important. Elders here have seen and know of the different populations but are unable to differentiate one from the other. As one elder said, "it is impossible to differentiate the populations as they have no boundaries to block their travels." Like the other communities they are certain that different Beluga whales are reaching S/E Baffin. The whales are first spotted at the floe-edge at the east side of Frobisher Bay, then they are seen and hunted on the west side in the spring and summer. These different populations may travel into the Iqaluit area in the latter part of spring as the ice recedes.

Outpost camps and the whales

Today it is hard to determine the populations of whales in the outpost camps as the elders and most families do not live there anymore. In the past, whales were only hunted when they reached the outpost camps and not from the lookout spots that are used today. In any case those interviewed felt that there has been a decrease in the number of whales reaching the camps today. In the past, there were also more successful hunts from the land, due to the fact that the hunters didn't have motorized boats to chase the whales with.

Because of the motorized boats, hunters are spending less time at the camps and are hunting in other areas. The elders felt that they would have to spend time at the camps in order to determine the populations. According to the participants, there have never been any studies done at or near the outpost camps. Airplanes have been used to do counts before, but the results are not felt to be accurate. See map #97-03 for locations of the outpost camps.

Hunting areas

Weather permitting, the hunters of Iqaluit hunt mostly in Frobisher Bay or in the Iqaluit area. Due to the strong winds in the bay, hunts rarely take place further out. See map #97-04 for areas of hunts. It was noted that the elders' knowledge goes back a long way, prior to when the studies or counts started in the 1960s. They find it difficult to understand why Inuit knowledge has not been included in the final reports of these studies, when it was they who had originally taken part in the actual counts or studies.

Since the commercial hunts were lifted in the late 1970s, there have been no noticeable differences in the populations of whales. It is with the noise motorized boats create, that the elders say there is a significant difference on the west side of Frobisher Bay, where today there are fewer encounters with whales.

Different hunting methods and equipment

In the Iqaluit area, high-powered rifles are being used to hunt Beluga whales. This is done to avoid unnecessary injury to whales. Hunters also prefer shallow to deep water; even though the whales can travel faster in the shallow waters, there is still less chance of loss. The 222 and 223 calibre rifles are less used today as Inuit prefer higher powered rifles such as the .303, 30-30, or higher. Today's hunts also include a sense of rush and urgency. This is due to hunters wanting to get their whale before the quota is filled, particularly if they encounter a whale after a long wait. There is also more random shooting and more scarred whales. Most importantly, there are a lot more boats out hunting whales. With the problems this has created, the participants would like to see instructions given to newer and older hunters alike on how to run more effective and safe hunts. They suggest harpoons

be used before the whales are killed to avoid loss, and that higher powered rifles be used from 22-250 and up. They also suggest guidelines be made available to all hunters (in both Inuktitut and English). These guidelines would include information that would make hunter safety a priority. Examples of other useful information would be: not to shoot at whales that are too far, hunt the injured first, use proper floats, bring proper equipment before the hunts and, that there be designated leaders at these hunts. The group feels that the creation of such guidelines would prove beneficial, help to organize hunts better, and make hunter safety a priority.

Traditional hunting laws

When people were still living at the outpost camps, traditional laws and rules were strongly adhered to. In hunting Belugas there were designated hunters who would take the first shot. Nobody would take the first shot except for the designated shooter in order to minimize any chance of loss. These designated hunters would usually kill the whale on the first shot. In times when the designated hunter was not available the whales were left alone. Also, in the past, kayaks were used to steer whales towards the land where hunters waited quietly with their rifles. Those in kayaks would create loud noises outside the perimeter of the whales' location. A long harpoon-like tool was used to kill the whale by striking at the heart. They also had designated harpooners who would strike, tug on the line to see if it was hooked properly, and then finally release the line if it was hooked right. This was done to avoid loss of equipment and game. The people in the kayaks had to be careful when harpooning a whale as the whale might turn on the side where it was struck and topple the kayak. So hunters always aimed for the far side of the whale from the kayak. These practices are hardly used anymore, if at all.

Traditional knowledge in the school programs

In Iqaluit there is no traditional material on the S/E Baffin Beluga in the school programs. Some elders feel that they are no longer able to educate the young with the knowledge they have accumulated. There is agreement that this knowledge gap should be addressed in order to help educate students about traditional Inuit ways and to help the younger generations understand why the beluga whale is so important to the S/E Baffin. Students would learn to make use of these traditional skills. Elders feel this would have to be written in both languages, and that a video should be produced on the step by step procedures involving hunting, traditional uses of parts, cutting and butchering, distribution of the catch, making sinew and ropes, and uses of blubber and meat.

The elders/hunters recognize there is a need to make this material available to the students and request that NWMB take note and address this issue.

Beluga surveys and counts

In the Iqaluit area and Frobisher Bay, counts by airplanes are not considered reliable. Hunters here who took part in counts by planes have been disappointed with the results, especially how and when the counts were taken. Inuit involvement and Traditional Knowledge have not been included in the reports. There were some hunters or elders that had or knew of somebody who had taken part in the counts and said that their input was often ignored. At times when they said whales had been spotted the response was, "No, it's a seal." But these elders and hunters knew better – because of the size and shape of fins and the size and colour of the animal, it was actually a Beluga. They also felt that aircraft were not covering the appropriate areas at the right time of year. For the counts to be accurate, they should be done when daylight is longer, around June and July, as more whales are known to be in the area at that time of the year. The hunters and elders feel that a cliff count would have to be carried out with the use of today's telescopes and communication means in order to determine the numbers accurately. This has proven successful in Clearwater Fiord and has been carried out several times. The surveys and counts should be done away from the ice and have parties on both sides of Frobisher Bay. By having parties stationed on both sides of the bay, they feel that more accurate data will be obtained, as hunters who know the area can pick the best

locations to conduct studies. Today's younger hunters, unlike the elders, have little knowledge on the whales in the fall and would like to learn more about them by running a fall count or survey. The hunters here would favor cliff counts and more Inuit Knowledge in the final reports.

Tudgat area (Resolution Island)

It was requested by the Iqaluit HTO that Traditional Knowledge be collected about the Beluga in the Tudgat area. As none of the participants had resided in that area, no information was available.

Whale hunting with nets

As far back as the elders at this workshop can recall, nets have always been used in hunting whales. These were used especially at the outpost camps. Today they are still used effectively. Back when the elders were growing up, net material was hard to come by and the nets were constructed of poor quality rope. Today they are made with stronger material and in the sizes needed. Some hunters had whales taken from their net by others, and there had been whales that got caught in the net while being chased. Nets are used in the summer when the area is free of ice but mostly in the fall when the ice is gone. Today about half of the nets in Iqaluit are used successfully. If a video and learning materials on nets could be put together, the elders and hunters would like to include information pertaining to the anchor, net tightness, location, floats, and the need to check the nets frequently.

Whales giving premature births in the area

As there is no known calving area near Iqaluit or in Frobisher Bay, births are scarce. Though according to the hunters and elders, births do happen in their waters. There are apparently not enough whales in the months of July and August for numerous births to occur. A small number of births are known to happen in the summer.

Traditional uses of meat, muktuk and bones

As modern tools and equipment were being introduced to the hunters and their families, the traditional needs met by the whale began to disappear quickly. Today hardly anything from the whale is used except as a food source. The way a whale was cut up before has also changed. Back when they were using the muktuk for rope, the muktuk was cut from the head area to the back according to the number of hunters. Everything was shared equally. The rope made from the muktuk was flexible and strong. It was also heavily used as a seal pup luring rope or made into a base for whips. It also served as an all purpose rope. The rope "Siaruaq" was an all purpose rope carried by most hunters. It was also used as "Sulujaq" the thin end part of the whip.

Fat from the whale's lower jaw was also used to oil rifles as a rust protection base. The intestines are also edible. Adults used the cartilage of the throat as a whistle. Bones from the flippers were used for dolls. The other bone parts were made into carvings after they had turned white which usually took a few years.

Ice entrapment of whales

According to the hunters and elders, there have been no such entrapments of any whales that they can recall. Some suspect there may have been the odd one that got trapped, but none in any great numbers.

Closing remarks by participants

Some elders said they are grateful for the opportunity of being able to take part in this very important meeting. Nooveya Ipeelee, "I am glad that I was able at my age to pass along this information at this meeting, as I am no longer able to instruct out in the land anymore." Others were also grateful that with the mix of hunters at this meeting they were able to bridge many existing gaps in Traditional Knowledge. "We show our sons by sketching on the sand on where to shoot the whale," said Noshuttaq.

Conclusion

It is apparent with the knowledge that has been shared that changes have occurred in both the hunters and the hunted. The hunters are adapting to new equipment, but also losing some of the Traditional Knowledge. The introduction of motorized boats has had an enormous impact on the whales and is suspected to be the main cause of the changes in the whales' behaviour in their natural environment, as hunters are able to travel faster and further with the motorized boats. The whales have had to learn new methods and ways of avoiding hunters.

With the realization of the existing knowledge and intergenerational gaps and the need to educate younger and older hunters alike, those interviewed suggested that educational material be made available to preserve Traditional Knowledge and the whales. Other suggestions to NWMB and DFO include:

1) To NWMB: An educational package be put together to be made available to school programs. These should include topics like: Preparation before hunts, Traditional Uses of Whales, Cutting and Butchering, Distribution of Catch, Hunting Equipment, Hunting Techniques, Using Nets at Whale Hunts, Safe Hunting Practices and Traditional Hunting Techniques.
2) A hunters' guide be put together to include: Uses of Proper Equipment, Safety Guides, Uses of Higher Powered Rifles, Leaders of Hunts, Chasing the Injured Only, Lethal Target Areas of the Whale, as well as other areas of importance to the community.
3) The sampling program should be reviewed as there are problems with the current setup and lack of communication. This applies to both the NWMB and DFO.
4) To DFO: That cliff surveys be considered because past survey counts with the use of airplanes have not been reliable and have resulted in negative feedback from the community. They feel that a cliff count would be best tried with people who know the area and the movement of the whales. A fall survey should also be considered as there is a lack of knowledge on the number of whales in the fall.

With the above information it is felt that this study has opened up new opportunities for both the community and the people involved with the hunters in understanding the S/E Baffin Beluga whales and their habitat. The participants expect this to produce new knowledge and a better understanding of the Beluga whale and hunting. It is obvious that improvements can be made to preserve the knowledge and use it to educate the less knowledgeable members and students in the community.

Inuit Ecological Traditional Knowledge on the S/E Baffin Beluga

PANGNIRTUNG NT X0A 0R0
MARCH 25, 26 & 27, 1997

INTRODUCTION

The collection of the material in Pangnirtung was done with the involvement of eight hunters/elders from the community. Material collected included the general knowledge, health, population, hunting and history of the S/E Baffin beluga. All the working materials and final documents are property of the NWMB and are available only through them.

The study was conducted at the Pangnirtung HTO Office with a group of eight selected elders/hunters consisting of:

Jaco Evic	Elder/Hunter
Enoosilk Nashalik	Elder/Hunter
Mososee Keyuayuk	Elder/Hunter
Peterosie Karpik	Elder/Hunter
Apak Qaqasiq	Elder/Hunter
Manasa Evic	Hunter
Joeelee Papatsie	Hunter
Levi Evic	Hunter/HTO Chairman
Peter Kilabuk	Study coordinator
Ricky Kilabuk	Camera man

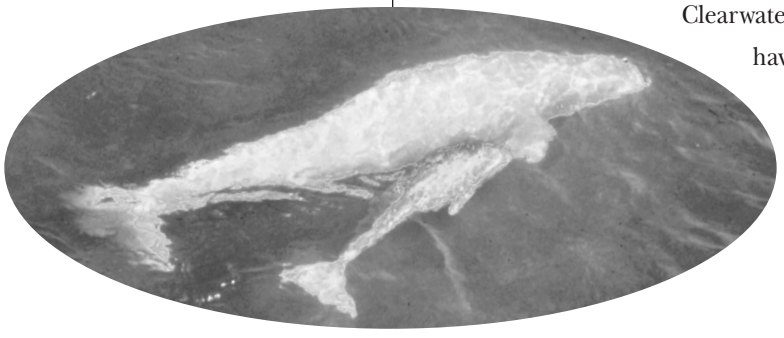
MIGRATION OF WHALES

According to the eight participants, the majority of the whales that migrate to and from the calving waters of Clearwater Fiord travel on the west side of Cumberland Sound. (See map 97-01.) Before the introduction of motorized transportation (snowmobiles and boats) in the 1960s, the Beluga whales would follow the newly formed ice cracks heading towards Clearwater. This was from June until the Sound was free of ice in July. The migrating whales upon arrival at these cracks were vulnerable and were only hunted then. At the floe-edge they were only hunted if they were very close to the ice where they could be harpooned when shot. Today, they migrate to and from Clearwater in groups within the same general period of time due to the noise created by the motorized means of transportation and hunting.

FEEDING

When whales reach the floe-edge they tend to feed off mostly Arctic cod and turbot under the ice. However, this feeding behaviour at the floe-edge has changed. Before the motorized means of transportation and more numerous hunts at the floe-edge the whales used to dive close to the ice to feed below the ice. This is known to take place less frequently nowadays probably due to the noise created by the hunters or in fear of the hunters' rifles.

Upon migrating to the Clearwater Fiord, whales used to feed in bigger numbers (as marked in map 97-01) and also upon leaving Clearwater Fiord. During their stay in Clearwater the whales are known to have less stomach contents probably due to shedding (moulting) and females giving birth in the area.



The reason for less feeding activity is not exactly known. The whales feed more on shrimp and some invertebrates that are available in that area. This reduced feeding activity explains why they are much skinnier when they leave Clearwater in the fall.

Births

As Clearwater is the only place where whales are known to give birth to their calves in S/E Baffin, hunters have learned a great deal about these Beluga whales. Most of the whales will come to Clearwater to give birth when Cumberland Sound is free of ice. Most of the young are born in July or early August. Inuit and hunters here believe a whale may give birth annually. A lot of the females are accompanied by new borns, yearlings and another from the year before.

In Clearwater more numerous births occur in certain areas as outlined in map 97-02. Fewer births are known to take place upon the whales arriving at Clearwater. It is only after spending some time in Clearwater that they will give birth.

Commercial hunts

Until the 1940s the Hudson's Bay Company was still active in the commercial hunts of Beluga whales in Clearwater. Some of these hunts were not documented and it is impossible for today's elders to estimate how many whales were taken. People from camps would gather in Pangnirtung before the hunts. Whales were taken by means of drive-ins, a method where whales were herded by many boats towards shore and left stranded on the falling tide. Here everybody was given a specific role to play in the drive-ins of whales at Clearwater. One successful drive-in area was near Usualuk where both Belugas and Narwhals were taken. (See map #97-03.) This also suggests that there were probably more whales travelling on the east side of Cumberland Sound and is indicative of there having been larger whale populations. According to the elders there were no drive-ins taking place in the 1940s and 1950s. The elders have since seen a decrease in the number of whales even after the commercial hunts were stopped.

Outpost camps

According to the elders there used to be more frequent appearances of whales during the arrival, departure and seasonal periods. At outpost camps (on map #97-04), whales were abundant near the camps while they were in Clearwater. At night the breaths of whales could be heard all night in front of Camp 6 until morning. Today, encounters with whales at the camp are rare.

Hunters at this camp had designated shooters most likely to make an instant kill should a whale come close to the land. This was a common practice at all camps. Even if there were numerous whales in the nearby waters they were not hunted unless a sure shot was determined. Back in the 1930s and until the 1960s ammunition was hard to come by and no shots were wasted. Despite the numerous whales in the area the camps would hunt only what they were going to use, minimizing wastage of meat and muktuk.

The meat back then was used mostly for dog food though usable parts were removed with care. These were mostly the tendons used for sinew. Certain sinews from the parts of the whale were used for certain types of women's work. There were also bones used for carving and there were certain parts that were considered a delicacy.

Motorized boats

Today the biggest factor that is considered to be causing a decline in the number of whales at the outpost camps and the whole Cumberland Sound area is the noise created by the numerous motorized boats. The noise is preventing the whales from reaching certain areas in the large numbers identified before the 1960s. Overall the behaviour of the whales is very different than in the past. The noise and activities of the boats are suspected to be a major factor as to why fewer whales are reaching the Clearwater area than before.

Health of the whales

Today's elders have seen a slight decrease in the thickness of the whales' fat. It is suspected that this is due to the whales needing to travel farther and faster to avoid the motorized boats.

In the past, when the whale muktuk (skin) was cut back it would overflow with oil and split along the cut easier. The whale's back would also appear to have smaller bumps, due to the fatness of the whale's body. It was noted also that the intestines used to have more fat surrounding them. The elders suspect it's not due to the whales being poor in health but due to the increased travel and runs they must do to avoid boats and hunters. Essentially, the whales today have to expend more energy.

The thickness of muktuk, its texture, taste and colour have not changed in any way or form. The muktuk is thicker in spring and summer than in the fall. This is a natural change that has always taken place.

Today the whales leave Clearwater as early as late August, whereas until the 1960s they would not leave until late October. Some suspect it could be that the smaller numbers of whales in the area are more sensitive to the motorized boats and noise; that a killer whale population is no longer in the area; and, that the ice is forming sooner in Clearwater. It was also noted that there are fewer premature births taking place outside the calving area which could be a change due to the decreased number of whales in the area.

Populations and distribution

Today's hunters are encountering smaller numbers in both male and juvenile pods as compared to the 1940s and 1950s. In one case a hunter at Camp No. 6 witnessed whales entering Clearwater from midday until sunset travelling in big numbers with no breaks. Today the male, female and juvenile pods have decreased in both numbers and groupings quite dramatically.

The commercial hunts before the 1940s were suspected to be the major factor in the decrease. Even after the commercial hunts were lifted at the end of the 1970s, hunters saw a decrease in numbers. Since then the numbers have steadied and are suspected to be rising in numbers due to the more numerous females carrying young and juveniles today. It is important to note the changes the hunters have seen over the years. The more recent decrease in numbers has not been due to overhunting, as some whales may stay elsewhere outside Clearwater or even Cumberland Sound. The participants feel that the heavy commercial hunts that took place during the drive-ins in the early 1900s have reduced today's populations substantially.

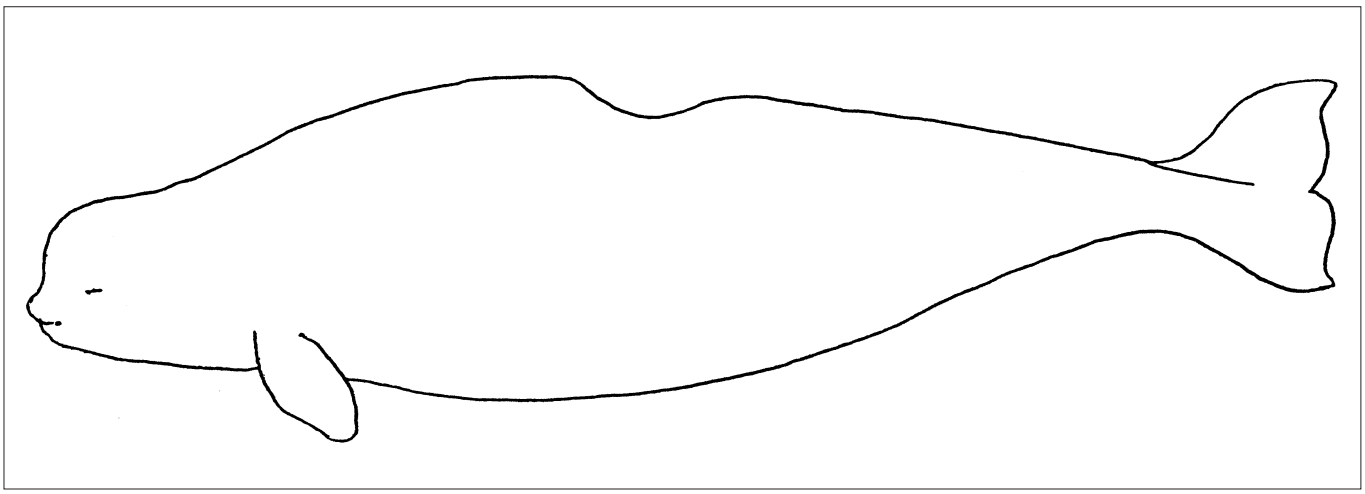
Scarring of whales

These whales appear to be more scarred with rifle shots than before. From the early 1900s to the 1960s it was a tradition that only the injured would be hunted as long as conditions permitted.

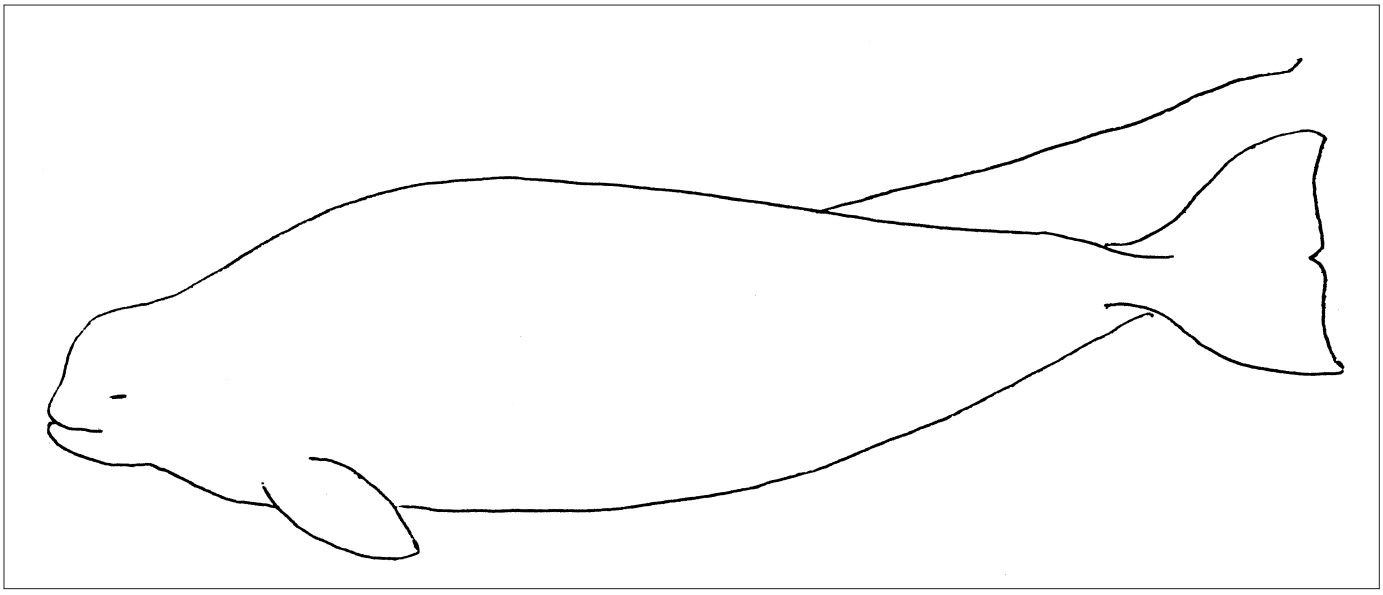
Motorized boats were also not available to these hunters and they were more selective in the methods they used. The motorized boats have been a major factor allowing hunters to chase the whales at random, therefore more shots are fired during a hunt. Today it is common to see more than 10 boats chasing a herd of scattered whales.

Badly scarred whales and their roles

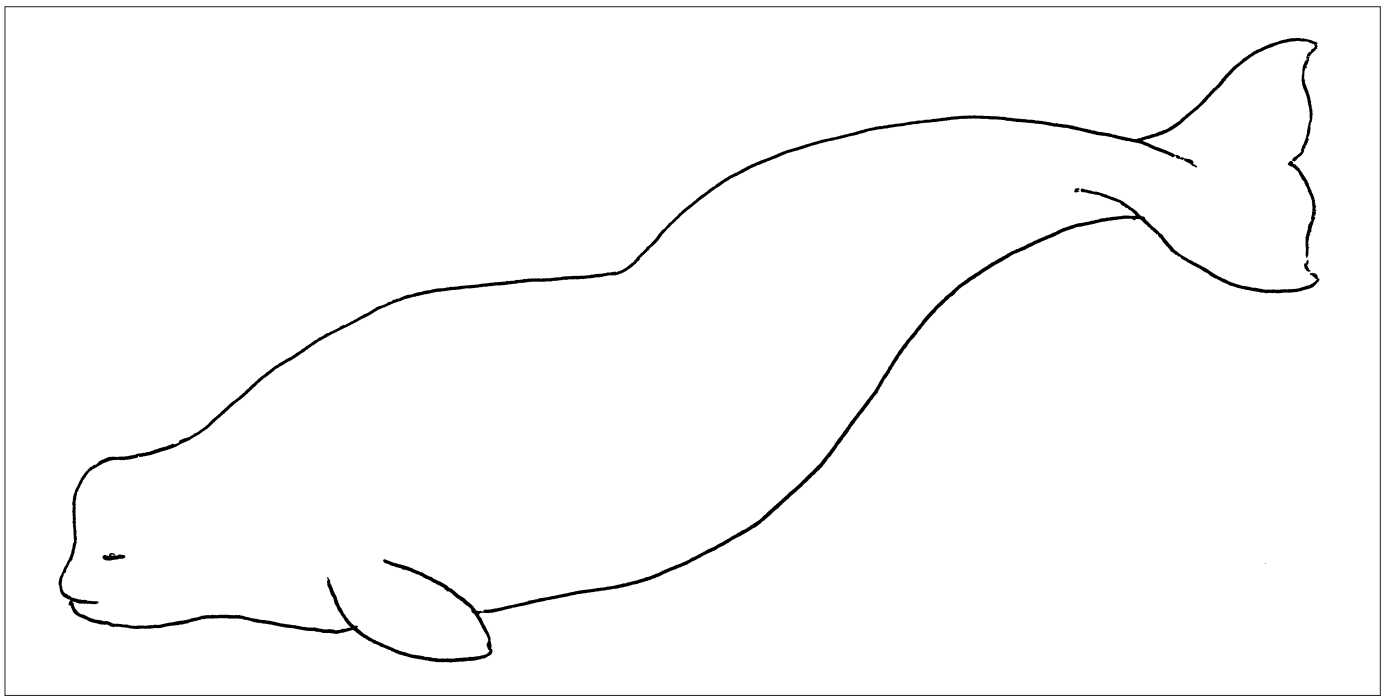
There is a certain group of badly scarred whales. These are ones with big notches in their back or disfigured bodies. They are known by most hunters to appear almost annually at the floe-edge or summer migration. The hunters respect these whales as they have been seen repeatedly scouting an area before the larger number of whales advance. Certain scarred whales scout for both the Narwhal or the Beluga. (The bigger scarred whales are shown below in diagrams A–D.) These are known to be found at a distance from the herds or groupings that are either travelling or resting. These badly scarred whales have been known for decades by the elders and hunters and their role has always been the same. Hunters avoid hunting them as they have proven to lead whales into this area year after year.



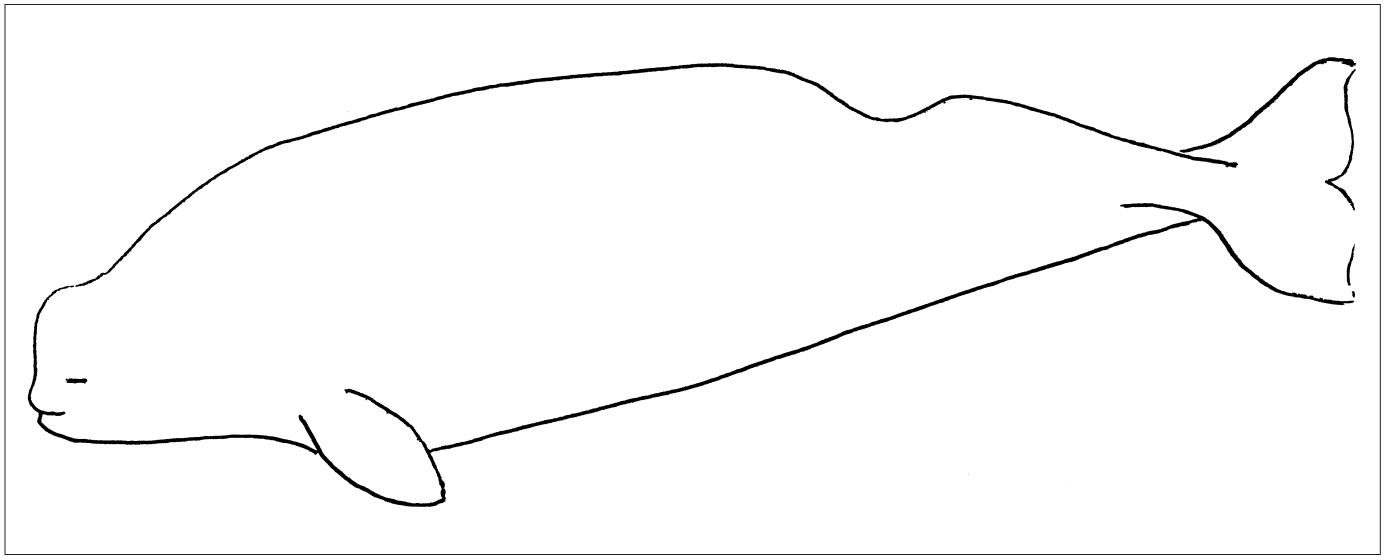
A) Notch in the back (still seen today).



B) Dragging a rope (still seen today).



C) Disfigured body (still seen today).



D) Notch near fin area (still seen today).

Sampling collection by DFO

The sampling collection program that has been conducted annually by DFO for the three communities has generated some mixed feelings and support. The hunters involved in this study and in the collection program, were not clear as to what was the purpose of the program. The general feeling was that if the hunters were made aware of the intent of the program, they would be more willing to provide information.

Possible solutions discussed to improve this program were:

1) Written reports be made available to hunters and the general public on the purpose and results of these studies.
2) More direct consultations between the DFO, HTO and the general public.
3) NWMB be notified of the problem and that they be included in the process.
4) That DFO and HTO should not rely on verbal conversations with small groups or individuals as a sufficient means of relaying the message to the public.

Distinguishing the different populations

In Cumberland Sound alone there are three different Beluga populations being hunted during the year. The main group is the Clearwater population. There is also a group of smaller whales being hunted at the floe-edge, and there is a small population that summers on the west side of Cumberland Sound.

These are distinguished by the hunters with the notable differences in appearance, size, health and behaviour. Differences:

1) The Clearwater whales are the biggest in body size of the three populations. Also upon arrival the outer layer of skin is yellow and in its early stage of shedding. These whales are fat and most float when killed. They reach Cumberland Sound usually in late June or early July and travel in big herds. These characteristics apply to most adult whales. The younger ones are not as white or are still grey in colour.
2) The whales hunted at the floe-edge are different in appearance and in size. They are noticeably smaller and skinnier and appear in the Spring – April, May or June. These whales are really white in colour and do not show any sign of shedding as the Clearwater whales do. Hunters suspect that these whales spend more time in the faster currents and that this is probably the reason why they are thinner and skinnier. Another difference they show in their behaviour is that they are much easier to hunt because they come closer to the ice and they do not stay under the water as long as the Clearwater whales do. These whales are usually not in as great numbers as the Clearwater whales. They also travel in smaller groups. It is not known from where these whales come or where they go.
3) The whales on the west side of Cumberland Sound are also smaller than the Clearwater whales. They are also not as fat and appear to spend their time along the coast and in faster currents of water. Though these are smaller in size, the skin (Maayak) is thicker than the other two populations. They also tend to sink when killed. The meat and muktuk is also stronger in taste than the other two populations and the muktuk tends to be more flexible.

Most counts have taken place only in Clearwater. The numbers found have been used in determining the size of the population and distribution.

To get a more accurate number of whales that are entering and being hunted in Cumberland Sound there should be more effort made to include the other populations. These are hunted and taken off the Pangnirtung quota annually. Further studies would help determine if these are different populations. The hunters feel that taking these other populations into account would improve the accuracy of the studies and counts. Another interesting note raised here was the fact that before the introduction of motorized transportation it was harder for the hunters to determine if there were different populations reaching the area. This was because they did not have the means of transportation to venture out to other parts of Cumberland Sound.

Beluga populations and distributions at the outpost camps

There is a great difference in the population and distributions of whales at the outpost camps. This is due to smaller numbers and changes in the behaviour of the whales at the northern part of Cumberland Sound. The decrease in numbers are the result of the commercial hunts by the Hudson's Bay Company into the 1940s, and local commercial hunts for a number of years until 1979. These hunts all took place at Clearwater. For years after the hunts, the number of whales continued to decrease. Today the hunters are seeing more whales carry young and suspect that the numbers are finally increasing.

At Nunatak (area 6 of map 97-04) at the mouth of the entrance to Clearwater where several families permanently resided into the 1960s, Peterosie Qarpik (elder/hunter) recalls that from the 1940s to the 1950s, the whales used to spend a lot of time near Nunatak in the summer months, almost right till freeze-up late in the month of October. These whales, he recalls, were in the hundreds.

He further recalls that while heading to the end of Clearwater, he used to see many whales, guessing the numbers to be over a thousand along one side of the fiord. He remembers the whales whistling and making noises near the Nunatak camp in the night.

Another Elder/Hunter, Mosesee Qiyuadyuk recalls when whales used to give birth at Iqalugadyuk (area 7 of map 97-04) outside Clearwater.

In Bon Accord (Illungayut, area 3 of map 97-04) Jaco Evic, an elder/hunter, recalls when there were much more whales travelling near the camp heading to or leaving Clearwater. He recalls that whales used to temporarily leave Clearwater more frequently and in bigger numbers. He recalls whales travelling closer to the land. Today the whales tend to travel further out in the open water. Hunts were limited to only what was needed and also to avoid spoilage of meat and muktuk. Manasa Evic, a Hunter, also recalls when they used to hunt them in the late fall; today the whales are leaving in late August or early September. This is also a behavioural change suspected to be due to the motorized boats or because of the lesser numbers of whales in Clearweater.

Enoosilk Nashalik, an elder/hunter who used to live at Sauniqtuuradyuk, (area 1 of map 97-04) recalls how the whales used to follow the new forming cracks towards land in the later part of spring near the camp. Then in the fall they would migrate back out, passing the same area. They used to hunt the whales in the newly forming cracks. The hunters killed only what they needed to share amongst the camp. He knows that today, most of the whales travel further out in the open water.

Whales used to travel below the ice of the high tide mark. This is rarely encountered today. In the past many of the whales would have travelled below the ice in a day or less. These comments were backed up by Apak Qaqasiq, an elder/hunter, who also resided at the same camp. Because there were no motorized boats in Clearwater when families camped for a part of a season, whales were left undisturbed in the waters.

In the late 1980s only one count study was ever taken involving the camps outside Clearwater. With the counts only taking place in Clearwater, it is felt by the group that it would be best if the counts were done at the entrance of Clearwater while they are entering, to determine how many really do enter.

General hunting areas

Pangnirtung hunters take advantage of all seasons to hunt Beluga, as long as the quota is still not taken. Most spring hunts are done at the floe-edge out in Cumberland Sound between April, May and June. The beluga are mostly hunted only if there are no Narwhals to hunt. Summer is when the heaviest of hunts will take place in Cumberland Sound and outside of the Clearwater boundaries. (This boundary is marked on map 97-03.) A gradual decrease in the number of whales has been noticed, and only in the last few years have hunters started noticing more Beluga carrying young and calves. As a result, they are certain there is an increase in the numbers of the Beluga in recent years.

Hunting methods and hunting of Beluga

Hunting methods and equipment have changed dramatically in the last 35+ years. The behaviour of the Beluga whales has also changed dramatically. Today hunters are using rifle shots to get the whales to go under water during chases. This has contributed to the number of scarred whales and to a general changed behaviour in the whales. A contributing factor in the wounding and chasing of whales at large is the quota of 35 which makes the hunter rush for his catch. At most hunts there are more than three times the hunters for the quota. This usually takes place at the time the Beluga arrives in Cumberland Sound. These rushed hunts originated with the introduction of the quota.

When a number of boats are chasing whales, hunters are taking shots with other boats and hunters in the line of fire. The group suggests that the hunter who first wounds the whale gets the whale when it is killed and not the harpooner. Another practice was that when a whale had been injured, the oil slick on the water's surface was used to pursue the wounded whale. Today the elders feel that to restore some order in the hunting of Beluga whales, traditional laws and practices need to be applied and adhered to more strictly. The group also feels there should be more community consultations to make the public more aware of the problems. This should be addressed at the school level.

Community knowledge and school programs re: traditional knowledge of the S/E Baffin Beluga

Today there are no libraries available for the students and instructors to educate themselves on Inuit Traditional Knowledge of S/E Baffin Beluga whales. Local knowledge is not available to the students and they learn of the Beluga elsewhere. The problem is recognized where a new teacher may have no knowledge or local information available to him/her at all.

It is strongly recommended that this be addressed to the local Education Council and system through NWMB so that Traditional Knowledge can be made available to both the school system, the teachers and to the students.

Some of the topics suggested for educating students could include:

1) Traditional hunting methods.
2) Research on Beluga by students.
3) Hunting and Hunting Methods before, during and after hunts.
4) Hands-on experience on traditional uses of meat and parts.
5) Butchering, cutting and distributing of the muktuk and parts.

Community hunts within Pangnirtung

Pangnirtung HTO organizes annual hunts to distribute muktuk and meat amongst the elders, to less supported members, and to the public through certain community events throughout the year. This serves a good purpose and has been welcomed by the community in general.

As the HTO does not have an adequate budget to run these hunts, they are getting harder to run because of rising costs. It is also getting harder to find hunters to participate.

Upon returning from the hunts community feasts take place. This event is thought to be a good way of bringing the community together and is encouraged.

Because of the problem of high costs, the following suggestions are being made to organize and run the hunts more cost-effectively:

1) Run the hunts in the spring while they can still use snowmobiles to reach the floe-edge to keep costs down.
2) The meat can be better prepared when the weather is not too warm to avoid spoilage.
3) Hunters should remain at certain look out spots at the time of hunt.
4) Activate the hunts only when whales have been spotted at the floe-edge.

5) Should hunts take place in the summer, they should be organized at the time the whales first start heading for Clearwater, in Cumberland Sound.
6) That the Hamlet of Pangnirtung assist more often in these hunts.

These suggestions are raised to help keep costs down and to further avoid any spoilage of meat or muktuk.

General health of Beluga in the spring, summer and fall

The elders and hunters share the same knowledge on the health of the whales from season to season. These whales are fat and healthy when they first arrive in Cumberland Sound. Clearwater whales will float when killed between the months of April to August. Later in the fall from September on, the whales have lost weight and tend to sink when killed.

When these whales leave Clearwater in the fall, they tend to be more adventurous and can be found in more of the inlets and fiords along their migratory route. The whales will travel closer to the coast more than they would have upon arrival and they feed on their way out. When these whales have thinned out, they will travel faster and go without air for much longer periods of time (in the fall).

Stomach contents of the whales have shown that they feed more towards the last part of their stay in Clearwater, and feed regularly upon leaving Clearwater. (Note: some of the elders had witnessed dead whales that had died while feeding on a "tupiyyutik" better known as the grenadier.)

Aging of meat and muktuk

This traditional method of aging meat is still practiced, depending on the season of kill. Most of the aging was done with the younger and smaller whale meat and muktuk later in the summer. Regardless of the age of whales, the muktuk can be aged and made into "Singittaq" which is the stripping of muktuk from the skin and blubber after it has been aged.

Hunting Beluga with nets

Today these nets are not used in any season to hunt Beluga. Some hunters avoid using seal nets fearing they will catch whales after the quota has been filled. In Pangnirtung or outside, whale nets are only used to hunt Narwhal. Elder/hunter Jaco Evic recalls that nets at the outpost camps were not used before the 1930s. This was probably due to no rope material being available to be made into nets. After the 1930s nets were introduced, but even these were made with very poor rope and material.

Ice conditions at the floe-edge and ice packs in the summer

When hunting at the floe-edge thin ice is always a threat and creates problems for the hunters. Heavy ice packs at the floe-edge can be used to the hunters advantage where whales may be found in small openings of water and are vulnerable.

In the summer when heavy ice packs are in Cumberland Sound, it is harder to hunt game. Losses may be greater and travel may be impossible due to the heavy ice packs.

Ice entrapment of whales

In 1956 over a hundred Beluga whales were trapped during the forming of ice on the west side of Cumberland Sound. It was only in later years that it was noticed that the whales were missing. There are other areas that trapped whales repeatedly on the west side of Cumberland Sound. Most of these whales may survive the winter if not hunted. Another area that is known to have trapped more than 35 whales is Irvine Inlet, (see map #97-04). There are fast currents there and shallow waters. Enoosilk Nashalik (elder/hunter) suspects that the whales could have been washed ashore by a sudden fast current of water as their remains were found above the high tide mark. Another area that occasionally traps whales is the openings of water in Nettilling Fiord. Enoosilk has encountered a few trapped whales a number of times in that area.

Studies and counts of Beluga whales

Inuit knowledge has always been lacking or not included in some of the studies, final reports or findings where Inuit hunters participated. Some individuals, during aerial surveys, returned feeling neglected or found their input not included in the final reports. The group feels that there needs to be improvements made in the studies and reporting methods to include Inuit knowledge in the final reports. Even in the last few studies and counts, adequate Inuit knowledge was not included. Changes have been requested with DFO to work closer with the communities on such activities.

Traditional uses of whale meat and parts

Today the uses of a whale and its parts are less known by the younger generations, even though traditional uses and needs are still an important part of our culture. This is an area where elders need to educate and pass on their knowledge. Elder/hunter Enoosilk Nashalik said, "We must restore this (practice of Traditional Knowledge) ... as it used to be part of our daily lives." In the past, most parts of the whale were used except for the head. People made thread, jerky, and used the meat for dog food. There were different kinds of thread made from the tendons of certain parts – the type used would depend on what the women were going to use it for. It was done this way because certain tendons were weaker than others. Even the meat is not used for food today as it was in the past. Certain parts of the whale that were considered a delicacy back then are still eaten today by some hunters. The stomach was boiled by some people, the skin was made into the base of whip handles. Hunters made from the skin a certain type of rope used in luring the seal pup's mother to the hole. This type of rope turned white after repeated use and would not freeze in the cold. This was cut out from the top part of the whale skin. Uncleaned bones were stored to be used in the winter as fox bait, or, eaten when there was no other meat available. The meat on the front part of the whale head was not consumed as it could make people or dogs dizzy or sick. The blubber was used extensively to fuel the "Qullik" (stove) which burns cleaner and brighter than most types of blubber. The blubber of the whale had even been used repeatedly as a gasoline mix to run motors.

The distribution of the whale parts were split evenly amongst the camp when a whale was caught either at the immediate camp site or elsewhere. There were also certain procedures followed in the preparation of the whale. Certain types of bones, the front flippers and tail fins were divided equally after being cut into smaller pieces.

"Today when a whale is caught, it is cut wherever it is convenient regardless of its possible uses. Very small parts of the meat or intestines are taken, and the parts that were eaten as a delicacy are hardly touched," said hunter Jooeelee Papatsie.

With the changing needs for whale parts and uses, respect by hunters for Belugas has changed too. "This is becoming a more common problem," says hunter Levi Evic. "This was never a problem when all parts and uses were divided equally amongst the camp," recalls elder/hunter Mosesee Qiyuayuk.

The elders and hunters recognize that the ignorance of traditional ways and laws are part of the problems today. Hunts are too rushed and too much eagerness is shown by most hunters. Even the elders are having to rush to get their catch or share. This was never done while living at the outpost camps. Before, more of the camp members were related unlike the many different families and community members today. The gaps between the elders and the younger generations are far and wide. "We the elders acknowledge that there is a need for us to give better guidance," says elder/hunter Enoosilk Nashalik. Elder/hunter Mosesee Qiyuayuk stated, "Hunters can obtain the elders' knowledge by listening to elders on the radio."

Closing remarks

Levi Evic, Hunter/HTO Chairman: "This study will bring out a lot of new information regarding educational views and other aspects on the hunting of Beluga whales."

Manasa Evic, Hunter: "I expect good results from this study and want to hear the outcome of this study sooner than later. I thank the elders for participating."

Jaco Evic, Elder/Hunter: "I have high expectations from this study, not only on hunting Beluga whales but on the way we live our lives and through the teaching of more of our traditional ways of living."

Enoosilk Nashalik, Elder/Hunter: "I express my thanks. We expect good things to come from these meetings. Hopefully, with this information NWMB can make improvements through further studies and such."

Peterosie Qarpik, Elder/Hunter: "I express my thanks and expect Question #11 on "Traditional Knowledge in the school programs" and Question #19 on "Traditional needs and uses of whale parts and meat," to be most beneficial as educational tools."

Jooeelee Papatsie, Hunter: "I also express my thanks. From 1960 to 1970 the younger generation has lost a lot of traditional skills and ways that used to be followed. Having lived with an elder and therefore recognizing how far we have to go, I expect that there may be more hardships along the way."

Apak Qaqasiq, Elder/Hunter: "I express my thanks. This study has been very informative, I also respect the questions that were raised as they were very relevant to our traditional ways of life."

Suggestions and recommendations to NWMB

The eight participants from Pangnirtung involved in this study and meeting would like to request that the need to put out educational material in a written format for students, teachers and local people be addressed seriously.

The educational videos to be used at the school programs should include such topics as:

1) Traditional uses of meat and whale parts.
2) Proper hunting methods before, during and after the hunts.
3) Butchering, cutting and distribution of muktuk and parts.

Another idea mentioned for teaching students is to have the students do research work on the Beluga whales.

Suggestions to DFO on the sampling program:

1) The purpose and intentions should be made clear to the hunters and public on the sampling program being carried out by DFO.
2) There should be more direct consultations between DFO, HTO and the public on the progress of the study.
3) That NWMB should be addressed and take a part in the progress of these studies.
4) DFO and HTOs should not rely on verbal conversations to small groups or individuals as sufficient for conveying the messages of the study.

($F = 1.09$; df = 1,121; $P > 0.25$). Thus, rates of weight gain do not vary between juveniles born in spring (0.7 g/day) and summer (0.8 g/day).

Food in spring consists of invertebrates and various parts of herbaceous plants, whereas mast is the major constituent of the diet in autumn (Wrazen, 1976). Spring foods are dispersed and small in size compared to mast items which are produced in abundant quantities and are relatively larger in size. Thus, the ratio of time spent foraging to eating is much greater in spring compared to autumn simply because autumn sources of food are more readily obtained and take more time to consume (Yahner, 1977). Yet weight gain of spring and summer litters are comparable regardless of type and dispersion of food resources (Fig. 1).

My data suggest that rates of weight gain do not vary with season and are for the most part genetically determined, provided that sufficient food resources are available. Limited data available in the literature indicate that chipmunks found in other geographic regions may gain weight at a similar rate. For example, rates of weight gain in 18 juveniles in Ontario, Canada, ranged from 0.3 to 1.5 g/day during a period of 16 days (Pidduck and Falls, 1973). These rates are roughly equivalent to those which I found in my population. Future studies may verify that rates of weight gain are uniform regardless of geographic region despite the fact that populations of *Tamias* in northern latitudes are active for a smaller proportion of the annual cycle compared to populations in southern latitudes (Yahner and Svendsen, 1978). In young yellow-bellied marmots, *Marmota flaviventris*, rates of weight gain in populations occupying high elevations exceed rates of populations in intermediate elevations. The length of the annual cycle of activity in marmots inhabiting high elevations is reduced because of a shorter growing season relative to intermediate elevations where the longer growing season permits additional time for marmot activity (Andersen et al., 1976). I therefore propose that although rates of weight gain vary markedly among species of sciurids (Hirshfield and Bradley, 1977), perhaps rates of weight gain are species-specific in certain species but differ among populations of other species which occupy a continuum of environmental conditions.

I thank G. E. Svendsen for his suggestions during this study. Funds were provided by the Department of Zoology and Microbiology at Ohio University, by a Grant-in-Aid of Research from Sigma Xi, and by an Ohio Biological Survey Grant (UT 1673) to G. E. Svendsen.

OBSERVATIONS ON OVERWINTERING WALRUSES IN THE EASTERN CANADIAN HIGH ARCTIC

The walrus (*Odobenus rosmarus*) is an abundant pinniped in the eastern Canadian High Arctic. For most of the year, walruses are associated with pack ice although during the open water season they may haul out on land in large numbers at certain traditional sites (Mansfield, 1967). During the winter, they congregate to feed in shallow water areas which are either relatively ice free or in which they can maintain breathing holes in the leads, thereby assuring access to the molluscs

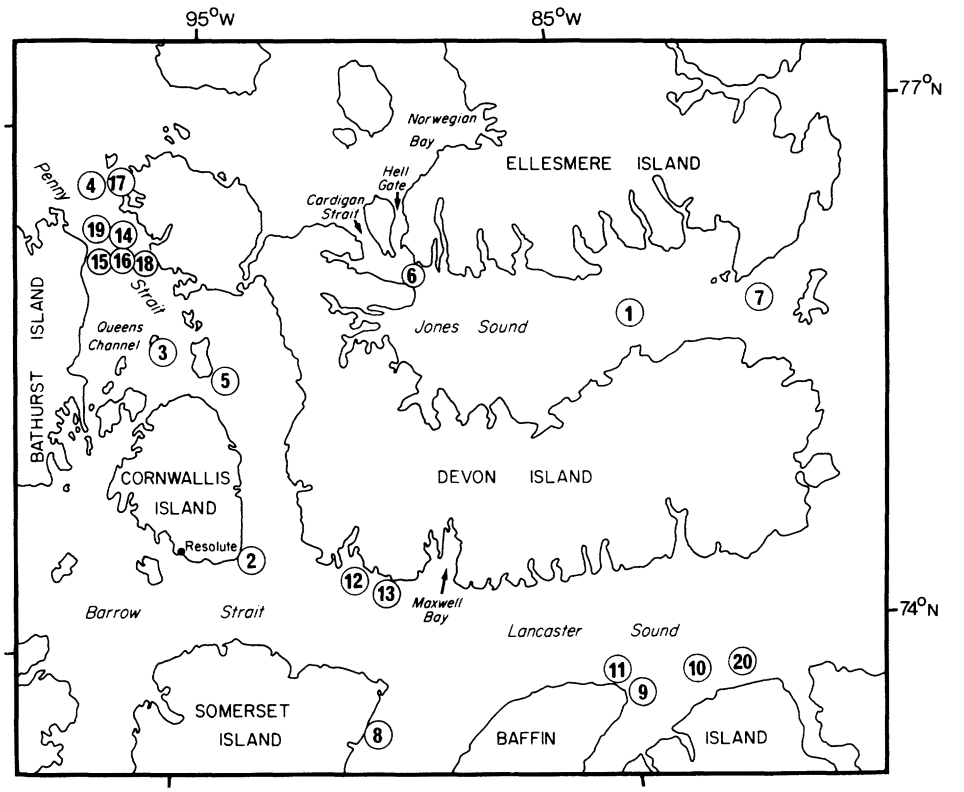

FIG. 1.—Observations on overwintering walruses in waters surrounding Devon and Cornwallis Islands, Northwest Territories: 1) one killed by Inuit at frozen out hole 90 km west of floe edge in Baffin Bay, March 1971; 2) two on tide crack 120 km west of floe edge, April 1971; 3) one beside hole in ice, April 1972; 4) 40 along polynias, May 1972; 5) 20 along polynias, May 1972; 6) 100 along polynias, May 1972; 7) 15 along cracks, May 1972; 8) three along crack, 30 April 1975; 9) seven along polynias, 8 April 1976; 10) one along open lead, 12 April 1976; 11) four along open lead, 14 April 1976; 12) two along open lead, 16 April 1976; 13) three along open lead, 16 April 1976; 14) one killed by polar bear by breathing hole, 19 April 1976; 15) one killed by polar bear beside small lead, 19 April 1976; 16) one along polynias, 19 April 1976; 17) one mauled by polar bear beside breathing hole, 20 April 1976; 18) one on ice by breathing hole, 29 April 1976; 19) one along open lead, 2 May 1976; 20) one along open lead, 2 May 1976.

upon which they feed. Walruses are apparently capable of breaking ice up to 15 cm thick in such areas (Vibe, 1950). The availability of such habitat is probably the limiting factor to walrus distribution. In areas where access to the water may be reduced because of heavy ice, walruses may become vulnerable to predation from polar bears (*Ursus maritimus*), although few such encounters have been documented.

The seasonal distribution of the walrus is reasonably well known around southeastern Baffin Island, Hudson Bay, and the Thule District (Vibe, 1950; Mansfield, 1958, 1967; Loughrey, 1959). In comparison, the seasonal distribution of walruses in the eastern Canadian High Arctic is less known, especially during the winter, because the area is largely uninhabited and visibility from aircraft that do travel in the area at that time is reduced by the extended dark period. However, human activities, such as offshore petrochemical exploration, are increasing there at a rapid rate, which makes it vital that areas critical to the survival of the indigenous fauna be identified so that adequate protection can be assured. This paper summarizes our information on areas which appear to be important to walruses overwintering in the eastern Canadian High Arctic.

Our observations were made from March to mid-May (which is late winter and early spring in those latitudes) from 1971 through 1976 during extensive travel by helicopter to tag polar bears

and by oversnow machine searching for polar bear dens (Stirling et al., 1977). Observations made by Eskimos and pilots are included.

Figure 1 summarizes 20 observations on the late winter and early spring distribution of walruses in the eastern Canadian High Arctic. These data indicate two areas where significant numbers of walruses apparently aggregate during winter—Hell Gate-Cardigan Strait and Penny Strait-Queen's Channel.

The Hell Gate-Cardigan Strait area is well known for strong tidal currents which may reach 4 km/h (J. R. Wilson, Dept. Environment, Ottawa, personal communication). Taylor (1955) quotes Sverdrup as stating, after viewing Hell Gate in March 1900, "none of us had ever seen waters so utterly impossible to navigate, as the sound here," and "great pressure hummocks were drifting along at terrific speed in a violent whirlpool caused by the strong tidal current." In May 1972, the ice in Hell Gate and Fram Sound was thin and perforated with walrus breathing holes and 100 walruses were observed. The combination of these currents and a water depth of only about 80 m (Canadian Hydrographic Service Chart 7930) apparently creates an area suitable for walruses during winter. Mansfield (1967) and Grise Fiord Inuit hunters report that walruses are abundant in summer to the east of Hell Gate, along the southern coast of Ellesmere Island. It may be some of these walruses that spend the winter near Hell Gate.

The second important area for overwintering walruses was Penny Strait-Queen's Channel (Canadian Hydrographic Service Chart 7950). There are no accurate records of ice thickness or current speeds in this area but cracks, polynias, and thin ice are characteristic there in April when the mean temperature at Resolute is still −22.7°C (Meteorological Branch, 1970). Thus, we suspect that strong currents prevail there as well. Summer sightings of walruses in Penny Strait and Queen's Channel are common (Soper, 1928; Loughrey, 1959; Mansfield, 1967 and this study), indicating that the area is important to walruses throughout the year.

The remainder of the sightings in Fig. 1 lie variable distances to the west of the floe edge, at the eastern ends of Jones and Lancaster sounds. Loughrey (1959) reported that walruses winter in the open water of Lancaster and Jones sounds and Baffin Bay and then move westward in the spring as the ice begins to break up. The floe edge in Lancaster Sound in most years runs south from Maxwell Bay on Devon Island, although in the winter of 1975–1976, the whole of the sound was frozen over. To the west of the floe edge, the ice thickness may exceed 150 cm and there is little movement until the beginning of break-up in late May to early June. Thus, although it appears that the walruses in observations 1 and 2 and 9–13 (Fig. 1) overwintered where they were observed, they probably do not do so on a regular basis. A similar instance of an isolated walrus overwintering on a winter lead was reported in the western Arctic (Stirling, 1974).

Walruses that overwinter in an area with restricted access to water become potentially vulnerable to predation by polar bears. Three observations support this. On 19 April 1976 one of us (HPLK) found two walruses that apparently had been killed by polar bears (Fig. 1, nos. 14 and 15). One was an adult female 22+ years old (289 cm long, estimated weight 400+ kg). There was blood on top of her frozen over haul-out hole, indicating that she might have been frozen out when the bear attacked. The other walrus (unsexed) was just under 2 years old (243 cm long, estimated weight 270 kg). A blood trail indicated that it had been captured beside or in a 60 cm wide channel that went around the circumference of a 25 to 30 m diameter grounded iceberg.

Examination showed that both walruses had large numbers of sharp deep punctures about their heads which could only have been made by bear claws, suggesting that they may have been killed by multiple blows. Soper (1928) quotes a report by Hantzch of a large bear in the vicinity of Kikerten Islands, Cumberland Gulf, attacking three walruses and killing a large male which it tore extensively about the head. Akpaleeapik, a Grise Fiord Eskimo, also informed us of a walrus that a polar bear killed with a blow in the head as it surfaced to breathe through a hole in the ice.

On 29 April 1976 Mr. Tai-Ho of Klondike Helicopters tracked a polar bear to a walrus that he estimated to be less than 3 m long with tusks 20 to 25 cm long (Fig. 1, no. 17). Tracks and blood in the snow around the walrus's breathing hole (1 to 1.5 m diameter) indicated a fight had taken place very recently. The walrus was covered with blood and one tusk was broken. Despite a careful search, no bear tracks leading away from the site were found, suggesting that the bear may have been killed and sunk in the water. Freuchen (1935) reported finding a polar bear that had been killed by a walrus, and Perry (1966) summarizes similar observations from the journals of early arctic explorers. Although predation by bears is likely not of any significance to the walrus population as a whole (Mansfield, 1958; Loughrey, 1959) such encounters may be more frequent than previously seemed apparent.

A WINTER STUDY OF SMALL RODENTS IN ASPEN PARKLAND

This note reports on a live-trapping study conducted during the winter of 1969–1970 on the northeastern shore of Ministik Lake, 37 air km east of Edmonton, Alberta, Canada. The area is aspen parkland (Bird, 1961) with scattered spruce. Our goal was to learn how circadian activity, territorial behavior, movement, and mortality are related to snow cover characteristics and temperature changes, and especially to the times of Pruitt's (1957) thermal overturn, hiemal threshold, and onset of snow.

Iverson and Turner (1972) and Turner et al. (1975) have studied winter interspecific relationships of *Microtus* and *Clethrionomys* in grassland and in spruce forest. Studies of some effects of snow cover have been reported both for tundra (Fuller, 1967; Pruitt, 1966) and taiga areas (Fuller, 1969; Fuller et al., 1969; Johnson, 1957; Pruitt, 1957), but at the time of our experiment no such work had been reported for the aspen parkland. Snow cover is more complex in aspen parkland than in either tundra or taiga. In open areas it is formed, shifted, and reshaped by wind and piled in the lee of woodlots and around every piece of brush growing separately in the fields; however, because the fields are interrupted by woodlots, the impact of wind is less severe than on completely open tundra or prairie. Woodlots, although offering some protection, are still more exposed to the action of wind and sun than is the continuous taiga because of their restricted size and the predominance of deciduous trees. Bowl-shaped depressions-qamaniqs (Pruitt, 1965) are weakly formed or not present under deciduous trees. Thus, rodents do not avoid tree bases, but use small spaces formed around the bases as passageways from undersnow tunnels to the surface. Such spaces are formed by wind moving trunks and stems.

A plot 130 by 60 m was laid out half in the open field and half in the woodlot. Longworth traps protected by plywood roofs (Iverson and Turner, 1969) were set in 10 m grids and operated for four nights every second week. All rodents were toe-clipped and released at site of capture. Air temperatures 60 cm above ground were measured with maximum-minimum thermometers and subnivean temperatures (at the ground surface) were recorded by thermistors. All measurements were taken in both woodlot and field. Snow depth, hardness, and density were measured with

Laidre, Kristin, L., Mads Peter Heide-Jørgensen, and Jack Orr. 2006. Reactions of Narwhals, *Monodon monoceros,* to Killer Whale, *Orcinus orca,* attacks in the eastern Canadian Arctic. Canadian Field Naturalist 120(4): 457–465.

A Killer Whale attack on Narwhals was observed at Kakiak Point in Admiralty Inlet, Nunavut, Canada, in August 2005. Behavioral responses of both Narwhals and Killer Whales were documented by direct observation. Data collected from Narwhals instrumented with satellite-linked transmitters 5 days prior to the arrival of Killer Whales were used to examine changes in Narwhal movement patterns (e.g., dispersal and clumping) five days before the attack, during the attack, and five days after Killer Whales left the area. A minimum of four Narwhals were killed by 12-15 Killer Whales in a period of 6 hours. Narwhals showed a suite of behavioral changes in the immediate presence of Killer Whales including slow, quiet movements, travel close to the beach (<2 m from shore), use of very shallow water, and formation of tight groups at the surface. These behavioral changes are consistent with Inuit accounts of Killer Whale attacks on Narwhals. During the attack, Narwhals dispersed broadly, the groups were less clumped (standard deviation of inter-whale mean latitudes and longitudes), Narwhal space-use doubled from pre-attack home ranges of 347 km^2 to 767 km^2 (kernel 50% probability), and Narwhals shifted their distribution further south of the attack site. After the disappearance of Killer Whales, north-south dispersal of Narwhals contracted and was similar to pre-attack levels, total space use decreased slightly (599 km^2), yet west-east dispersal remained high. Narwhals were distributed significantly ($P < 0.001$) more broadly offshore in areas not used before the occurrence of Killer Whales. In general, short-term reactions of Narwhals to Killer Whale presence were obvious; yet normal behavior (as observed from shore) resumed shortly after Killer Whales left the area. Long-term (five day) Narwhal behavioral responses included increased dispersal of Narwhal groups over large offshore areas. This is among the few reports of eyewitness Killer Whale attacks on Narwhals in the high Arctic and is the first time changes in Narwhal behavior have been documented in response to a predation event through the use of satellite telemetry.

Key Words: Killer Whale, *Orcinus orca*, Narwhal, *Monodon monoceros*, predation, satellite telemetry, Admiralty Inlet, Nunavut, Canada.

Killer Whales (*Orcinus orca*) occur widely in Arctic waters, yet their abundance, movements, site fidelity, and specific distribution are poorly known (Forney and Wade 2006). Generally, Killer Whales are sighted during ice-free months and often near areas with high densities of other marine mammals, such as summering grounds for Belugas (*Delphinapterus leucas*) and Narwhals (*Monodon monoceros*). In the eastern Canadian High Arctic, this includes eastern Lancaster Sound and associated inlets or fjords around Baffin Island (e.g., Eclipse Sound, Admiralty Inlet, and Prince Regent Inlet) (Markham 1874; Reeves and Mitchell 1988).

Few eyewitness accounts are available of Killer Whale attacks on Narwhals (Steltner at al. 1984). This is because Killer Whales occur over large, sparsely inhabited Arctic areas and the timing and location of attacks are unpredictable. Thus, the majority of descriptions, both of Killer Whale attacks themselves and of the response of Narwhals, come from Inuit observations (Degerbøl and Freuchen 1935; Freuchen and Salomonsen 1961) or from scattered opportunistic reports (Campbell et al. 1988). Generally these accounts made by locals are limited in that observations extend only as far as what can be observed from shore and generally cover short time scales (hours). Also, Inuit observations of Killer Whale occurrence or Killer Whale attacks may not always be reported. There is little information about the natural mortality of Narwhals and generally, Killer Whales are assumed not to significantly depress Narwhal populations (Davis et al. 1980). Furthermore, the extent to which Killer Whales affect the behavior of Narwhals (e.g., movement patterns) is unknown.

In August 2005, a Killer Whale attack on Narwhals was observed from a camp operating a month-long Narwhal satellite tagging operation in Admiralty Inlet, Canada. Several kills of Narwhals by Killer Whales were inferred from vigorous surface and diving activity of Killer Whales within large oiled areas on the surface and congregations of seabirds. In combination with eyewitness observations of behavior of Narwhals and Killer Whales, data collected from satellite tags deployed on Narwhals up to five days before Killer Whales arrived in the area were used to examine clustering and dispersal of Narwhals prior to and following the predation events. These are the first quantitative movement data obtained from Narwhals subjected to Killer Whale predation.

Visual Observations of Attack

Killer Whales were reported by Inuit hunters in a camp about 3 km north of Kakiak Point (72º31'N 86º38'W), in Admiralty Inlet, Nunavut, Canada, on 19 August 2005. On 20 August, we witnessed a Killer Whale predation event on Narwhals just offshore of Kakiak Point. Approximately 12-15 Killer Whales arrived in a single group at Kakiak Point at 12 noon local time. At least several hundred Narwhals had been seen daily in the area for at least two weeks preceding the arrival of the Killer Whales and also on the morning of 20 August. On several occasions thousands of Narwhals had been seen moving past Kakiak Point over periods of 2-3 hours.

The Killer Whale group consisted of one adult male, 7-10 adult females, and several juveniles of undetermined sex. Narwhals were attacked less than 1 km from shore. At least two Narwhals were killed during the first observed attack between 12:00-13:00 local time. After this event, the Killer Whales left the vicinity of Kakiak Point for approximately 3 hours and returned at 16:00, when at least two more Narwhals were killed ~0.5 km from the coast. Killer Whales were not seen or reported again in the area until 25 August. Active subsistence hunting for Narwhals was practiced at several hunting camps along the shore north and south of the research camp.

The four independent kill events occurred over a 6 hour period in daylight hours. Narwhal kills were inferred from large oil/blubber slicks at the surface, congregations and diving of Fulmars (*Fulmarus glacialis*) in surface waters, and focal movements of Killer Whales diving in the center of oiled areas for 15-30 minutes at a time (Figure 1). No body parts or pieces of Narwhals were directly seen.

Narwhal Movements

Narwhal satellite tagging operations were ongoing prior to the Killer Whales' arrival at Kakiak Point. Narwhals were captured using nets set perpendicular to the shoreline 50-100 m from shore (details described in Dietz et al. 2001) and instrumented with SPOT4 and SPOT5 satellite tags made by Wildlife Computers (Redmond, Washington). Tags recorded daily geographic positions based on Doppler shift of tag transmissions received by polar orbiting satellites through Service Argos (Harris et al. 1990). Transmitters were attached to Narwhals on the dorsal ridge with three 6-10 mm polyethylene pins. The Narwhals were usually released after less than 30 minutes (Table 1).

Only data collected from Narwhals instrumented prior to the Killer Whales' arrival were used in the analysis to control for differences in sample size (number of individuals monitored before and after the predation event). Since the Narwhals were instrumented and released on different occasions, they were assumed to represent different groups or pods. Average daily geographic positions were calculated for each Narwhal based on good quality Argos locations (location quality >=0). Average daily positions for each whale were averaged to create inter-whale means. The standard deviation of daily average inter-whale positions was calculated for each of three time periods: five days before Killer Whales arrived (14–18 August), during the immediate Killer Whale observations or attacks (19–20 August), and five days after the Killer Whale attack (21–25 August) when no Killer Whales were seen in the area. Narwhals were distributed along a north-south gradient along the west coast of Admiralty Inlet; therefore the variation in latitude was interpreted as coastwise dispersion and the variation in longitude was interpreted as inshore-offshore dispersion. Narwhal space-use patterns were quantified in each of the three time periods with a kernel home range polygon (probabilistic measure of space use) [ArcView 3.1 Environmental Systems Research Institute] based on average daily positions from each whale.

Results

Pre-attack Narwhal behavior (> 5 days)

Narwhals observed passing Kakiak Point before the Killer Whale attack moved in groups of 3-8 whales at a distance of 20-200 m from the beach. Most whales were heading south. Between 14 and 17 August, seven Narwhals were instrumented with satellite tags before the Killer Whales arrived in the vicinity of Kakiak Point (Table 1). These Narwhals moved along the western side of Admiralty Inlet south of Kakiak Point and less than 1-2 km from shore. No tagged Narwhals were located in the center or eastern side of the inlet and the linear home range along the west coast was <100 km.

TABLE 1. Seven Narwhals instrumented with satellite transmitters prior to Killer Whale occurrence and attack at Kakiak Point, Admiralty Inlet, Canada, 2005. Calf accompanying female on 17 September 2005 was not tagged.

ID	Tagging date	Time of release	Sex	Body length (cm)
20685	14 September 2005	15:06	F	360
20686	14 September 2005	15:56	M	483
20689	17 September 2005	06:25	F	360
37235	17 September 2005	10:45	F + calf	358
37236	17 September 2005	21:20	F	380
37280	17 September 2005	21:27	F	380
37282	17 September 2005	21:45	F	364

FIGURE 1. Oil film on the surface created by Killer Whales feeding on Narwhals in Admiralty Inlet, Canada, August 2005. Large aggregations of Fulmars appeared in the area shortly after each kill. Photo by M. P. Heide-Jørgensen.

The standard deviation of average daily positions indicated that dispersal of Narwhal groups varied approximately 19.9 km north-south, and 13 km west-east before Killer Whales arrived (Table 2). The core of the pre-attack kernel home range (50% probability area) was concentrated just offshore of Kakiak Point and distributed along the west coast of the inlet encompassing 347 km^2 (Table 2).

Immediate Reactions of Narwhals to Killer Whale Attack

On 19 August, Killer Whales were reported by Inuit hunters north of the camp, yet no detailed observations of predation events or behavior were collected. On that day, we observed Narwhals passing very close to the shore (within the surf zone approximately 2-3 m from land) and remaining still at the surface in large groups.

TABLE 2. Dispersal of Narwhals before, during, and after a Killer Whale attack in August 2005 as measured by the distance between average daily satellite positions obtained from seven Narwhals instrumented at Kakiak Point prior to the arrival of the Killer Whales. The standard deviation (SD) in latitude and longitude is reported and also converted to north-south dispersal and west-east dispersal with distance units of km.

	Latitude SD	Longitude SD	N-S dispersal (km)	W-E dispersal (km)	Kernel core (50%) km^2
Before attack (5 days)	0.18	0.12	19.9	13.0	347
During attack (2 days)	0.33	0.29	36.4	32.8	767
After attack (5 days)	0.18	0.25	19.7	27.6	599

FIGURE 2. When Killer Whales arrived in the vicinity of Kakiak Point, Narwhals formed tight groups and remained close to the shore lying still. Photo M. P. Heide-Jørgensen.

On 20 August, Killer Whales were visually observed arriving at Kakiak Point traveling a northbound route along the west side of the inlet. Narwhals were already present in the coastal area (<500 m from the shore) around Kakiak Point and in a small bay just behind the point. When the Killer Whales were within 2-4 km, Narwhals suddenly moved closer to the shore in shallow water (<2 m). Some Narwhals formed tight groups and others moved slowly or lay very still at the surface (Figure 2). One Narwhal stranded on a flat gravel beach (<0.5 m of water) and made violent tail thrashes for >30 seconds (Figure 3), either as a warning signal or in attempts to remove itself from the beach.

Satellite telemetry data indicated instrumented Narwhals clearly responded to the presence of Killer Whales (Figure 4). During the attack, both the north-

FIGURE 3. During the Killer Whale attack, Narwhals beached themselves in sandy areas and made tail slaps. Coastline can be seen in lower left. Photo by K. L. Laidre.

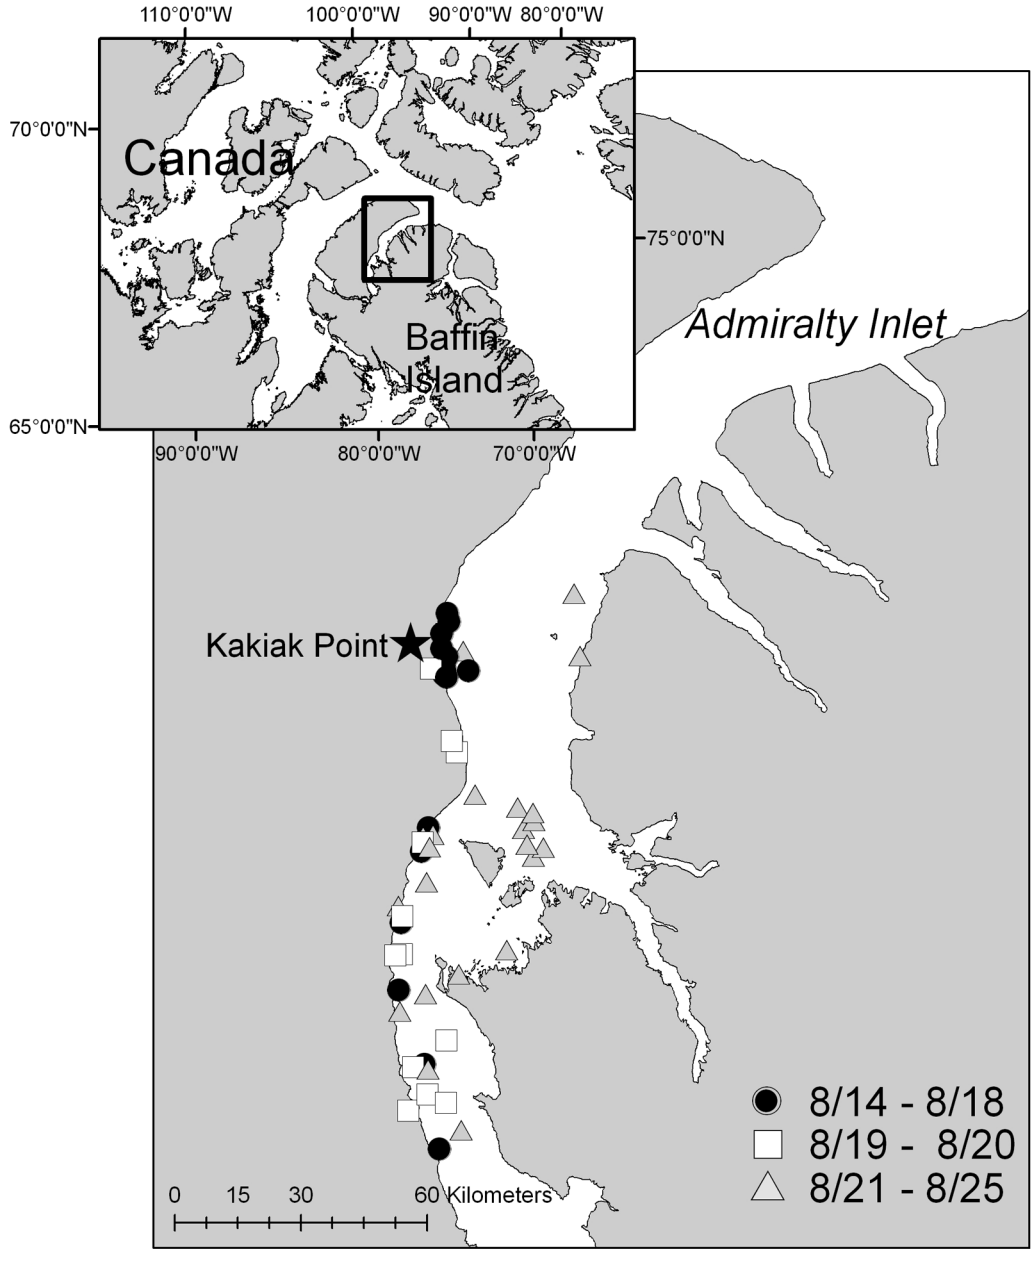

FIGURE 4. Average daily positions received from seven Narwhals instrumented with satellite tags before the Killer Whale attack. Average positions are shown in 3 time periods: the five days prior to Killer Whale arrival (14-18 August), the two days Killer Whales were observed (19-20 August), and the five days after the Killer Whale departure (21-25

south and west-east dispersal (as measured by inter-whale mean latitude and longitude standard deviations) doubled (Table 2). When Killer Whales were in the area, the core kernel home range shifted south by approximately 80 km and doubled in size (767 km^2) (Figure 5, Table 2). Generally, the groups of Narwhals were more widely dispersed in all directions during the attack than before the Killer Whales arrived.

Post-Attack Narwhal Behavior (>5 days)

Narwhals resumed their normal swimming behavior and distance from the coast within an hour after the Killer Whales left the locality. No whales were ob-

served closer than 20 m from the beach and tight groups at the surface broke-up and dispersed.

The instrumented Narwhals moved offshore and utilized a wider area after the attack (ANOVA on longitude, $F_{2,9}$=17.6, $P < 0.001$). Standard deviations of the mean inter-whale latitude (19.7 km) were reduced by half after the departure of the Killer Whales and were nearly identical to pre-attack values (19.9 km), demonstrating a contraction of the north-south dispersal (Table 2). The mean inter-whale longitude standard deviation was slightly lower than during the Killer Whale attack (27.6 km), yet did not return to pre-attack value, indicating a general inshore-offshore dispersal from the attack site.

Post-attack kernel home range core area (599 km^2) was less than that during the attack, yet the core area was located east of the pre-attack core in the center of Admiralty Inlet extending across to the eastern shoreline (Figure 5, Table 2). In general the Narwhal groups maintained a wider offshore dispersal and ranged more widely than before the Killer Whale attack.

Discussion

Narwhals exhibited clear reactions to the immediate presence of Killer Whales. Their suite of behaviors included slow, quiet movements, travel very close to the beach in the surf zone, movement into very shallow water less than 2 m, and formation of tight groups at the surface. All of these observations are consistent with Inuit accounts. Within an hour after the Killer Whale attack and when Killer Whales had left the area, direct observations suggested Narwhals resumed normal behavior (e.g., distances from the coast increased and tight groups dispersed).

Satellite telemetry data revealed long-term (multi-day) observations of Narwhal movements before and after the attack, in addition to observations during the attack. Average daily positions indicated that Narwhal groups were more dispersed during and after the Killer Whale attack. Dispersal primarily increased in the offshore (west-east) direction as measured by longitude standard deviations and home ranges. Cores of area use calculations demonstrated that the range of Narwhal movements increased two-fold during the Killer Whale attack, shifted south in a direction away from the attack point, and then expanded to offshore areas afterwards (where Narwhals had not been observed previously in 2005).

Later in the season, Killer Whales were reported in "fairly large numbers" in Admiralty Inlet and vicinity (especially Adams Sound) until October 2005 (Niore Annie Iqalukjuak, Arctic Bay, personal communication). The exact location and movements of these Killer Whales between August and September are not known, nor is it known whether other attacks on Narwhals occurred. Satellite tagging data showed that Narwhals remained in Admiralty Inlet until the third week of October, after which the southbound fall migration was underway. Thus, it appears that even on longer time scales (~2 months) Narwhals do not alter their site fidelity to the summering grounds (see Heide-Jørgensen et al. 2003) or depart early in response to the presence of Killer Whales.

Killer Whales were also reported in Admiralty Inlet in late August 2004 but no data or specific observations were available. It is unknown if the occurrence observed in 2004 involved the same group of Killer Whales as observed in 2005. On 25 August 2004, one of the authors (J.R.O.) observed a young Bowhead Whale (*Balaena mysticetus*) killed by Killer Whales at Kakiak Point, and bones were found on the beach less than 1 km away from the attack site the following year in 2005. Furthermore, on the same date as the attack reported here, several Killer Whales were observed attacking Narwhals in Repulse Bay, Hudson Strait, Canada (Joani Kringayark, personal communication). Therefore, at least two separate groups of Killer Whales feed on Narwhals on their summering grounds in the eastern Canadian Arctic in August.

When Killer Whales attacked Narwhals, there was limited action at the surface with no struggle or splashing observed. Killer Whales consumed the Narwhals below the surface of the water, and made multiple dives in the center of oiled areas (presumed kills) for 15-20 minutes. An eyewitness account of a Killer Whale attack on Narwhals in Inglefield Bredning, West Greenland in August 2004 noted Killer Whales jumping on top of Narwhals and holding them under the surface until they drowned (Gretchen Freund, personal communication).

If the predation level observed at Kakiak Point (4 Narwhals over 6 hours) is representative of the daily predation level of a similar sized pod of Killer Whales in the High Arctic, then consumption of Narwhals during a two-month stay in Admiralty Inlet would amount to approximately 200-300 Narwhals. A photographic survey estimated 5,556 (CV=0.22) Narwhals in Admiralty Inlet in 1984 (Richard et al. 1994). If the photographic survey results are corrected for whales that were diving using a correction factor of 0.38 (0.06) developed by Heide-Jørgensen (2004), then the abundance would have been in the order of 14,621(0.23). A mortality of 200-300 Narwhals from Killer Whale predation would represent <3% of this abundance estimate. It is possible that predation constitutes a larger proportion of the annual natural mortality of Narwhals than previously expected; however, it is not known if this natural mortality is fully compensatory. In this case, a continued high level of Killer Whale predation in combination with a population reduction by subsistence harvest could reinforce a decline. Killer Whale predation has been responsible for the decline of sea otters in Alaska (Estes et al. 1998; Doroff et al. 2003) and has been hypothesized as the driver for a decline of other top predators in the North Pacific (Springer et al. 2003).

The reason Narwhals occupy deep and narrow fjords during summer is unknown and it has been hypothesized that their summer distribution may be related to

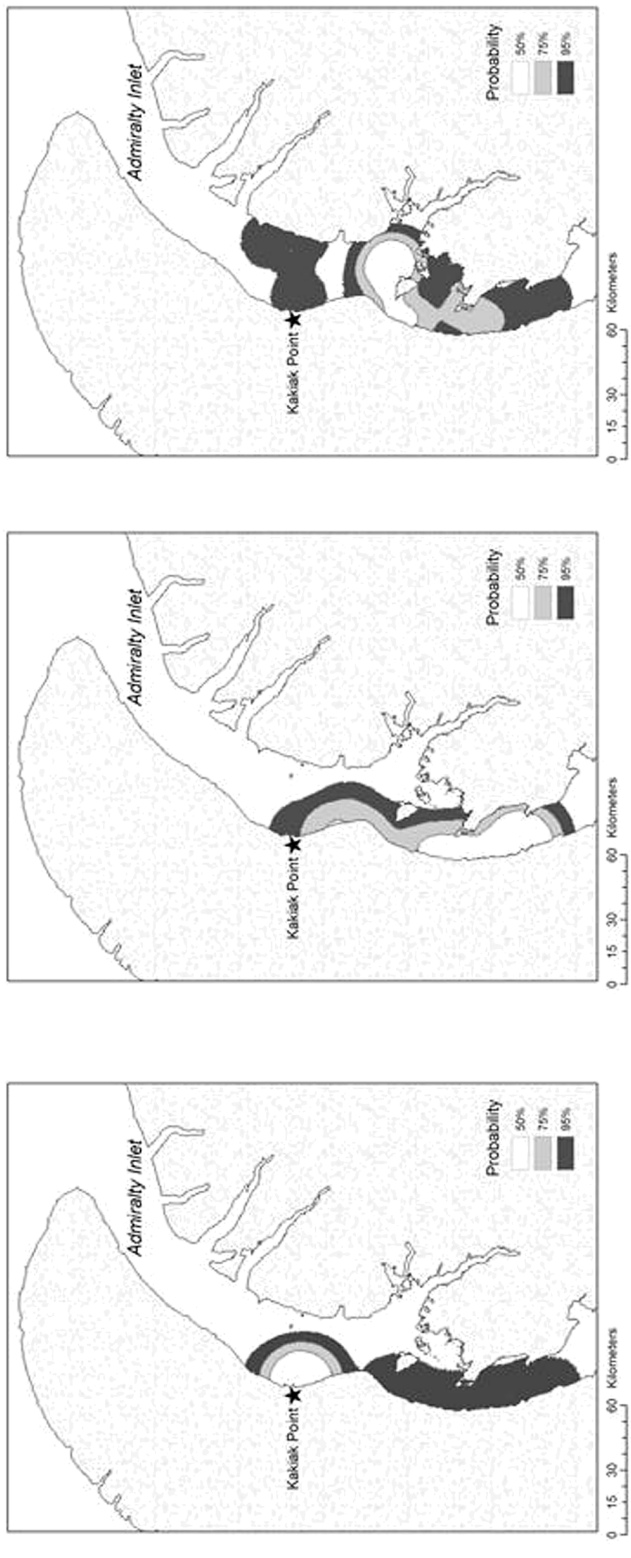

FIGURE 5. Narwhal space-use patterns before, during, and after the Killer Whale attack estimated with kernel home range polygons (50% is white). Home ranges were calculated for three time periods: The five days prior to Killer Whale arrival (14-18 August), the two days Killer Whales were observed (19-20 August), and the five days after the Killer Whale departure (21 August-25 August). The Killer Whale attack was observed at Kakiak Point (star symbol) on the west coast.

potential predation by Killer Whales (Kingsley et al. 1994). Narwhals feed very little during the summer season (Laidre and Heide-Jørgensen 2005a), and summering grounds do not appear to be related to calving needs given calves are born in the spring. The summer refuge from Killer Whales hypothesis lacks conclusive evidence as Narwhal distribution in other seasons is clearly driven by biological needs, such as sea ice formation, open water, or access to prey resources (Laidre and Heide-Jørgensen 2005b) and Narwhals did not seek refuge or depart early in response to the observed attack. Little is known about what proportion of different types of Killer Whales occurs in Arctic waters (i.e., mammal-eating vs. fish-eating). Stomach contents of 30 Killer Whales harvested in Disko Bay, West Greenland in February 2003 contained only Lumpsucker fish (*Cyclopterus lumpus*), despite the fact these Killer Whales were taken in an area with a large abundance of Bowhead Whales, Ringed Seals (*Phoca hispida*), Narwhals, Belugas, and other potential marine mammal prey items (Greenland Institute of Natural Resources, unpublished data).

Few observations have been collected of Killer Whales during winter in Arctic ice conditions. It is generally assumed that Killer Whales avoid the Arctic pack ice (Heide-Jørgensen 1988) despite the fact many Killer Whales occur and thrive in the dense pack-ice of the Antarctic. It is possible that changes in sea ice (lighter sea ice cover and earlier break-up) will alter (or have already altered) the occurrence of Killer Whales in Arctic waters. These changes may facilitate increased or longer visits by Killer Whales to ice-free Arctic areas.

The predicted reduction of annual sea ice, together with a longer open water season, will likely lead to an increase in Killer Whale predation on Narwhals. At the same time, reduced sea ice will also decrease the probability that Narwhals succumb in ice entrapments (also known as Sassats), another important source of natural mortality (Laidre and Heide-Jørgensen 2005b). It is unclear how the interplay between these two elements of natural mortality will evolve under changing sea ice regimes.

Acknowledgments

Research was funded by the Greenland Institute of Natural Resources, Fisheries and Oceans Canada, and the Nunavut Wildlife Management Board. The Polar Continental Shelf Project in Resolute supported logistics for field work in August 2005. The work was also supported by the Arctic Bay Hunters and Trappers Organization. Narwhal tagging was conducted under permits from Fisheries and Oceans Canada and Animal Care Permit FWISLACC#013. Robert Pitman, Randall Reeves, and an anonymous reviewer improved earlier drafts.

Dear Sir/Madame:

RE: 2D Seismic Survey offshore Baffin Bay/Davis Strait 2011.

TGS-NOPEC Geophysical Company ASA (hereinafter referred to as TGS) & Multi Klient Invest AS (hereinafter referred to as KMI or the Operator) a company associated with Petroleum GeoServices (herein referred to as PGS) have entered into a joint venture to conduct a regional marine 2D (two-dimensional) seismic reflection survey offshore Baffin Bay, Davis Strait within the regulatory jurisdiction of the National Energy Board (NEB).

As you are aware, Federal coordination was initiated for this project in the spring of 2010, however the project was suspended until 2011 and the project area has since expanded and Federal coordination initiated for 2011 program.

Under section 5 of the Canadian Environmental Assessment Act, an Environmental Assessment is required because the National Energy Board may take action in relation to paragraph 5 (1) (b) of the Canada Oil and Gas Operations Act for the purpose of enabling the project to be carried out in whole or in part.

Attached you will find three hard copies of the Environmental Assessment and three electronic copies.

If you require anything further, please donot hesitate to contact me.

Regards,

Darlene Davis

NON TECHNICAL SUMMARY

TGS-NOPEC Geophysical Company ASA (hereinafter referred to as TGS) & Multi Klient Invest AS (hereinafter referred to as KMI or the Operator) a company associated with Petroleum GeoServices (herein referred to as PGS) have entered into a joint venture to conduct a regional marine 2D (two-dimensional) seismic reflection survey offshore Baffin Bay, Davis Strait within the regulatory jurisdiction of the National Energy Board (NEB).

This Environmental Assessment prepared by RPS Energy assesses potential impacts from the proposed operations on the surrounding environment.

The main sensitivities and environmental constraints identified in this area include marine mammal and fish species, benthic and pelagic habitats, and resident breeding and migrant bird species.

An appreciation of the traditional knowledge was obtained by consulting two major studies: The Nunavut Wildlife Harvest Study (Nunavut Wildlife Management Board, August 2004), and the Final Report of the Inuit Bowhead Knowledge Study (Nunavut Wildlife Management Board, March 2000).

The operator will use mitigation measures to minimize the impacts on the marine environment, in particular “The Statement of Canadian Practice with Respect to the Mitigation of Seismic Sound in the Marine Environment.” (Appendix A).

Contractors must have in place Shipboard Oil Pollution Emergency Plans (SOPEP) to combat any spills and ensure adequate training for all crew members. For port spills Port Oil Contingency Plan must be adhered to.

It must be ensured that waste segregation, handling and disposal are carried out in line with existing company and contractor environmental policies and standards. Any hazardous wastes produced throughout the course of operations should be disposed of with great care and in conformity with environmental aims, objectives, and Canada legislation.

The environmental performance of any project is dependent largely on the commitment of the contractors involved. MKI must employ best practice in pollution prevention programmes to effectively protect the environment. They must also ensure that contractors employ best environmental practice in their waste disposal programmes and spill contingency planning.

To this end, an Operational Project Plan incorporating the measures specified in the Environmental Protection Plan will be implemented to ensure operations are completed in full compliance of the company's stated environmental aims and objectives. This will facilitate the final planning, implementation, and follow-up activities associated with the operations.

MKI representatives need to monitor contractors and measure their practices through active programmes that are reviewed at regular intervals. This will help ensure that operations are carried out in an environmentally acceptable manner.

1. INTRODUCTION

In accordance with the Canadian Environmental Assessment Act (CEAA) and based on the information presented in the project description “Project Description for 2D Marine Seismic Survey Offshore Baffin Bay, Davis Strait (MKI December 2010). This document is a screening level environmental assessment (EA) as defined by the Canadian Environmental Assessment Act (CEAA) for a multi-year seismic program (2011-2015) proposed for Baffin Bay/Davis Strait by MKI.

In early January, representatives of RPS Energy and Environmental Manager for PGS travelled to Iqaluit for consultation meetings with several Federal and territorial groups for in person meetings to explain the potential project and seek information which could be used in this assessment and project planning.

They included:

- Department of Economic Development
- Department of Environment
- Fisheries and Sealing’s
- Manager of Mineral Resources
- Resources Development Advisor
- Department of Fisheries
- Indian Northern Affairs Canada
- Nunavut Development Corporation
- Nunavut Research Institute
- Quikiqtani Inuit Association (QIA)

It was determined in these meetings that based on the previous years concerns re: Lancaster Sound, that there were many concerns and questions with regards to seismic activity in Baffin Bay with the local communities.

In mid February RPS representatives on behalf of MKI travelled to several Inuit communities to share information and seek assistance in the preparation of the program. A representative of INAC (Petroleum Advisor) travelled along with our group. The Petroleum Advisor attended the meetings to advise the communities that INAC would be returning to speak with them on a future date concerning the possibility of opening lease blocks in Baffin Bay. A member of QIA also was invited and attended our meeting in Pond Inlet. (QIA/ Nigel Qaumariaq).

We had tried to schedule a meeting in Pangnirtung with no success. The manager of their Hunters and Trappers Association had left the position and they were in the process of seeking a replacement.

The Meetings were held in the following communities:

- Clyde River
- Pond Inlet
- Qikiqtarjuaq
- Iqaluit

A brief meeting was held in Iqaluit with the Manager of the HTO group, to briefly explain the project.

In addition to the above meetings, direct email contact was made with the following stakeholders;

- Parks Canada
- WWF-Canada
- Nunavut Planning Commission
- NIRB
- Baffin Fisheries Coalition
- Nunavut Wildlife Management Board
- Nunavut Tunngavik Inc.

You can find the minutes of the meetings in (Appendix B).

The meetings were held with Hunters and Trappers Association members in each community listed here. It was asked that we return for a public meeting in the communities.

Time didn't seem to allow for these meetings between our return and end March. As I understand it; INAC and NEB were also scheduling meetings in March month. In April a notice was sent around advising the communities of our intention to conduct public meetings from May 1-6th in Iqaluit, Clyde River, Pond Inlet, Quik and Pang. However, these meetings were cancelled at the last minute due to negative feedback with regards to public meetings during election week.

Best efforts are now being made for public meetings prior to the end of May 2011.

This EA has been based on the information available, which we believe is adequate to complete this assessment.

2. REGULATORY REQUIREMENTS AND JURISDICTION

Authorizations to Conduct a Geophysical Program will be required from the National Energy Board (NEB). As the federal authority that received the project description, the NEB will distribute to the other federal authorities, which may also have a responsibility or interest and need to be notified. The NEB has been appointed Federal Environmental Assessment Coordinator (FEAC) under the CEAA for this project, and in this role is responsible for coordinating the review activities of the federal and provincial authorities participating as expert departments in the environmental assessment.

Geophysical programs (seismic surveys) in the area proposed for this project require authorization from the National Energy Board (NEB). The Canadian Environmental Assessment Act (CEAA) requires federal authorities to conduct environmental assessments (EA) before issuing regulatory permits for certain projects (Section 5(1) d).

Legislation that is relevant to the environmental aspects of this Project is provided
Table 1

Table 1. Summary of Authorizing Agencies

Instrument and Legislation	Agency	Activities	Remarks
• Canada Environmental Assessment Act (CEAA) • Canada Environmental Protection Act (CEPA) • Oceans Act • Fisheries Act • Navigable Waters Act • Canada Shipping Act • Migratory bird Convention Act • Species at Risk Act (SARA) • Canada Oil and Gas Operations Act	National Energy Board (NEB)	Geophysical Operation Authorization	Screening required pursuant to CEAA. EA submission herein.

3. PROJECT DESCRIPTION

MKI proposes to conduct an offshore two-dimensional (2D) seismic reflection survey within Baffin Bay and Davis Strait over the next 5 years scheduled to start sometime after mid-end July as weather and ice conditions allow.

All proposed program activities will occur seaward of Canada's 12 nautical mile boundary, to the east of the land-fast ice limit. No Geophysical data will be recorded within the Land Fast Ice Zone. The survey is approximately 180km from the mouth into Lancaster Sound. The majority of the survey lines to be collected are in deep water. MKI requests approval of all lines in the program in order to allow flexibility in the collection of the data in 2011.

3.1 PURPOSE

The proposed project is a regional survey designed to provide a better understanding of the offshore geology in Baffin Bay and Davis Strait and to use this information to introduce new exploration opportunities to the industry. This information will be used to determine the regional extent of geological formations. This program is being used to develop geological concepts and is not the basis of an exploration drilling program, as the survey line spacing is much too coarse for that purpose.

3.2 LOCATION

Figure 1 shows the location of the entire multiyear survey area. Subsequent years will include infill lines within the same assessed area.

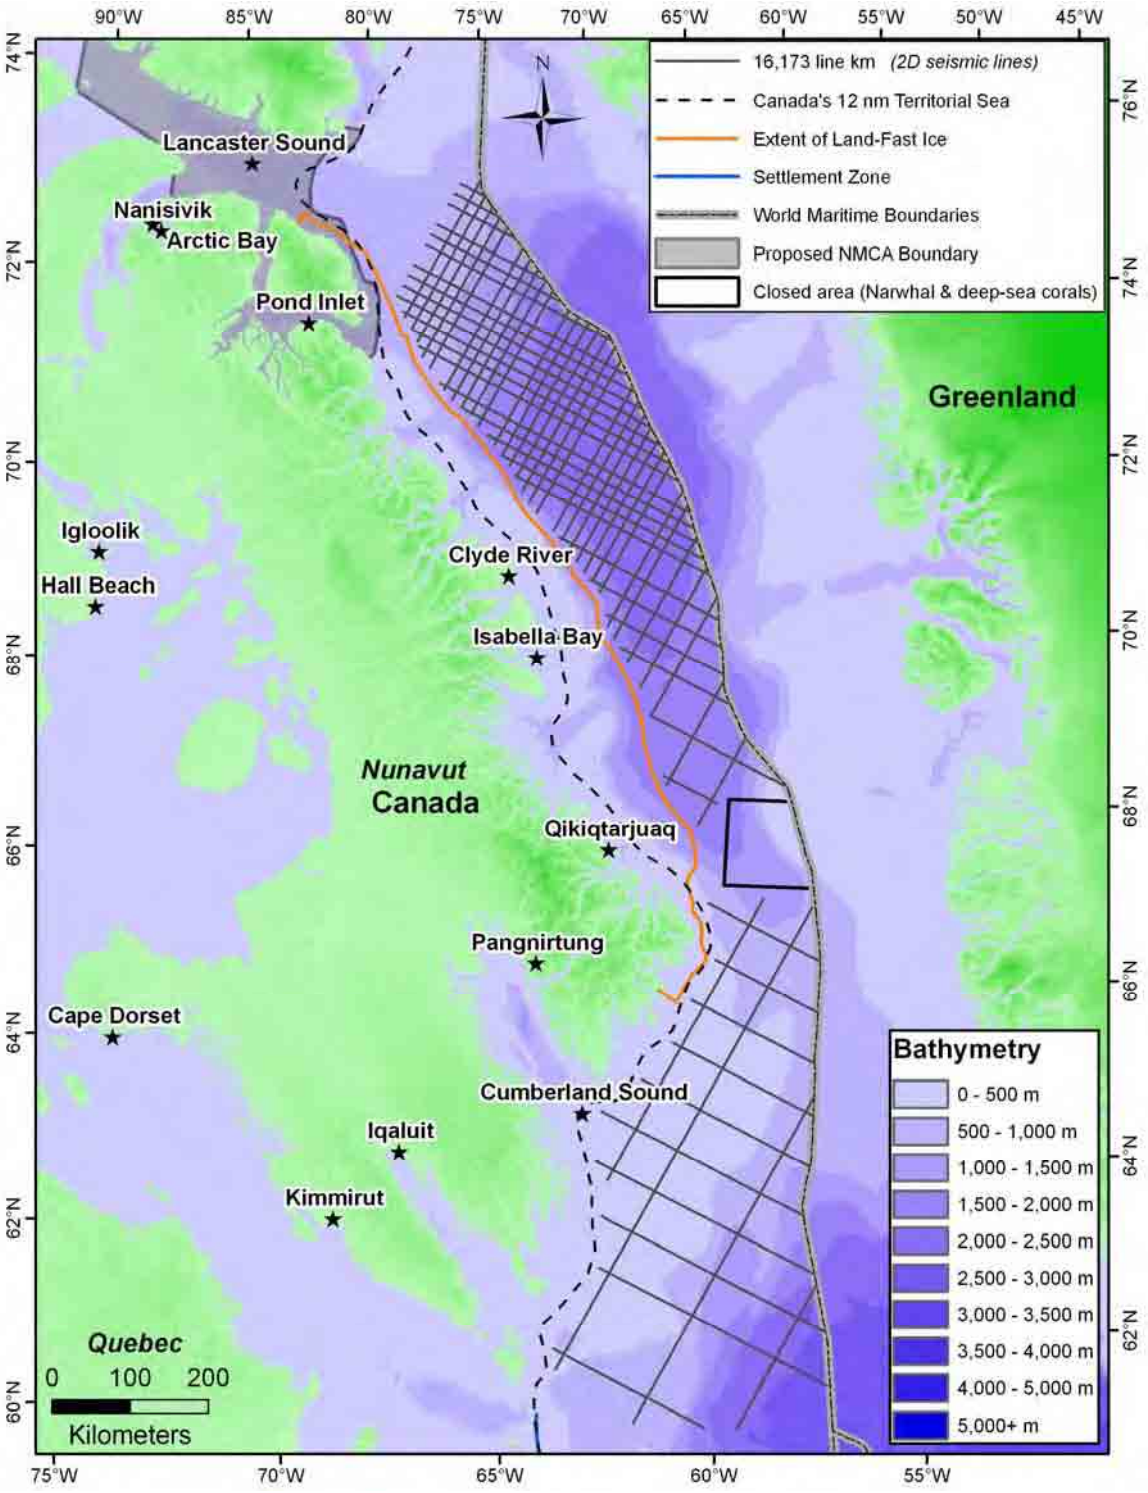

Figure 1. Location of Survey

3.3 SITE HISTORY

Marine geophysical data has been acquired over the Baffin Bay / Davis Strait area since 1969. Figure 2 illustrates these data as documented by the Geological Survey of Canada – Atlantic (GSC-A) BASIN database (http://basin.gsca.nrcan.gc.ca/index_e.php). BASIN is a federal government archive of geological, geophysical, and engineering information (including seismic data) acquired during the many years of petroleum exploration offshore northern and eastern Canada.

A full listing of these geophysical projects is provided in Appendix C, and consists of approximately two hundred (200) seismic reflection surveys (2D and 3D), seismic refraction surveys, and shallow seismic / seabed surveys, and five (5) aeromagnetic surveys. The most recent program in the area of the proposed 2010 survey was acquired by Husky Oil in the Davis Strait / southern Baffin Bay in 2008. TGS's most recent exploration program in the area was also in 2008, with fairly continuous work completed in the Davis Strait through the 1990's.

The proposed project represents a small program relative to the historic totals. The acquisition of a high-quality modern regional dataset is required to compliment this vintage data. Advances in seismic technology, in particular advances in longer receiver arrays (streamers) and recording systems, have allowed geophysicists to use advanced signal processing and image the subsurface geology with much greater accuracy, and to much greater depth below the seafloor, than was previously possible.

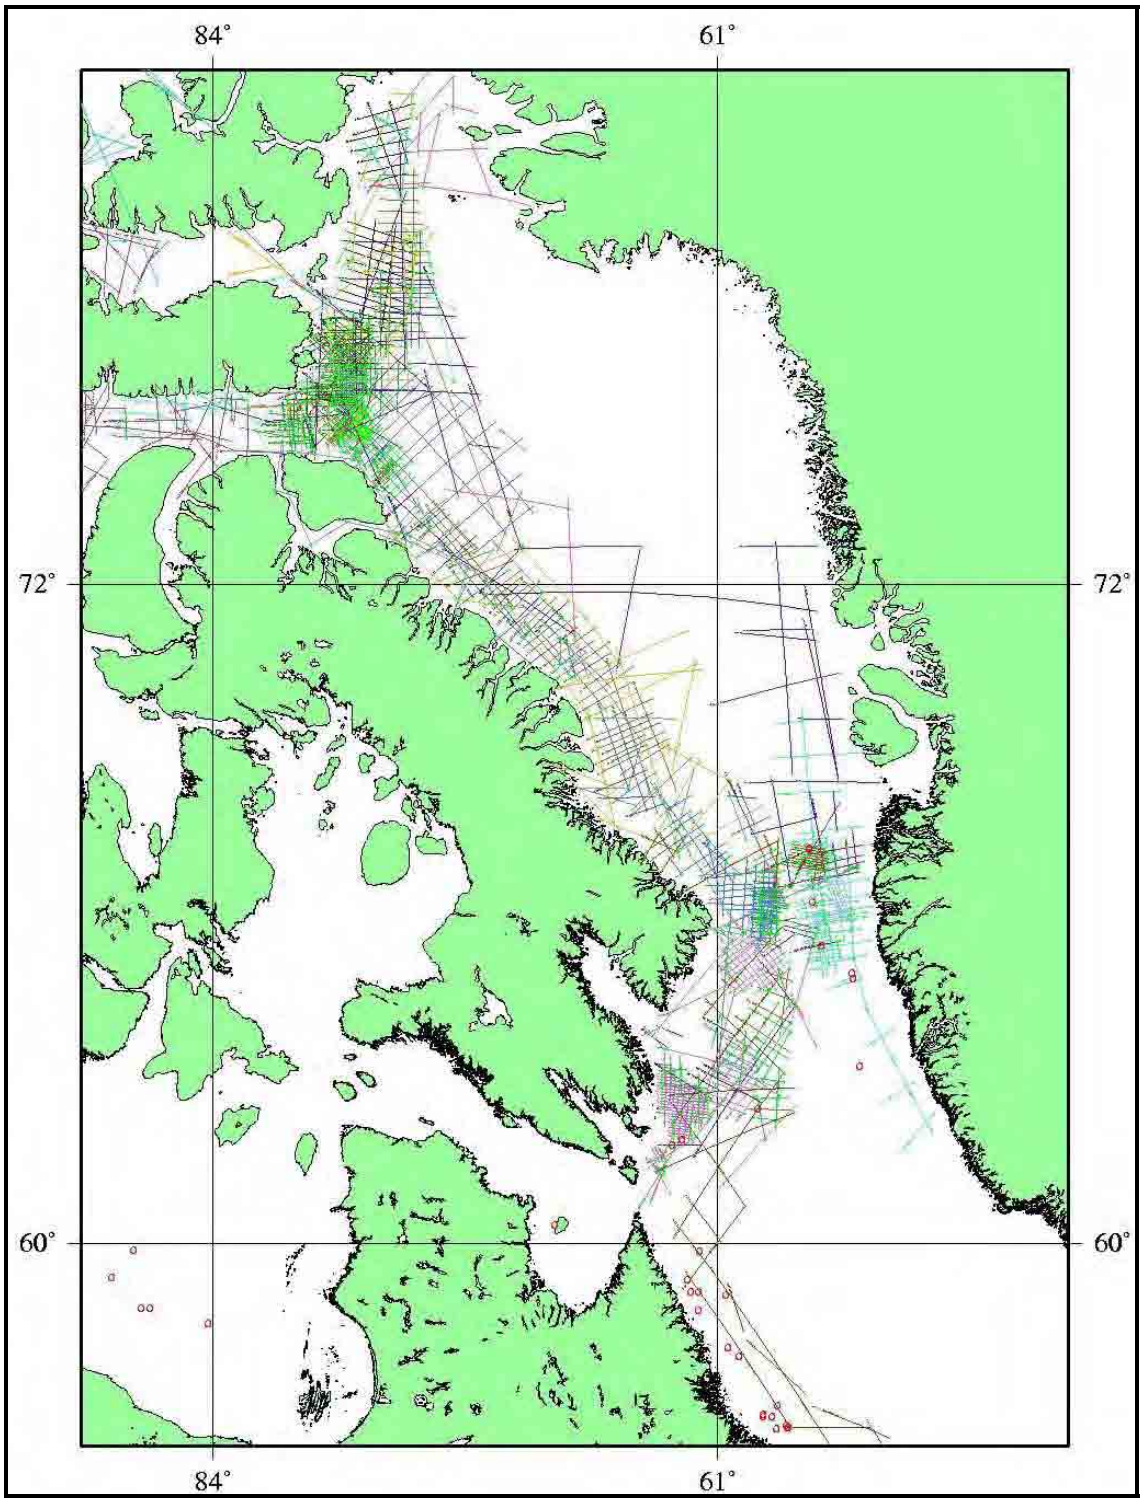

Figure 2. Exploration History within the Project Area
(BASIN, 2007)

3.4 SCHEDULE

The proposed survey season is end July through mid November 2011, depending on the location, weather conditions, and vessel availability. Based on previous work in Davis Strait/Baffin Bay weather usually allows productive recording until approximately mid October. It is possible that work might be able to continue as late in the year as November. The proposed survey lines (Figure 1) represent the proposed program for 2011. Infill lines will be acquired in subsequent seasons.

Although the proposed survey vessel is an ice-class vessel (1A1 Ice C) data will not be acquired in areas of pack ice. The survey data will be acquired such that ice-free areas are surveyed first (i.e. the southern portion of the survey area) then, as the season progresses, the vessel will move north.

It is possible that there may be transects in pack ice waters; however, the sound source will not be active during these periods and the vessel will merely be transiting through. Marine mammal observations will still be made during these transects, which will serve to enhance the database of observations that will be obtained during the project. Due to the seasonal nature of offshore marine conditions, it is hoped that work will also take place in future years, as the area is mapped.

The vessel will be at sea and operate continuously (i.e. 24-hour operations) during survey operations. Seismic vessels typically operate on a 5/6-week crew change schedule, which will be maintained for this project.

3.5 OFFSHORE SEISMIC SURVEY

The follow is an introduction to seismic surveying.

“A marine seismic survey is a method of determining geological features below the seafloor, by sending acoustic sound waves into the various buried rock layers beneath the seafloor and then recording the time it takes for each wave to bounce back as well as measuring the strength of each returning wave. It is the most reliable form of initial exploration for oil and gas and is essential in identifying geological features that may contain oil or gas deposits.

Seismic surveys generally take place over a few weeks in a given area. Once geophysicists have studied the subsurface “picture”, they may ask for some parts of the area to be surveyed again to provide greater detail. This extra data helps them to map potential prospects more accurately and to decide the best place to drill exploration wells. Shallow seabed surveys can also be used to detect changes in the sub-surface rock layers that may present a safety hazard during drilling operations.

A marine seismic survey is conducted using purpose-built ships, towing a number of air guns as the acoustic energy source at depths of 6-10 metres below the sea surface. The sound (or seismic) waves are generated by the rapid release of compressed air from an underwater piston. These seismic waves are directed down toward the seabed. They are reflected back to the surface by the layers of different rock types under the

seafloor. The returning sound waves are detected and recorded by hydrophones that are spaced out along “streamers” that are typically 6 – 10 kilometres in length, towed behind the survey vessel (Figure 3). For regional surveys (often referred to as 2D surveys) the seismic vessel sails up and down gridlines which can be 5 to 100 kilometres apart.

Seismic waves travel through different rock types at different speeds, so it is possible to calculate the depth and the shape of the rock layers by measurements such as the two-way travel time taken for the reflected seismic waves to reach the hydrophones and the strength of each returning wave. In 2D surveys the resultant picture is a general view because the cross sections are far apart.

As further background on marine seismic surveys, Appendix D contains the International Association of Geophysical Contractors (IAGC) overview document *Marine Seismic Operations – An Overview*, which provides a thorough introduction to all aspects of marine seismic operations, including the underlying principles of seismic data acquisition, methodology, and equipment. This document is also available on the Canadian Association of Geophysical Contractors (CAGC) website (IAGC, 2002). The reader is also referred to *Seismic and the Marine Environment* (APPEA, 2004).

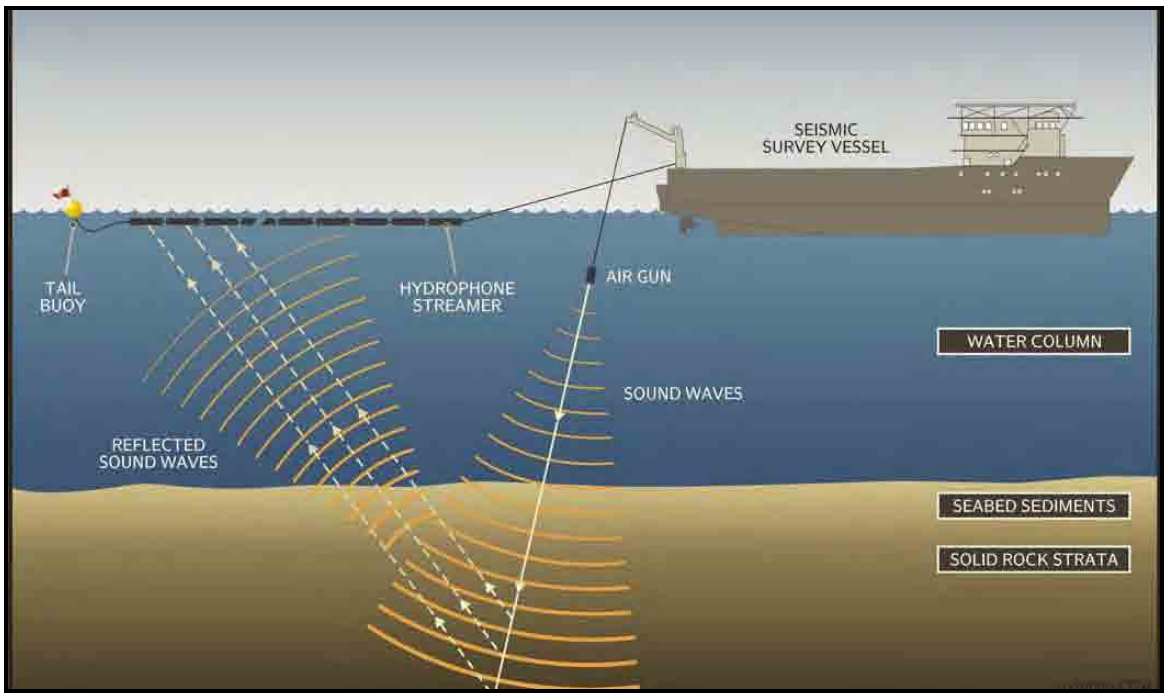

Figure 3. Seismic Acquisition using Seismic Reflection Method (Sikumuit 2008)

A 2D marine seismic survey will be conducted within the proposed project areas. The field acquisition program will consist of the following four activities:

- Mobilization to the survey area
- Deployment and calibration of the seismic gear
- Data acquisition, and
- Seismic gear retrieval and demobilization.

3.6 SEISMIC EQUIPMENT

3.6.1 Survey Vessel

The M/V Sanco Spirit is the dedicated research vessel that has been chosen to conduct this project. The vessel is a new build in 2009 with state of the art technology and equipment. The vessel has a total of 47 berths, and a dedicated hospital. The vessel has all equipment, systems, and protocols in place for prevention of pollution by oil, sewage, and garbage in accordance with international standards and certification authorities, specifically the Arctic Shipping Pollution Prevention Act (ASPPA) and Arctic Shipping Pollution Prevention Regulations (ASPPR). Regulations require that the survey vessel possess an Arctic Pollution Prevention Certificate. The vessel will be subject to pre-survey audits by the operator in the port of mobilization prior to survey commencement. Transport Canada will conduct a Safety Inspection of the vessel in accordance with the issuing of the Coasting Trade License to operate in Canada.

The survey vessel will comply with all applicable regulations concerning management of waste and discharges of materials into the marine environment. The vessel has a ballast water management plan. The International Maritime Organization (IMO; http://www.imo.org/) is the United Nations specialized agency with responsibility for the safety of shipping and the prevention of marine pollution by ships. Canada became a member of the IMO in 1948. Full specifications of the vessel M/V Sanco Spirit are shown in Appendix E.

Figure 4. Survey Vessel Sanco Spirit

3.6.2 Supply Vessel

The primary function of the supply vessel is to provide supplies for the seismic vessel and to assist in emergency situations (including oil spills). At least one support vessel will be utilized for the proposed seismic survey.

Seismic vessels are recognized as having a restricted manoeuvrability and, in this respect, under marine sailing directions, they have priority over vessels that are not similarly restricted. In areas where poor charting, or the presence of other vessels, may pose a potential problem to the survey operation, the chase boats will ensure that other vessels do not cross over, or otherwise interfere with, the towed equipment. The supply boat may also check that the way ahead of the survey vessel is clear of obstructions, such as uncharted shallow water and fishing equipment. Fishing nets are a particular problem to seismic operations as they can become entangled around the survey equipment and force operations to stop. It is likely that the FLO and one of the two MMO's will travel onboard the supply vessel, ahead of the research vessel.

3.6.3 Energy Source

Manufacturer and type	Sercel – G Gun 2
Effective volume of standard array(s)	4135 ci
Maximum number of sub-arrays	6
Standard array depth(s)	7 M
Position of depth transducers	Front and tail of sub-array
Working pressure	2000 psi psi
Type of firing sensors	Pressure activated
Position of firing sensors	Mounted directly on the gun.
Type of firing synchroniser unit	RTS BigShot
Timing resolution	0.1ms ms
Timing accuracy	+/- 1.0ms
Position of near field phones	1 mounted on each gun hang frame.
Air compressors capacity	Neuman & Esser, 2200 cfm each
Number of air compressors	2

3.6.4 Streamer

Manufacture and type	PGS GeoStreamer® Solid
Skin material	Polyurethane
Outside diameter	62mm cm
Length of each group	12.5m m
Streamer set-up	Typical 1 x 10050m
Manufacture and type of hydrophones	Hydrophones: Teledyne T-2BX or equivalent, Velocity Sensors: PGS

	confidential (MarkIII)
Type of array (e.g. linear, binomial)	Linear
Number of hydrophones per group/distance apart	Hydrophones: 12 per 12.5m, Velocity Sensors: PGS confidential
Coupling between phones and pre-amp	Capacitive
Sensitivity of near group at 1/P to recorder	20V/Bar
Sensitivity of far group at 1/P to recorder	20V/Bar
Bandwidth over which above sensitivities apply	Specified at 100Hz
Availability of shore-side spares if required	Pool system
Manufacturer and type of depth controller	ION DigiCourse 5011
Manufacturer and type of compass	ION DigiCourse 5011

3.7 PROJECT ALTERNATIVES

Alternatives to survey method:

No method for surveying deep marine geology has been developed that is more accurate, time efficient, or has fewer environmental impacts than the use of a towed airgun array and hydrophones contained in a long streamer. Prior to the development of airguns, dynamite was used for marine seismic surveying, but that survey method was abandoned over 30 years ago by the exploration industry.

Alternatives to survey parameters:

The main survey parameters such as line position, line length, line spacing, shot-point interval, and streamer length are determined by geophysicists considering the objectives of the survey. With regard to location, proposed survey lines are carefully selected based on a current understanding of the geological conditions of the study area and are intended to test geological concepts at those specific locations. The survey lines tie into the grid established offshore Greenland. Extensive geophysical survey work, over the past 10 years, of the same nature proposed here, has been taking place.

Parameters such as airgun array and streamer tow depths may be adjusted at the start of the survey to optimize data quality. Gun types, array configurations, and streamer type are limited to what equipment is available on the vessel and, therefore, cannot be easily changed.

Alternatives to program timing:

Specific timing of the program will depend on a variety of factors, including ice conditions, weather conditions, timing, and sensitivities associated with biological and socio-economic constraints. For example, mitigation options to minimize potential impacts can potentially include modification of the operations schedule within specific areas, and the survey plan has been developed on this basis.

Because there are no viable alternatives that can be genuinely considered from an environmental viewpoint (as described above), the two alternatives may simply be proceeding or not proceeding (i.e. no-go alternative).

No-go alternative

In the case that the project does not proceed, the mitigated impacts of seismic operations on the environment will of course not occur, however, the environment will not necessarily maintain its current baseline condition as impacts from fishing and vessel activity (i.e. ice breakers, cargo vessels, cruise ships, and other research vessels), waste materials, sedimentation, fall-out of atmospheric pollutants, discharge of ballast waters, etc. will still take place.

The 'no-go alternative' would also mean that the renewed interest in exploration in this area would cease, or at least be significantly set back, as geologists would not have the information required to map the sub-surface in this area. This would consequently mean

that the potential to assess the hydrocarbon potential of this area would not proceed, along with the assessment of opportunity for further subsurface exploration and drilling programs. Ultimately, the project not proceeding in this case would effectively preclude the potential to evaluate the area's offshore hydrocarbon resources. This would result in the removal of future potential business, royalty, and tax revenue sources and the data would not exist for future knowledge and research.

It would also lead to significant reduction in direct employment opportunities on the vessel and the opportunity to collect biological observation information.

3.8 PHYSICAL SETTING

The north seismic survey area is proposed to take place in portions of Davis Strait, and Baffin Bay (Figure 1). Davis Strait is situated between Baffin Island and Greenland and is the entrance to Baffin Bay from the North Atlantic. This large body of water is over 950 kilometres across at its greatest width and never less than 300 kilometres wide.

3.9 CLIMATE

The Davis Strait is within the Arctic Climatic Region with mean air temperatures below 10° C annually. The coldest month is February and the warmest is August (July in coastal regions). In summer air temperatures will be similar to those of the surface water. Freezing temperatures may occur over sea ice. In winter, very low air temperatures occur over snow covered pack ice. Over open water, air temperatures are generally below those of the sea surface. Coastal regions may experience summer temperatures as high as 15° C. Visibility within this region is mainly reduced by fog (visibility < 1 km). Fog is primarily a summer phenomenon, with increasing frequency during May and peak occurrences in June / July. It is uncommon by late August. In winter, advection fog may form as a result of mixing of warm moist masses advected from the south. Sea smoke is often very local in occurrence and is formed from cold air flowing from pack ice or from cold land over open water.

Most precipitation falls in late summer or early autumn. In winter, it will be in the form of snow. In summer, light snow or freezing rain may fall over pack ice or open water with surface temperatures near the freezing point. Generally, the months of June and October are the rain / snow transition months in the north, with May and November the transition months in the south. Freezing rain often occurs with the advection of warm air from the south in the winter. It is unlikely to occur over a sea with surface temperatures greater than 5° C.

Freezing fog is typically a summer event occurring over vast ice fields. It is not likely to occur over open waters with surface temperatures above 1° C. Freezing spray may be frequent from November to April but rare in October and May.

Wind in the northern part of the region, north of 65° N, has an annual speed of 5-6 metres/second that increases south of 65° N to 7-8 metres/second. In the north the maximum wind speed occurs as early as October / November but elsewhere in midsummer. The minimum wind speed is in midsummer throughout the region (MacLaren, 1978a).

3.9.1 Sea-Ice Climate

In June, the ice in the North Water Polynya of Northern Baffin Bay disintegrates, and then clearing extends southward across the approach to Lancaster Sound. Since pack deteriorates more quickly around the eastern shores (i.e. Greenland) than it does in the centre of the bay, by the beginning of August ice remains near the coast from Cape Dyer to Clyde River and in central parts of the Bay northward to near latitude 74° N. The pack is finally reduced to offshore isolated patches between Cape Dyer and Home Bay late in August. Clearing occurs on the average by September.

Historically the north-flowing current along the Greenland coast is relatively warm, and the south-flowing current along eastern Baffin Island is relatively cold. Consequently, ice formation along the west side of the bay (Canadian side) begins earlier than on the Greenland side. In September, new ice begins to form in the north western reaches of Baffin Bay. By the end of the September a fringe of new ice forms all along the Baffin Island coast. Ice formation accelerates through October, such that first-year ice becomes predominant north of Cape Dyer. On average, the southern extent of sea ice achieves equilibrium near a line from the Greenland Coast near latitude 68° N generally southwest-ward to a point some 200 kilometres off Resolution Island.

In general, Baffin Bay and Davis Strait have cleared of all sea ice as early as mid-August. Freeze-up in north western Baffin Bay has developed as early as the last week of August and been delayed until the middle of October. In Frobisher Bay, new ice formation has begun as early as mid-October, and as late as the second week of November.

The typical retreat of the sea ice cover from the late winter to late summer is shown in Figure 5 below. Melting of sea ice begins in spring in the Gulf of St. Lawrence and East Newfoundland, retreating northward towards the Labrador coast. In June openings appear in Baffin Bay and the Beaufort Sea, while clearing is already underway in Hudson Bay. Break-up continues throughout the summer months, reaching a minimum extent around mid-September.

With the changes seen in the ice this past year, it is anticipated that work may start sooner and end later.

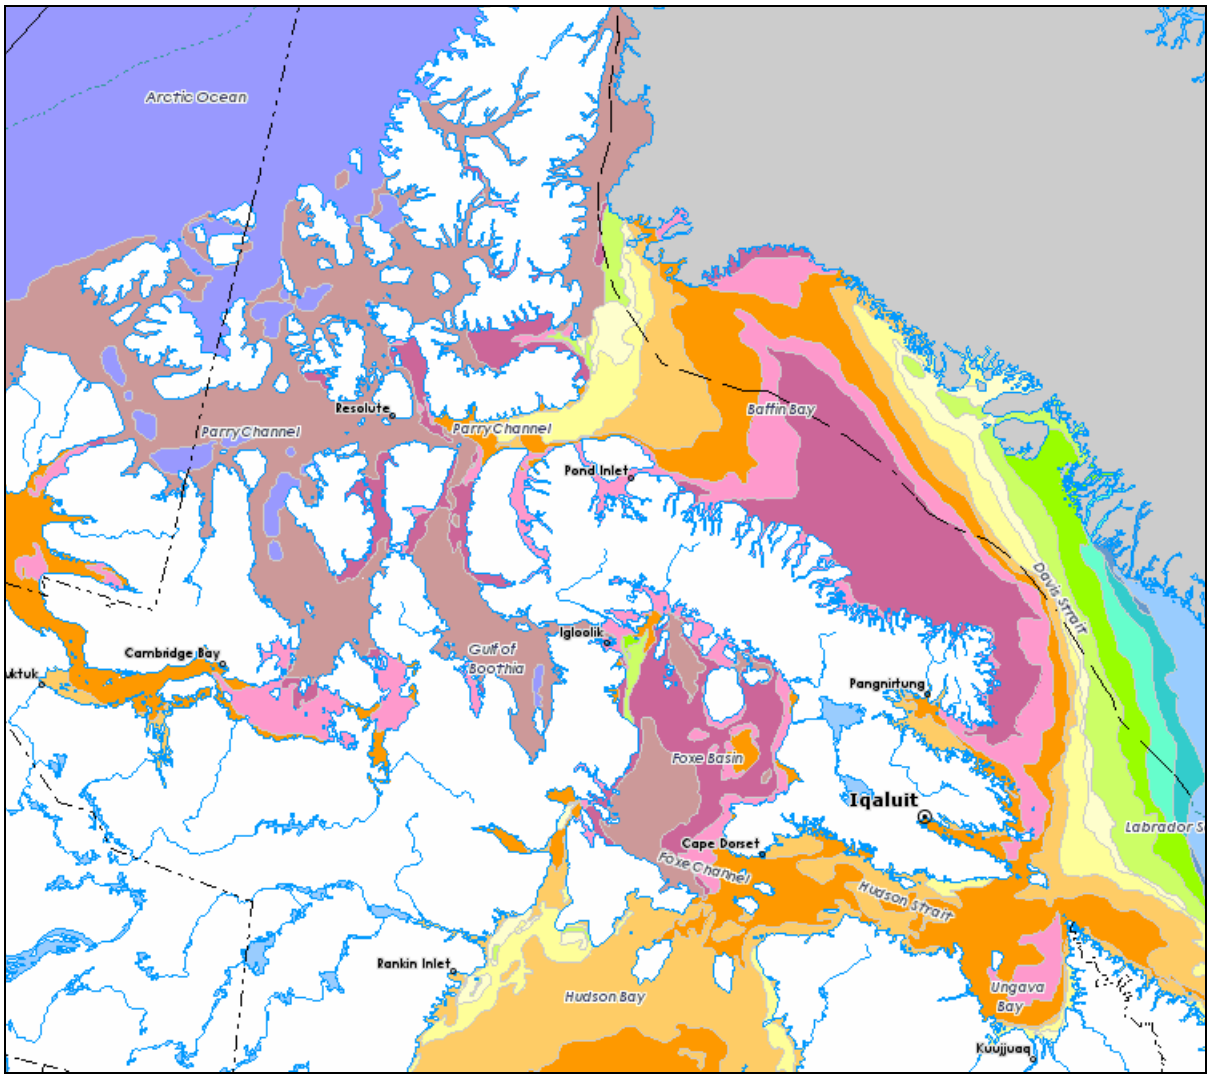

Figure 5. Break up of Sea Ice NRCAN 2007

3.10 OCEANOGRAPHY

The physical oceanographic environment of the eastern Davis Strait and north-eastern Labrador Sea has been well documented and an excellent overview is provided in a Mineral Resources Administration for Greenland (Nazareth and Steensboe, 1998) publication. uch of this overview includes the survey area and it indicates that there are no physical oceanographic environmental conditions that can significantly affect the proposed seismic program within the scheduled period (Nazareth and Steensboe, 1998).

The surface water circulation in Davis Strait is strongly affected by counter-clockwise flowing currents.

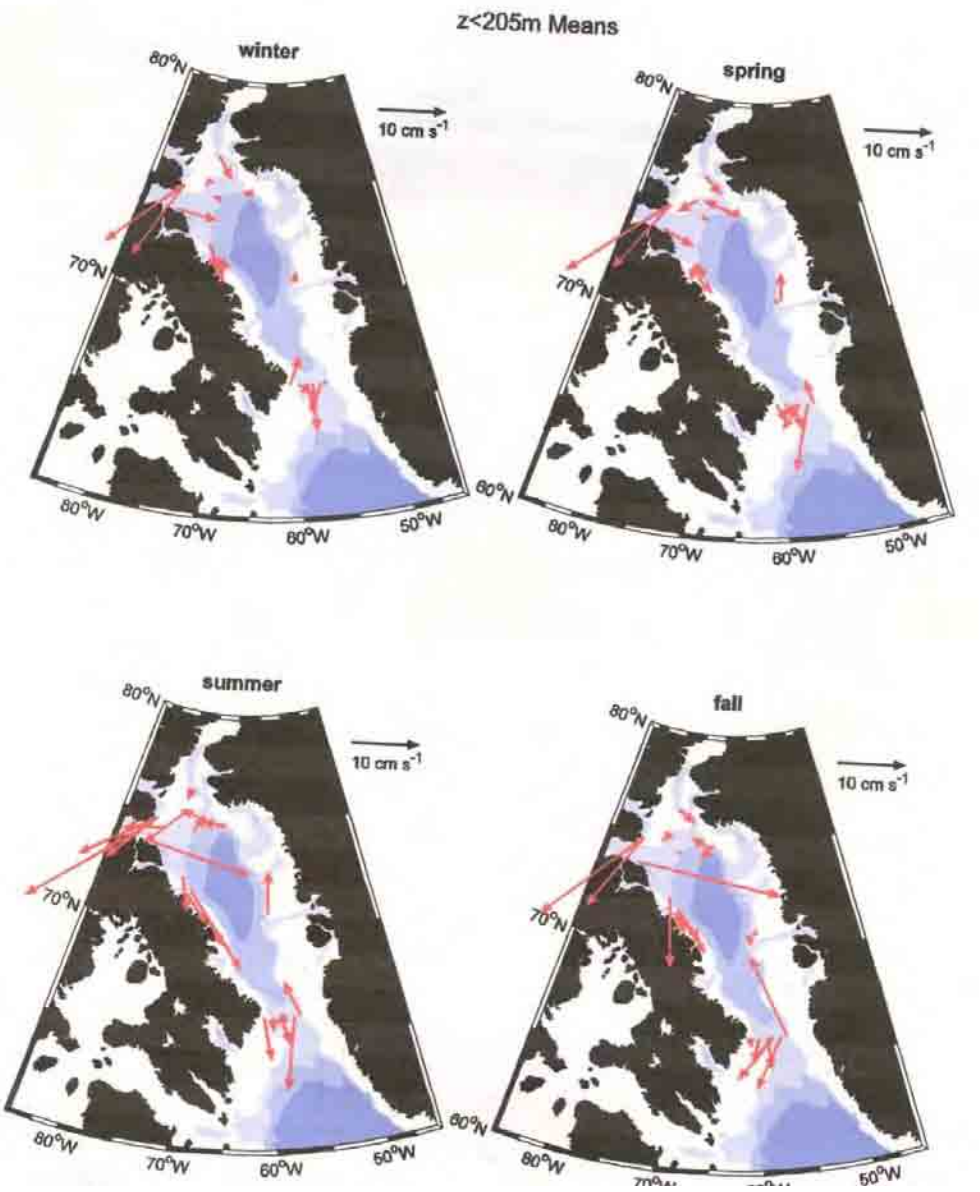

Figure 6. Circulation, within Baffin Bay (Tang et al. 2004)

3.11 BATHYMETRY

Its submarine topography includes an undersea ridge that is the continuation of the mid-Labrador ridge. This ridge extends from the coast of Baffin Island to Greenland. The shallowest waters in Davis Strait occur along this sill and extend from 350 to 500 metres depth before dropping down to the abyssal basins on either side. In the southern end of Davis Strait, some of the greatest depths on the eastern Arctic are reached (3,660 metres).

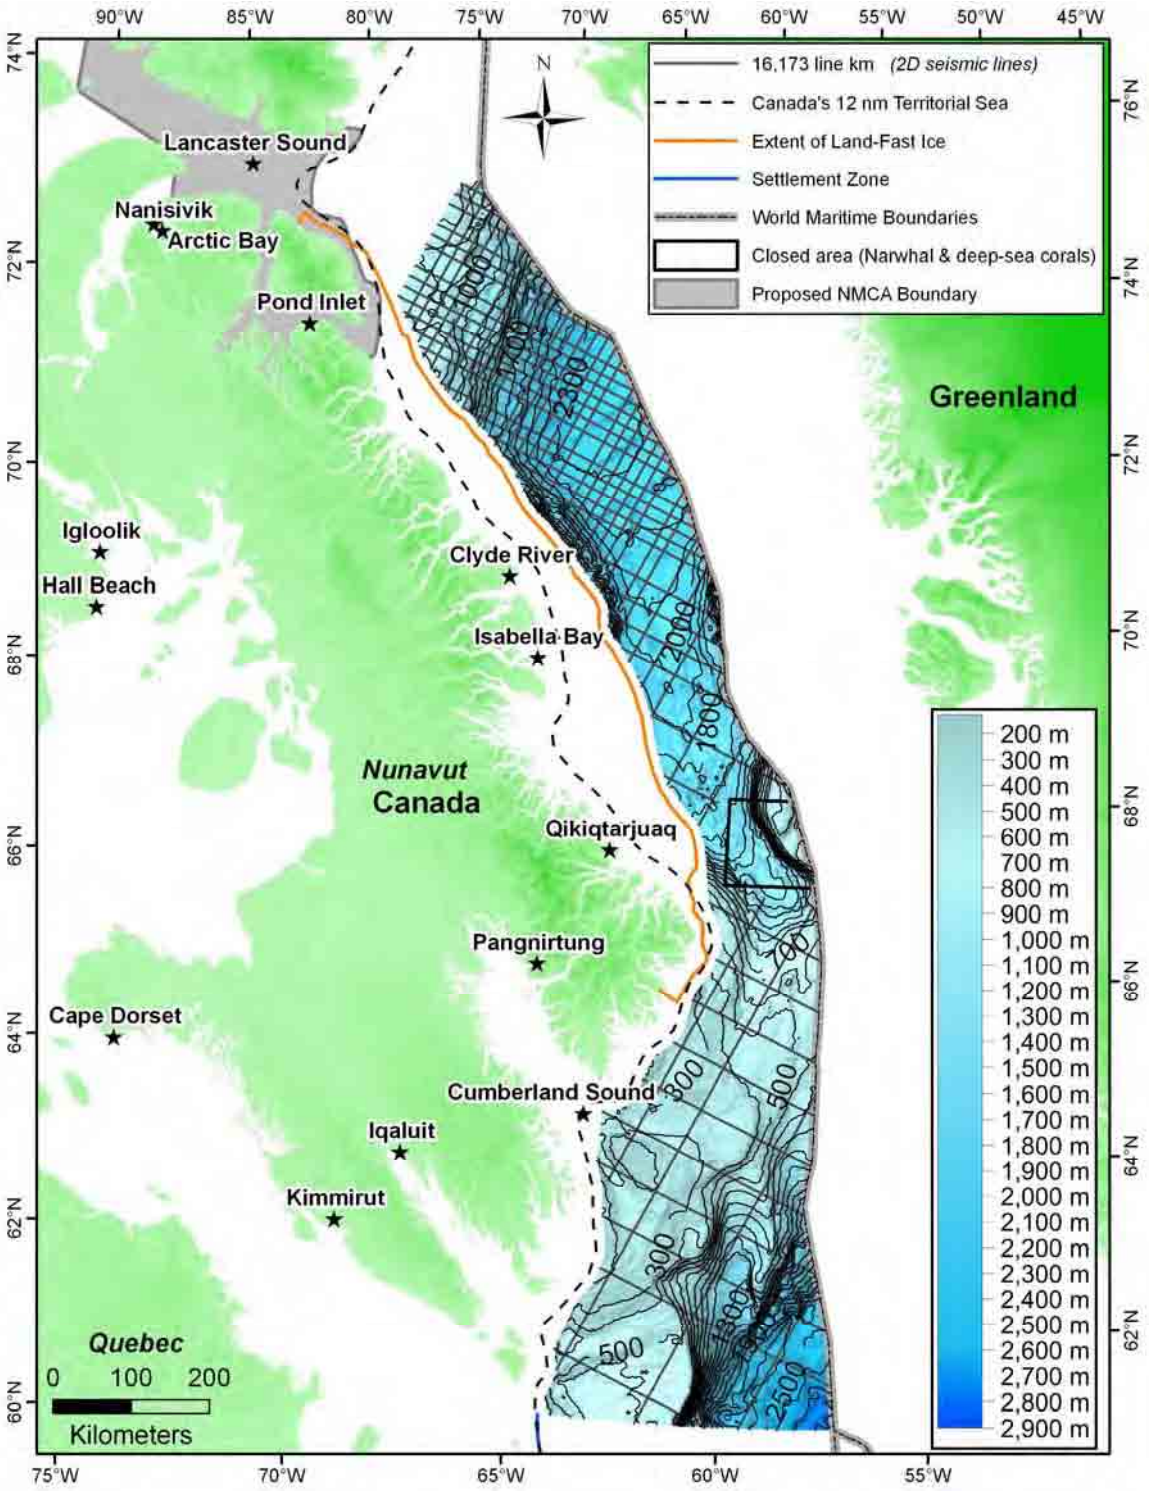

Figure 7. Bathymetry Baffin Bay

3.12 GEOLOGY

Baffin Bay is the north western extension and terminus of the North Atlantic-Labrador Sea rift system. The progressive northward stepping of sea floor spreading in the North Atlantic resulted in graben development in the incipient Baffin Bay area in the Early Cretaceous. Oceanic crust began to form in Baffin Bay in the Paleocene but sea-floor spreading appears to have ceased in the Oligocene. Baffin Bay is bounded to the north by Nares Strait, a probable transform fault, and to the south by the Ungava transform underlying Davis Strait. Sedimentary strata are thickest along the narrow east Baffin shelf and the opposing and much broader west Greenland shelf. A major depocentre is present at the northern end of the Baffin shelf opposite the mouth of Lancaster Sound. Sedimentation has been characterized by the influx of coarse elastic material across the rifted and rapidly foundering margin of Baffin Island. The sediments were derived from the surrounding highlands of the Baffin coast and by clastics brought from the lower Paleozoichinterland of the Canadian Arctic Islands by major rift controlled drainage systems (MacLean et al.1990).

3.13 EXPLORATION HISTORY

No wells have been drilled in Baffin Bay, with the exception of ODP site 645. In 1976-77, five wells were drilled in Davis Strait, at the southern entrance to Baffin Bay. These dry and abandoned wells are in Danish waters on the west Greenland Shelf. The Geological Survey of Greenland suggests that they failed to test prospective pre-Tertiary sequences indicated by seismic. Seismic exploration of the north-eastern Baffin shelf has been limited. The few reconnaissance program shot are insufficient to delineate drilling prospects (Rice and Shade, 1982).

3.14 STRATIGRAPHY

The Mesozoic sediments of Baffin Bay are probably underlain by Proterozoic rocks comparable to those now exposed on Baffin Island. Ordovician to Silurian rocks may be preserved in the offshore, but there is no seismic evidence to suggest that this is the case.

4. BIOLOGICAL ENVIRONMENT

4.1 PRIMARY PRODUCTION

Arctic climatic conditions impose a variety of conditions on the open water annual cycle phytoplankton production. The presence of ice inhibits light penetration, and the annual growth cycle of free living (non-ice algae) may be more compressed in high latitudes such as is experienced in the Davis Strait Region. Nonetheless, a considerable contribution to the overall plant production is attributed to ice algae that develops prior to and independent of the phytoplankton.

The spring phytoplankton bloom in the western Davis Strait begins in May and June with *Fragilaria oceanica* playing an important role (Gran, 1929) along with *Thalassiosira* sp. and *Leptocylindrus danicus* by July and August. In contrast, the waters of the western side of Davis Strait experienced different phytoplanktonic species assemblages. Here the species include the dinoflagellate *Ceratium arcticum* and various diatoms (*Chaetoceros*, *Asteromphalus*, and *Coscinodiscus*) (MacLaren, 1978a, 1978b). Ice flora in the western Arctic consist primarily of diatoms (*Nitzchia* sp., *Amphipora hyperborean*, *Nitzchia coterie*, *Pleurosigma stuxbergii*, *Gomphonema exiguuem arctica*, *Navicula* sp., and dinoflagellates *Peridinium* sp.) and flagellates (*Dimema litorale*, *Eutreptiella* sp. and *Platymonas* sp.) (Horner and Alexander, 1972; MacLaren, 1978a, 1978b). Jensen et al. (1999) have studied phytoplankton biomass distribution and productivity in the Davis Strait region and determined that overall primary phytoplankton production is in the range of 67-3,207 mgC m^2 $d^{1,}$ which is within the range of the few results published for eastern Canadian Arctic and West Greenland waters. Hsaio and Pinkewycz (1987) conducted a detailed survey of the area. A list of species recorded from their investigations is presented for the region in Appendix F. Additional information on the phytoplankton species composition within the area of study may be gained through review of Dunbar and Moore (1980).

4.2 ZOOPLANKTON

Zooplankton species, found in north-eastern Baffin Bay, Davis Strait area are common to Arctic regions in eastern Canada (LGL 1983, Granger 1965, Dunbar and Moore 1980). Like other Arctic regions, copepods are the most important group of zooplankton, both in terms of numbers and biomass (LGL 1983). Species of Calanus (C. finmarchicus, C. hyperboreus and C.glacialis) along with Oithona similis, Pseudocalanus minutus, Microcalanus spp. and Metridia longa are the most common (LGL 1983, Granger 1965 and Dunbar and Moore 1980). Other important groups include: chaetognaths, amphipods, gastropods ctenophores and hydrozoans (LGL 1983). A tabulated list of marine zooplankton occupying the study area may be reviewed by consulting Appendix G (Kennedy 2005).

Here in the Davis Strait region, the marine arctic zooplankton planktonic ecosystem is characterized by a brief summer period of intense productivity following the spring phytoplankton bloom. Young zooplankton stages feed in the surface waters (Grainger,

1959) and there may be spatial and temporal variation in zooplankton reproduction that varies from year to year (Grainger, 1959).

Specifically in the Davis Strait region, the *calanoid copepods Calanus finmarchicus, Calanus glacialis, and Calanus hyperboreus* and *the cyclopoid copepod Oithona similis* are the most numerically abundant species (Bainbridge and Corlett, 1968; MacLaren, 1978a, 1978b). In more coastal realms the *calanoids Acartic longiremis* and *Pseudocalanus minutus* may also be numerically important (Grainger, 1961). According to Grainger (1961, 1963), *Calanus glacialis* and *Calanus hyperboreus* are thought to be indicators of cold arctic waters while Calanus finmarchius indicates a boreal watermass. The zooplankton found in eastern Davis Strait by Bainbridge and Corlett (1968) is similar to that seen in the North Atlantic (Matthews, 1969), and is dominated by Calanus finmarchicus. Bainbridge and Corlett (1968) found that the second most abundant species were the *euphausiids* specifically *Thysanoessa inermis, Thysanoessa rashii, and Thysanoessa longicaudata.*

The Northern shrimp (*Pandalus borealis*) is the most important commercial invertebrate species within the project area. They are generally found in deep depressions and captured using trawl nets. Northern shrimp spawn during late summer and fall, with the eggs remaining attached to the female until spring. Females with eggs move inshore in late autumn and winter to release the eggs (Parsons, 1993).

Table 2 lists the major zooplankton species occurring in the Davis Strait (MacLaren, 1978a, 1978b).

Table 2. Major Zooplankton Species Occurring in the Davis Strait

Euchaeta norvegica	*Pandulas borealis*	

4.2.1 Marine Benthos

Investigations of the marine benthic community of the region of concern have focused primarily on bivalves. Dunbar and Moore (1980) list 51 species of bivalve (their chart 20) occurring in the Eastern Canadian Arctic. They also record 3 crab species (their chart 19), none of these listed species are of commercial importance to the area. An extensive list of marine plants, benthic invertebrates, and other bivalve mollusks and decapods crustacean collected in the Eastern Canadian Arctic is provided also in Dunbar and Moore (1980). Further to the region, Lubinsky (1980) has published a definitive

monograph on the faunal composition and zoogeography of marine bivalve mollusks of the Canadian Central and Eastern Arctic.

Specific to the Davis Strait and Western Baffin Bay Region, LGL (1983) presents information on the *infaunal, epibenthic* and *epifaunal* species. None of these species are commercially harvested. Thompson (1982) has described the marine benthic community of Lancaster Sound and northern and central Baffin Bay. More recently, Mohammed (2001), in a study of the energy flow within Lancaster Sound, found that the benthic species *Mya truncata, Hiatella artica, Serripes groelandicus* and *Macoma calcarea* were key players in the energy transformation within the benthic community. Other important groups included echinoderms (sea cumbers, brittle stars), annelids, terebellid polychaetes and small crustacea.

4.3 MARINE FISH

Dunbar and Moore (1980) in a biogeographic study of marine life in the Canadian eastern Arctic, indicated, for that period, that the state of knowledge of the fishes occurring in the eastern Canadian Arctic was rudimentary. In their report, they list only 13 species of marine fish of which only five species could be attributed to the study area. The five species included: *Boreogadus saida* (Arctic cod), *Moxocephalus scorpius* (Arctic sculpin), *Gymnelis viridis* (fish doctor), *Icelus bicornic* (two horn sculpin) *Coryphaenoides repestris* (rock grenadier) and *Oncocottus quadricornus* (now called Triglopsis quadricornis, fourhorn sculpin). Since then, there has been considerable more information revealed on the species of marine fish that inhabit the region of Lancaster Sound, Jones Sound and Baffin Bay. LGL (1983) in a study of the biological environment of eastern Lancaster Sound and western Baffin Bay recorded 28 species of marine fish (see their Table 2.6.1 for a listing of species). More recently, Coad and Reist (2004) have expanded our knowledge of the species of marine fish that inhabit the Canadian Arctic. In their comprehensive study of Canadian Arctic Ecozones many more species of marine fish have been identified. Here, for the region three Ecozones are represented. These zones are: Baffin Bay-Davis Strait near shore, Lancaster Sound region (including Jones Sound) and Baffin Bay-Davis Strait Offshore. For these three Ecozones combined, a total of 183 species of marine fish have been recorded. This list is presented in Appendix H.

In particular, Davis Strait region of the proposed seismic survey supports a wide variety of fish species. In excess of 80 species from Otter trawls taken between 400 and 1,500 metres have been identified (Treble et al., 2001; Table 3). Earlier studies sampling shallower waters and the benthic environment for fish found several other species (MacLaren, 1978a, 1978b; Table 4). The seasonal distribution of eggs and larvae of several of the more commercially abundant species is documented below for this area of the Davis Strait.

Table 3. Fish Species within the Davis Strait Region

Alepocephalus agassizii	*Coryphaenoides rupestris*	*Malacosteus niger*

Eurnicrotremus spinous	*Myoxocephalus quadricornis*	*Salvelinus alpinus*
Gadus ogac	*Myoxocephalus scorpioides*	

Greenland halibut is a commercially important species that spawn in deep waters (600 to 1,000 metres) in the Davis Strait in the winter or early spring and produce bathypelagic eggs that rise to the surface where larvae are released. These larvae are in the water column during the months of March to June (Smidt, 1968; MacLaren, 1978a, 1978b). Recently however, Morgan and Treble (2006) suggest from gonad development studies that Greenland halibut spawning takes place in the winter or early spring in Davis Strait. The only recognized major nursery area is near the northern end of its distribution, west of Disko Bay, approximately 69° N.

The roundnose grenadier is thought to spawn all year round in this area (Parsons, 1976), while redfish larvae are found from May to August (Dunbar, 1970). Atlantic cod (COSEWIC, 2003) and Greenland cod have similar spawning periods, February to April (Postolaky, 1969; Dunbar, 1970). In general, the eggs and larvae of the major commercial species are not in the water column nor is there significant spawning activity when project-related seismic activity is proposed.

Commercial fisheries within the Davis Strait region are discussed in Section 4.9 of this document.

4.4 MARINE ASSOCIATED BIRDS

There are many species of seabirds and related bird species that can be found associated with the waters of Davis Strait. Not all are breeding populations and may only contact water or the shore area for brief period in the summer (Mallory and Fontain 2004). Both food and nesting site availability affect seabird distribution locally and seasonally and many variations in the summer habitat and feeding areas will occur each season. A list of seabirds associated with Davis Strait is presented below and adapted from MacLaren (1978a, 1978b) Table 5. There are no endangered or threatened species within the seismic survey area according to the latest information on the Species at Risk (SARA) Registry. The Ivory Gull is however a species of special concern (COSEWIC, 2006).

Table 5. Major Seabirds within the Davis Strait Region

Thick-billed Murr (*Uria lomvia)*	Greenland Mallard (*Anas platyrhynchos conboschas)*
Dovekie *(Alle alle)*	Common Mallard (*Anas platyrhynchos platyrhynchos)*
Atlantic Puffin (*Fratercula arctica)*	Brant *(Branta bernicla)*
Black-legged Kittiwake *(Rissa tridactyla)*	Lesser Snow Goose *(Anser Caerulescens)*
Icelandic Gull *(Larus glaucoides)*	Northern Fulmar *(Fulmarus glacialis)*
Herring Gull *(Larus argentatus)*	Greater Sherewater *(Puffinus grabis)*
Glaucous Gull *(Larus hyperboreus)*	Red Phalarope *(Phalaropus fulicarius)*

Great Black-backed Gull *(Larus marinus)*	Parasitic Jaeger *(Stercorarius parasiticus)*
Arctic Tern *(Sterna paradisaea)*	Pomarine Jaeger *(Stercorarius pomarinus)*
Northern Eider (*Somateria mollissima borealis)*	Long-tailed Jaeger *(Stercorarius lonicaudus)*
King Eider *(Somateria spectabilis)*	Skua *(Catharacta shus)*
Oldsquaw *(Clangula hyemalis)*	Redthroated Loon *(Gavia stellata)*
Harlequin Duck *(Histrionicus histrionicus)*	Common Loon *(Gavia immer)*
Red-Breasted Merganser *(Mergus serrator)*	Arctic Loon *(Gavia arctica)*
Barrow's Goldeneye *(Bucephala islandica)*	Ivory Gull *(Pagophilia eburnea)*

According to Dr. M. Mallory of the Canadian Wildlife Service (Nunavut) the following list of seabirds may be encountered, to a greater or lesser degree (Table 6). In addition, the distribution and abundance of some of these seabirds has been studied for the region by D. Fiefield (Canadian Wildlife Service, St. Johns Newfoundland).

Table 6. Likelihood of encounter of major seabird species within the northern study region

Species	Likely hood of encounter
Thick-billed Murr (*Uria lomvia)*	Certain
Dovekie *(Alle alle)*	Certain
Atlantic Puffin (*Fratercula arctica)*	Possible
Black-legged Kittiwake *(Rissa tridactyla)*	Certain
Icelandic Gull *(Larus glaucoides)*	Certain
Common Eider (*Somateria mollissima)*	Certain
Glaucous Gull *(Larus hyperboreus)*	Certain
Northern Fulmar *(Fulmarus glacialis)*	Certain
Arctic Tern *(Sterna paradisaea)*	Probable
Parasitic Jaeger *(Stercorarius parasiticus)*	Probable

King Eider *(Somateria spectabilis)*	Certain
Long-tailed Jaeger *(Stercorarius lonicaudus)*	Probable
Thayer's Gull (*Larus thayeri*)	Certain
Long-tailed Duck (*Clangula hyemalis*)	Probable
Sabine's Gull *(Xema sabini)*	Possible
Black Guillemot (*Cepphus grylle)*	Certain
Ivory Gull *(Pagophilia eburnea)*	Possible
Pomarine Jaeger *(Stercorarius pomarinus)*	Possible
Ross's Gull (*Rhodostethia rosea)*	Doubtful

(Dr. M. Mallory CWS, Nunavut)

It is not expected that seismic activity will measurably impact seabirds within the study area for the period of August through September (Lacroix et al 2003, Evans et al.1993, Stemp 1985, Huettmann and Diamond 2000). The surveys will begin far offshore and mitigation measures such as "ramping-up" the airgun array will aide in the dispersion of any concentration of seabirds that may be within the immediate area being studied. Nevertheless there are several seabird and related species that merit closer attention including the Thick-billed Murre, Black-legged Kittiwake, King Eider, Northern Fulmar and Ivory Gull; they are discussed below.

4.4.1 Thick-billed murres

Thick-billed murres are the most abundant colonial seabird in eastern Canada (Orr and Ward 1982, Gaston 1980, Figure 8). They breed along the Labrador coast and the northern islands between May and August (McLaren 1982, McLaren and McLaren 1982). At this time flightless birds (adults and chicks) from both western and eastern arctic colonies utilize surface water currents and travel rapidly through Hudson Strait, Davis Strait and the Labrador Sea (Orr and Ward 1982). During this period, August to October, sever hundred thousand flightless adults and chicks will be migrating. However as Figure 8 indicate these birds may be encountered during seismic activity.

Figure 8. Thick-billed Murre seasonal distribution (Gaston 1980)

Common and Thick-billed Murres are divers and may be affected by seismic activity. This is also true for *Alcidae* that breed in Newfoundland and Labrador including Razorbill and Atlantic Puffin. The largest colony of Razorbill in North America is at the Gannet Islands in southern Labrador. Shearwaters also dive for their food and may be susceptible to seismic interactions. Although diving birds may be susceptible to seismic interactions studies by Lacroix et al (2003) found no measurable impact of seismic activity on diving ducks (*Clangula hyemalis*), see also McLaren and McLaren 1982.). Stemp (1985).

4.4.2 Northern Fulmars

Northern Fulmars that reside in the Canadian Arctic in summer, winter in offshore open water areas in southern Baffin Bay, Davis Strait and the Labrador Sea (McLaren 1982). From May to June, prior to nesting, Fulmars generally occur in similar densities on coastal and ice edge habitats.

4.4.3 Black-legged Kittiwakes

Black-legged Kittiwakes that summer in the eastern Canadian Arctic winter pelagically in open waters of the Labrador Sea and North Atlantic (McLaren 1982). During the spring and early summer their densities were found to be higher along coastal areas than along fast ice edges and both higher than in offshore areas (McLaren 1982).

4.4.4 King Eiders

King Eiders, according to Mosbech and Boertmann (1999) will not be in the survey area during the period scheduled for this seismic activity (Figure 9).

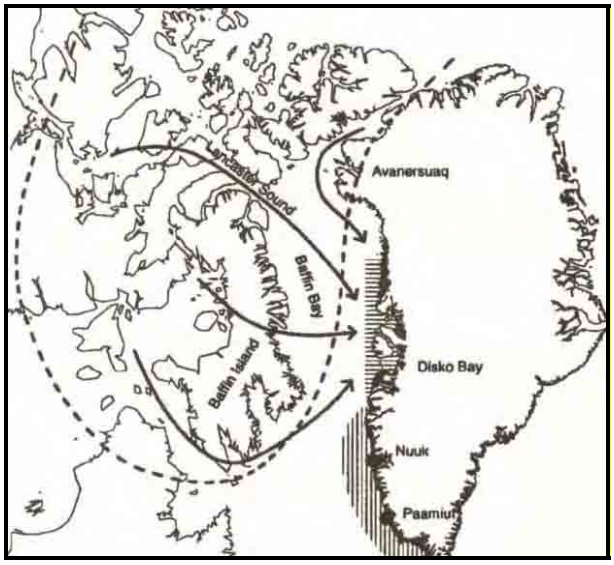

Figure 9. Molt migration of King Eiders and main molting area off Greenland (Mosbech and Boertmann 1999)

Most recently, D. Fiefield, CWS (Newfoundland) has compiled the latest abundance and distribution of several bird species within the region of concern. The distribution and estimated abundance for some of the above mentioned species from July through September over the period 2006 to 2009 is presented in the following figures (Figure 10 to Figure 14). Graphic distribution and abundance for the period of the northern field program in the eastern Arctic for some of these species is presented below. (We gratefully acknowledge the assistance of C. Gjerdrum CWS, Dartmouth, Nova Scotia for these figures.) Additional information on regional seabirds may be acquired through review of Mallory and Fontaine (2004).

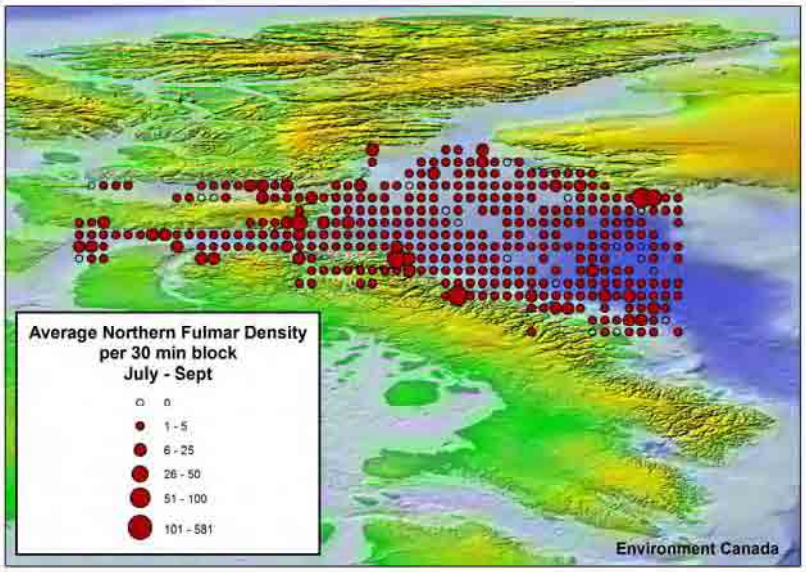

Figure 12. Average distribution and abundance of Northern Fulmars for the period of July to September

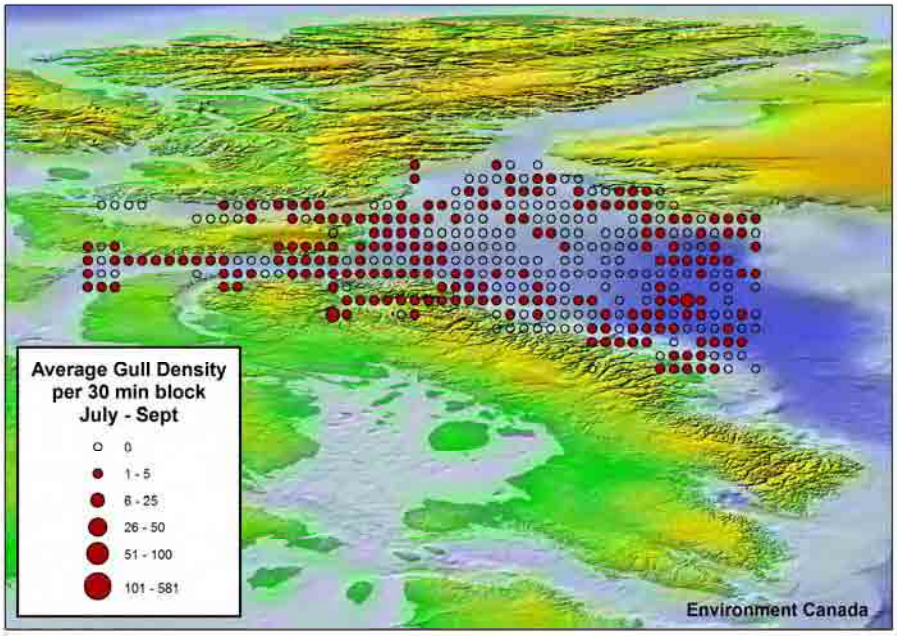

Figure 13. Average Gull distribution and abundance for the period of July to September

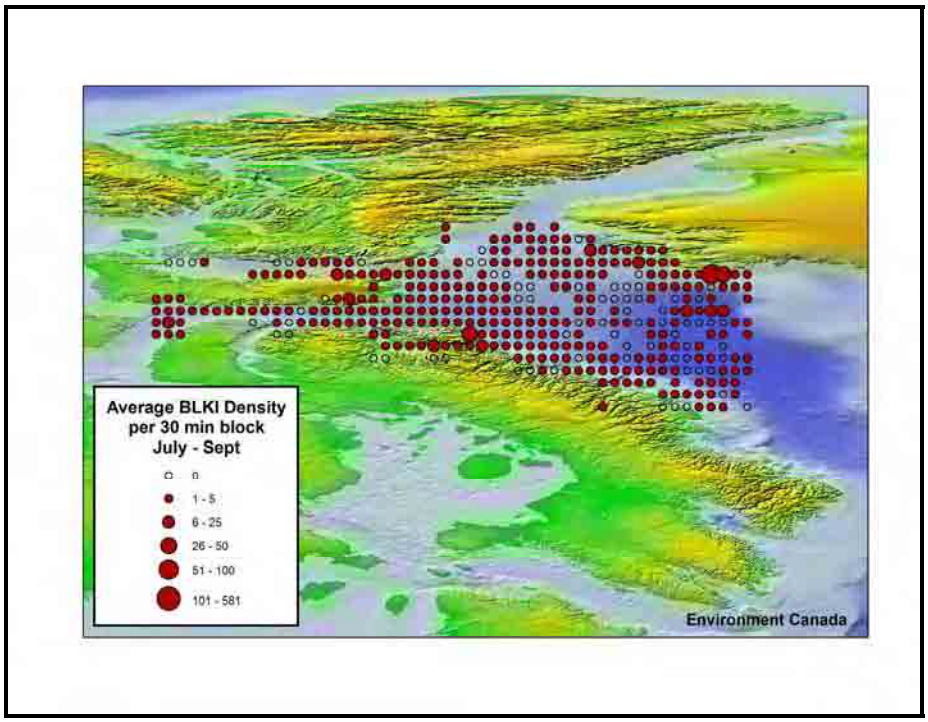

Figure 14. Average Black-Legged Kittiwake distribution and abundance for the period of July to September

4.4.5 Ivory Gull

Although the east coast of northern Baffin Island, Lancaster Sound and Jones Sound support many seabird colonies only one species has been identified as at risk by SARA and COSEWIC 2006. The Ivory Gull was assigned as an endangered species by COSEWIC (2006c) and SARA due to decline in their distribution and abundance (Gilchrist and Mallory 2005). Although the historic winter range (Figure 15) shows that the species may frequent areas of the proposed seismic survey in the late fall the seismic survey will be completed by the end of September. Consequently, these birds that may frequent the most southern regions of the seismic survey area for wintering (November) are less likely to be exposed to measurable influences related to human activity undertaken in the summer.

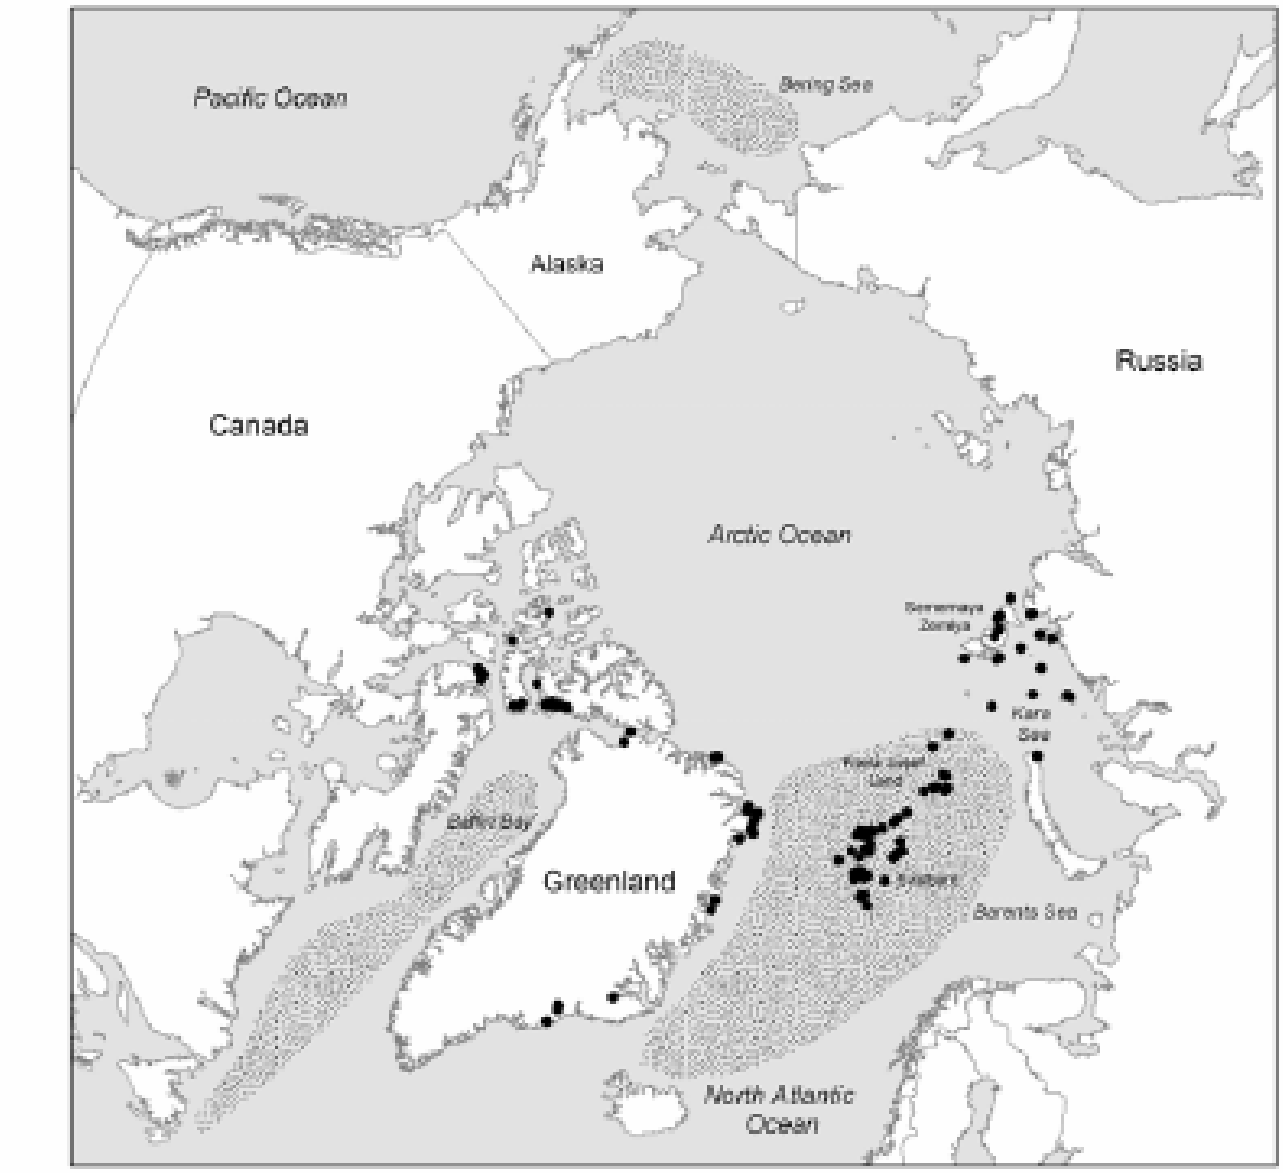

Figure 15. Distribution of ivory gull, stippled indicates winter range, dots identified colonies (active and inactive, COSEWIC 2006c).

4.4.6 Dovekies

Dovekies (*Little Auks*) breed in northwest Greenland and migrate through Davis Strait during the latter part of April and early May (Renaud et al., 1982). The number of dovekies wintering in North American waters and breeding colonies in northwest Greenland has been estimated to be in the tens of millions (Montevecchi and Stenhouse, 2002). The only known breeding area in the Canadian Arctic is in Home Bay on eastern Baffin Island (Montevecchi and Stenhouse, 2002). This species winters in low arctic waters of the Labrador Sea, Grand Banks, and coastal Newfoundland (Montevecchi and Stenhouse, 2002). Colonies are abandoned by late August and birds start to leave northern Baffin Bay through to October, where they remain at the edge of pack-ice in southern Baffin Bay and Davis Strait. Here, in these offshore habitats, dovekies generally occur in higher densities associated with moderate to heavy pack-ice. Ice-free areas or areas with total ice cover are generally avoided (Renaud et al., 1982). Because ice-free areas are the only areas where seismic activity will take place, it is unlikely that significant numbers of dovekies will be encountered during the survey period. Nevertheless, mitigation measures will be adopted to reduce potential interaction of seismic activity on dovekies.

4.4.7 Long-tailed Ducks

Long-tailed ducks (*formerly Oldsquaws*) may occur in large numbers along coastal areas and shore-ice areas of eastern Lancaster Sound and northern Baffin Bay from May to July (McLaren and McLaren, 1982); however, they are rarely seen greater than 1 kilometre from the coast or shore-fast ice. Although densities may peak in September, by mid-October only a few individuals remained when surveys were undertaken in Lancaster Sound (McLaren and McLaren, 1982). Since these ducks are rarely seen out as far as 1 kilometre from the shore, it is unlikely that the seismic survey will encounter this species.

4.4.8 Black Guillemots

Black Guillemots within Baffin Bay and eastern Lancaster Sound, during the spring and early summer, have densities that are higher along fast ice edges than along coasts, and densities offshore were lower than along interfaces (McLaren and McLaren, 1982). Their distribution in the most northern areas during early to mid-summer. Like Murres, Guillemot densities were highest in light to heavy pack-ice and lowest in ice-free areas and areas with total ice cover. Since the proposed seismic activity will take place in ice-free waters, the potential for interaction with this species is significantly reduced. Nevertheless mitigation measures to reduce the potential for interaction will be in place

4.5 MARINE MAMMALS

Marine mammal occupation of this region of eastern Canadian high Arctic may include up to 22 species: 5 seal, 1 walrus, 6 species of baleen whale, 6 species of toothed whale, 3 porpoises, and the polar bear (MacLaren Atlantic Limited, 1978, McLaren et al.1982). The proposed study area forms the northern most range extent for several species and the likelihood of their presence here is therefore less understood during the proposed period of seismic activity in this area of the high Arctic. Most notably, the marine mammal species that could be encountered during this portion of the northern survey include: ring, harbour, bearded and harp seals, possibly hooded seals; the walrus, polar bear as well as beluga, narwhal and bowhead whales and possibly killer whales (LGL 1983, Dunbar and Moore 1980).

Pinnipeds

4.5.1 Ringed seal (*Phoca hispida*)

The Ring seal, (*Phoca hispida*), has a circumpolar distribution (DF0 2009) and they are generally closely associated with the distribution of land fast ice. They are the most common seal within Nunavut (MacLaren, 1958, LGL 1983, Dunbar Moore 1980). Immature ringed seals may move offshore during open water season, but adults remain around islands and within the bays and fiords (MacLaren, 1958, LGL 1983, Dunbar Moore 1980). Consequently, they are unlikely to be encountered during the seismic survey that will take place in the summer. There is no evidence of large scale migrations. The native harvest within Nunavut takes place throughout the year (Priest and Usher 2004, Table 7. Their general distribution/range is shown in Figure 16

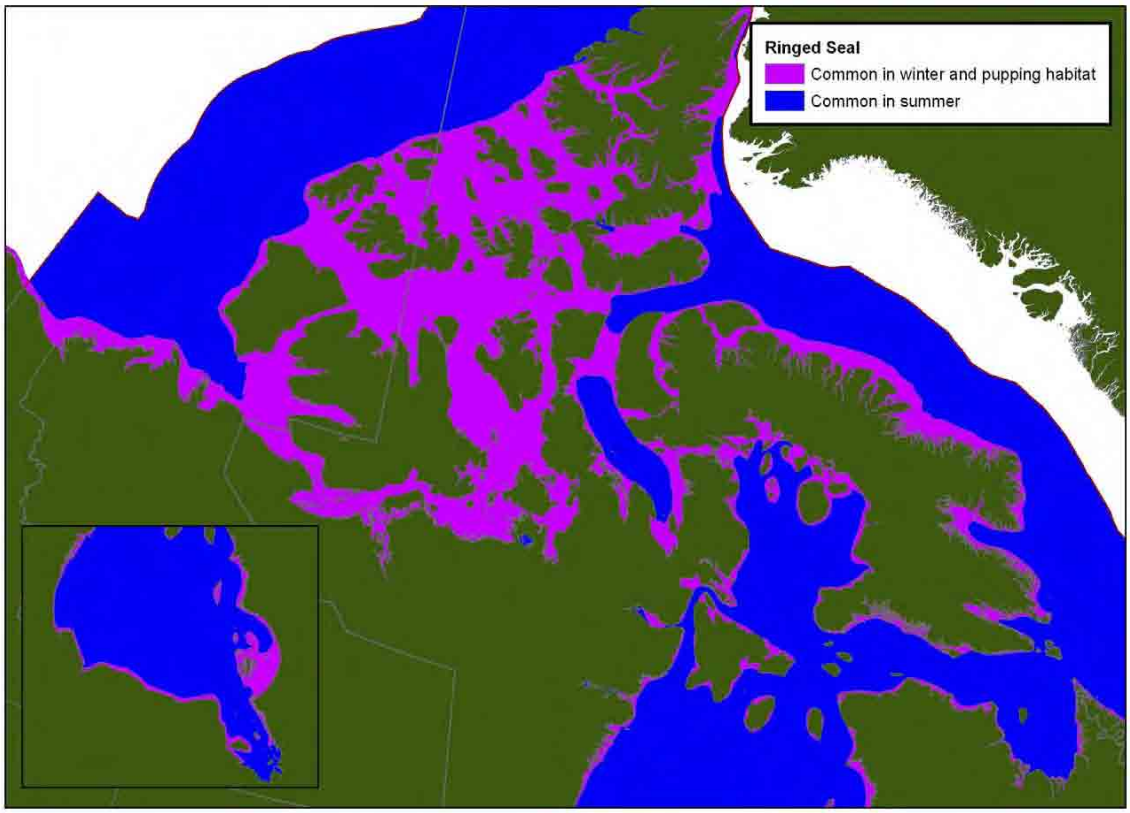

Figure 16. Distribution of Ringed Seal (*Pusa hispida*) in the Canadian Arctic. (Stephenson and Hartwig 2010)

4.5.2 Bearded Seal (*Erignathus barbatus*)

The Bearded seal, *Erignathus barbatus*, is sparsely distributed throughout the Canadian Arctic and restricted in distribution by the extent of pack ice and shallow water (MacLaren, 1958, LGL 1983, Dunbar Moore 1980, CNLOPB 2008). Unlike many of the other seal species occurring in the Canadian Arctic, this species has not been well investigated (Stephenson and Hartwig 2010). Studies of their general distribution have lead to adopt the 250 m benthic contour interval as a measure to delineate the area in which Bearded Seals are commonly seen (Stephenson and Hartwig 2010). Their general distribution/range is shown in Figure 17. Note that they are absent from the central portion of Baffin Bay and Davis Strait where the northern portion of the survey will take place and they generally occur near shore. Bearded seals are harvested throughout the year by native populations (Priest and Usher 2004).

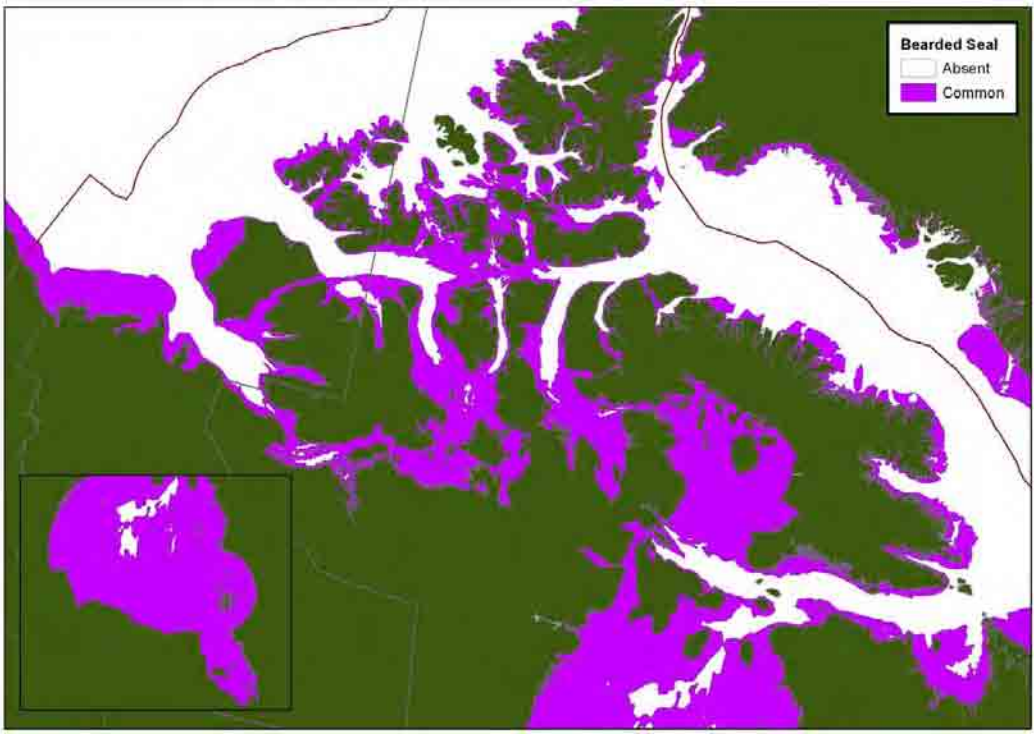

Figure 17. Distribution of Bearded Seal (*Erignathus barbatus*) in the Canadian Arctic. (Stephenson and Hartwig 2010)

4.5.3 Harp seals (*Phoca groenlandica*)

Harp seals (*Phoca groenlandica*) are known to occur in large numbers during the summer season in the region. The population of Harp Seals is presently estimated to be about 6 million individuals (Stephenson and Hartwig 2010). Harp seals migrate westward throughout the summer, from Baffin Bay into Lancaster Sound (Stephenson and Hartwig 2010) and may travel in large groups (50 to 500+) during ice break-up (Fallis et al., 1983). They are common at the floe edge feeding or hauled out on ice floes (DFO, 2005). Their migratory pathways and whelping grounds are shown in Figure 18. Groups tend to be smaller during the open water season. Harp Seals are hunted throughout Nunavut primarily during the months of June through September Table 7 (Priest and Usher 2004). Their general distribution/range is shown in Figure 19.

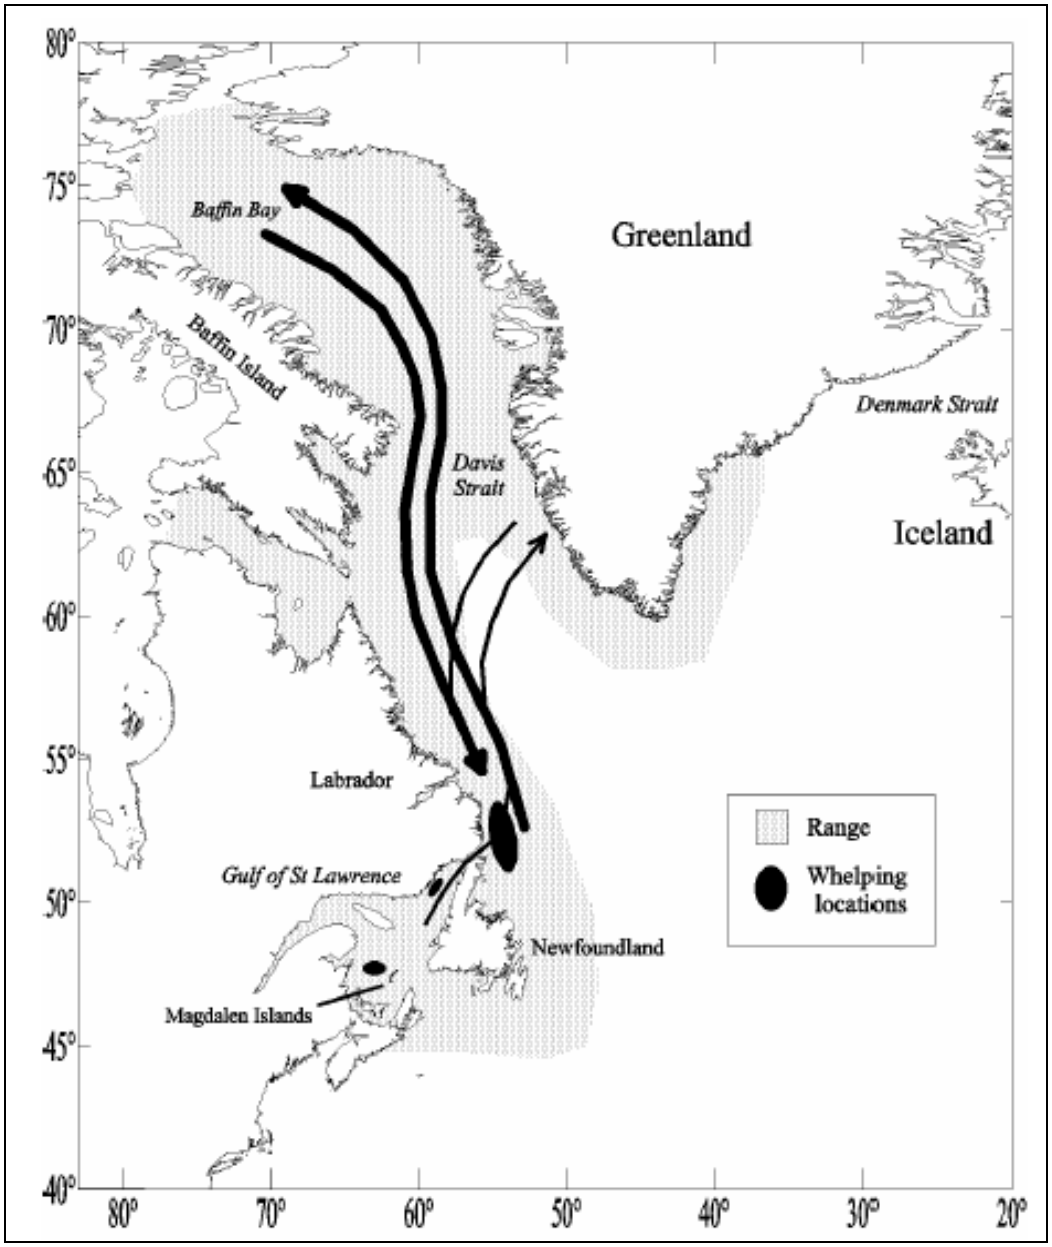

Figure 18. Range, Migratory Pathways, and Whelping Locations of Harp Seals in the Northwest Atlantic (DFO, 2005)

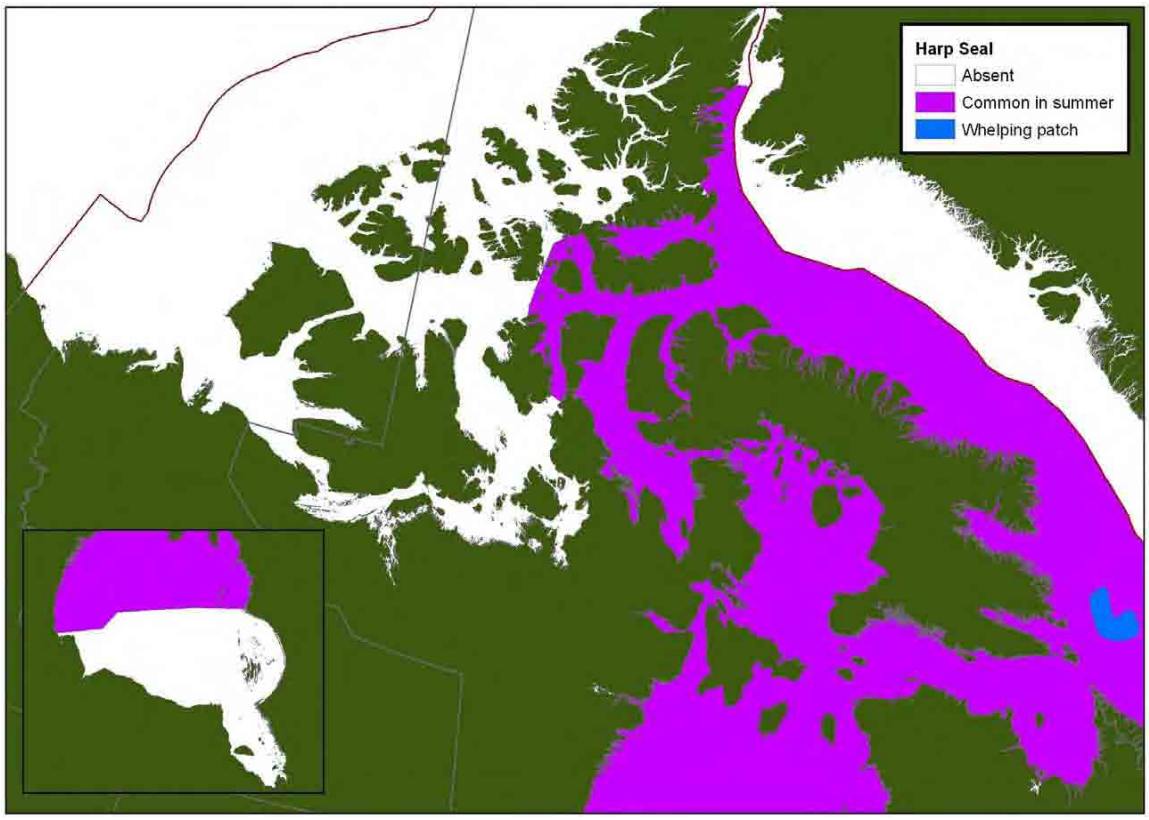

Figure 19. Distribution of Harp Seal (*Pagophilus groenlandica*) in the Canadian Arctic (Stephenson and Hartwig 2010)

4.5.4 Harbour Seal (*Phoca vitulina*)

The Harbour Seal, *Phoca vitulina*, is a coastal species and is generally associated with near shore shallow water with regions of up welling and tidal action or out on the floe edge (Mansfield, 1967). In general they prefer not to venture greater than 11 km offshore in waters that are in the order of 50 m (COSEWIC 2007). This depth limitation has been supported by radio telemetry studies that have indicated that the 50 m benthic contour line may be used to demarcate their offshore limit of distribution (Stephenson and Hartwig 2010). This distribution pattern may be related to the fact that this species of seal does not maintain breathing holes in the ice and thus they are restricted in their offshore distribution to areas with open water during ice-covered seasons (Stephenson and Hartwig 2010). Harbour Seals are harvested by members of the Nunavut community primarily during the period from July through October (Table 7). Their distribution and range is shown in Figure 20.

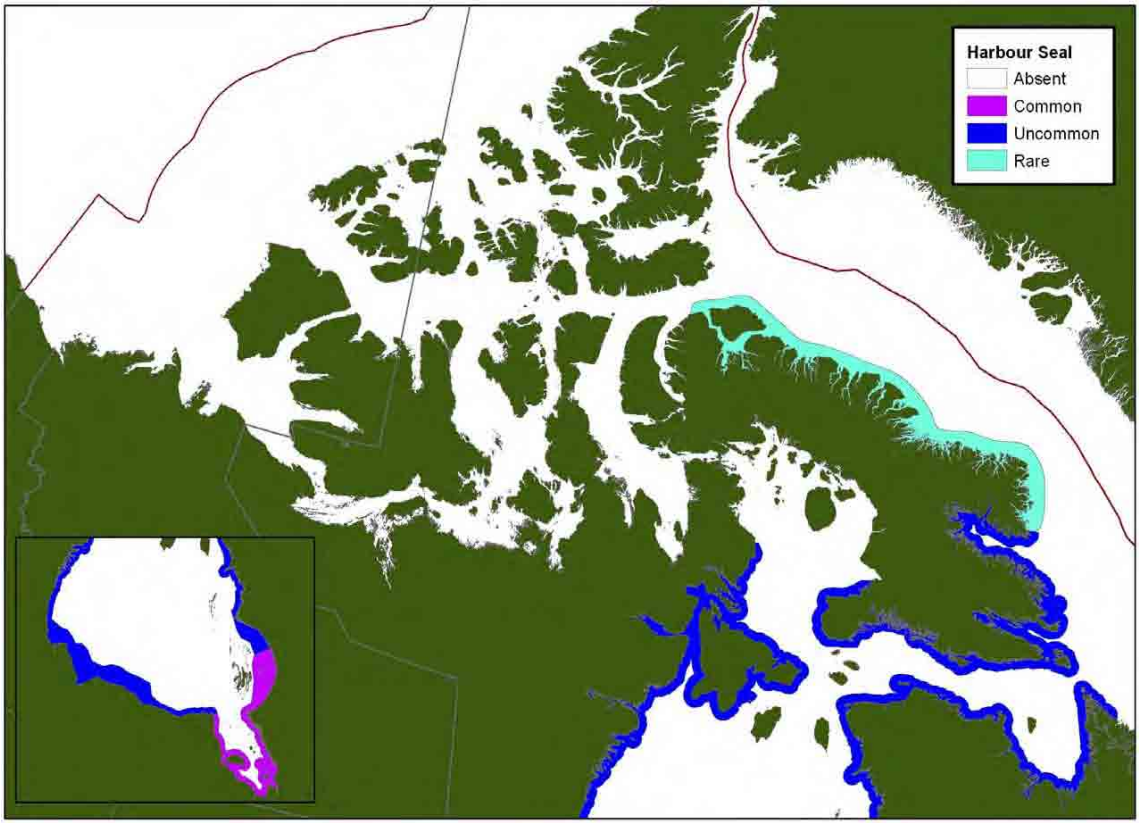

Figure 20. Distribution of Harbour Seal (*Phoca vitulina*) in the Canadian Arctic. (Stephenson and Hartwig 2010)

4.5.5 Hooded seals (*Cystophora cristata*)

Hooded seals (*Cystophora cristata*), within Nunavut are occasionally seen migrating into Lancaster Sound from Baffin Bay (Sergeant, 1976, Hammill and Stenson 2006). Although they have not been extensively studied, they are generally associated with heavy pack ice and their presence would extend until ice break-up (Sergeant, 1974). Hooded Seals are considered a deep-water feeder (Stephenson and Hartwig 2010). Since they are primarily deep-water feeders, the 200 m bathymetric contour interval has been adopted to estimate the offshore distribution boundary of this species (Stephenson and Hartwig 2010). Native hunting for this seal takes place primarily during the months of June through December (Priest and Usher 2004, Table 7). Their general distribution throughout the region is presented in Figure 21. Furthermore, the Nunavut Wildlife Management Board has produced a series of species distribution maps for resources that occur within the Nunavut Settlement Area. These maps, based on many years of traditional ecological knowledge (TEK), provide insight on the local distribution patterns of marine related aquatic resources important to the members of the Nunavut community.

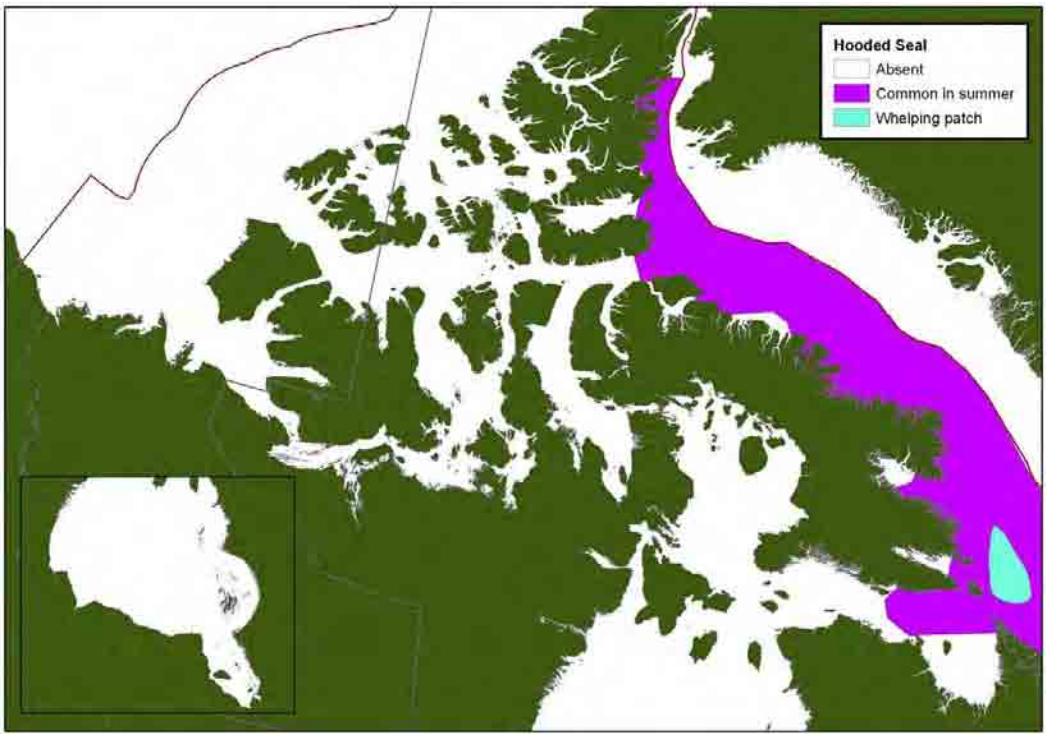

Figure 21. Distribution of Hooded Seal (*Crystophora cristata*) in the Canadian Arctic. (Stephenson and Hartwig 2010)

Nunavut traditional ecological knowledge for the sea species in their jurisdiction has been mapped. This map, Figure 22, shows the high density distribution pattern of the most important species to the Nunavut, notable the Harp Seal, Ring Seal and to some extent the Bearded Seal (Nunavut Planning Commission 2009).

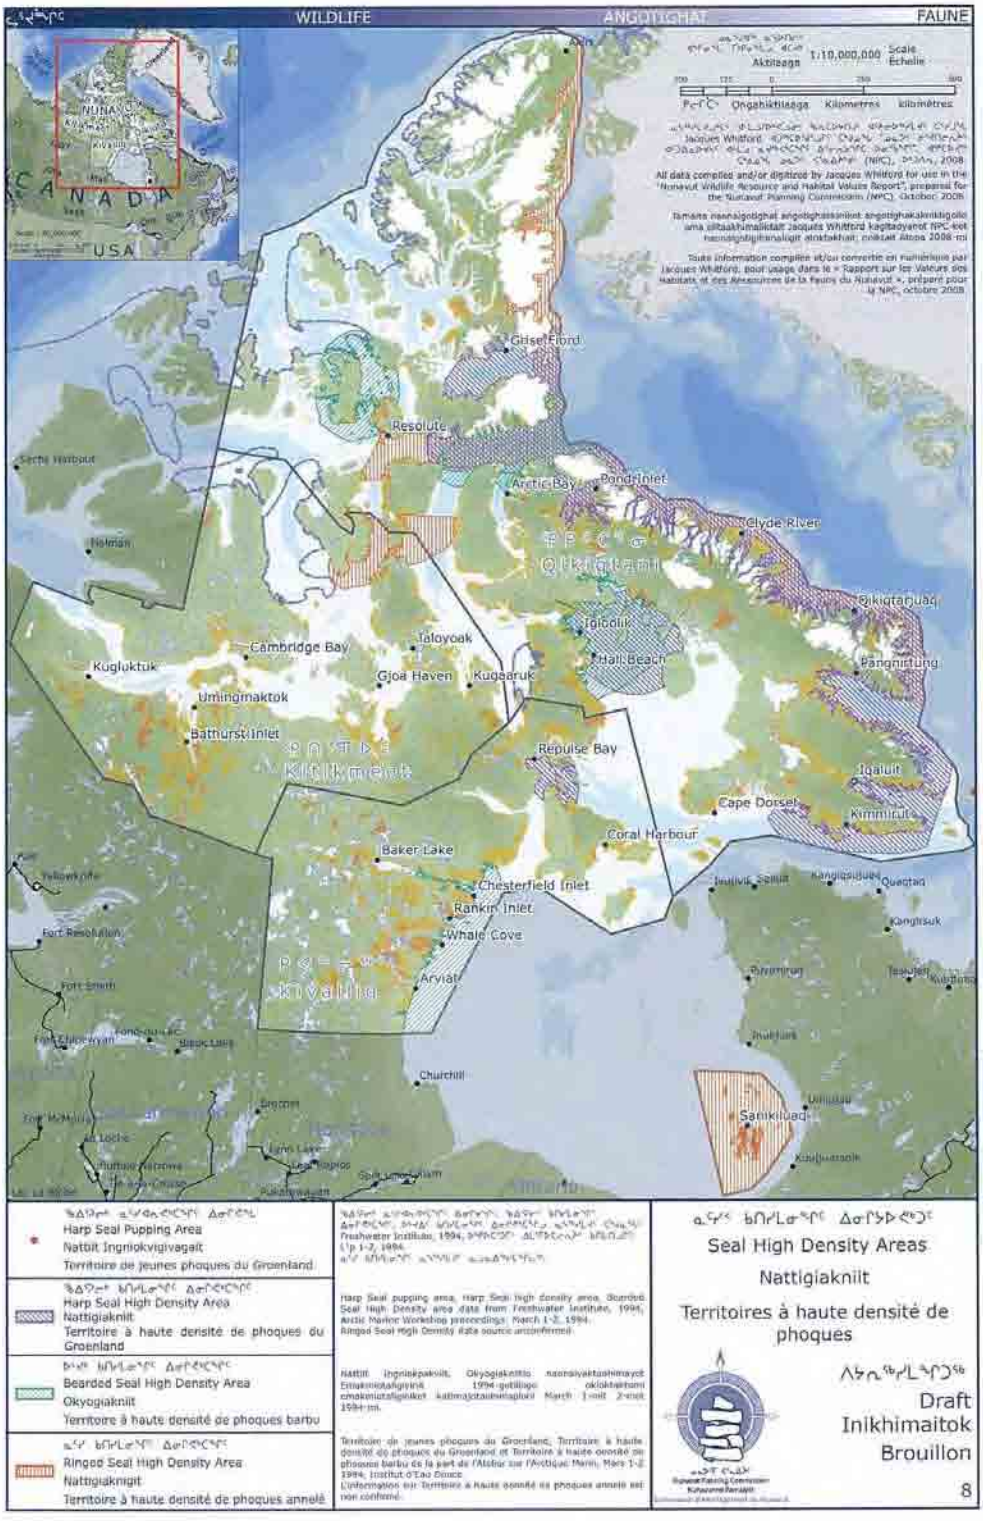

Figure 22. High density distributional pattern of major seal resources within Nunavut (Nunavut Planning Commission 2009).

4.5.6 Atlantic walrus (*Odobenus rosmarus*)

The Atlantic walrus, *Odobenus rosmarus*, once common in the region, is now more rare and has recently been up-listed by COSEWIC from a designation of “not at risk” to a designation of “Special Concern” (COSEWIC, 2006). Ecologically, the Atlantic walrus prefers shallow water (<80 metres) regions with high bivalve productivity. Bivalves are their primary prey (Evans and Raga 2001). The general distribution and range of this species is shown in Figure 23. There are several populations within the Canadian Arctic and their specific distribution pattern is presented in Figure 24 and Figure 25. The Nunavut Wildlife Management Board has mapped the seasonal distribution of walrus for the Nunavut region, this pattern of seasonal distribution is presented in Figure 26. Walrus are hunted in the Nunavut region year round (Priest and Usher 2004). The general distribution pattern and their habitat preference for shallow near shore areas substantially reduce the potential for interaction with this project in far offshore regions.

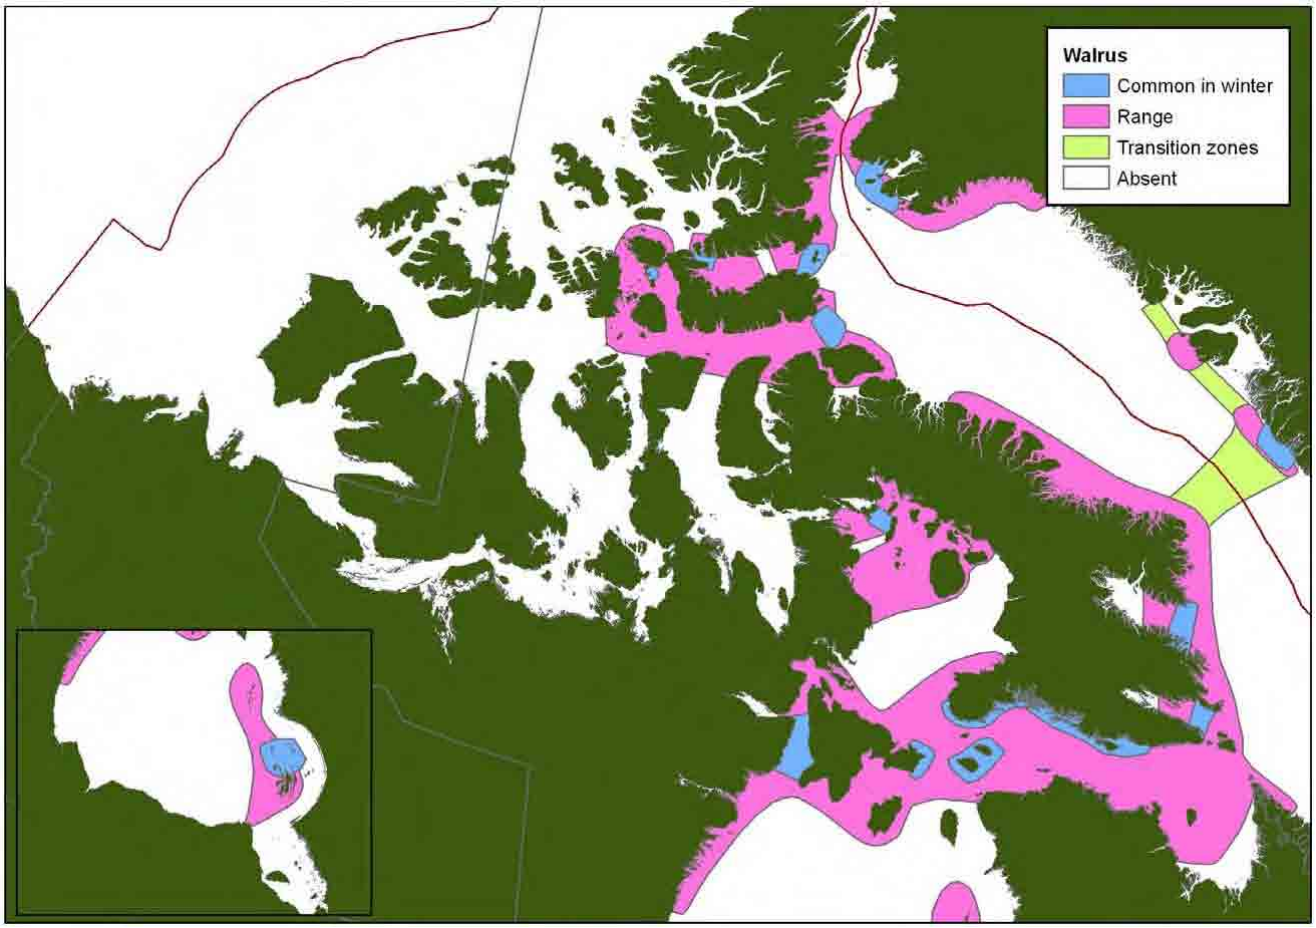

Figure 23. Distribution of Walrus (*Odobenus rosmarus*) in the Canadian Arctic. (Stephenson and Hartwig 2010)

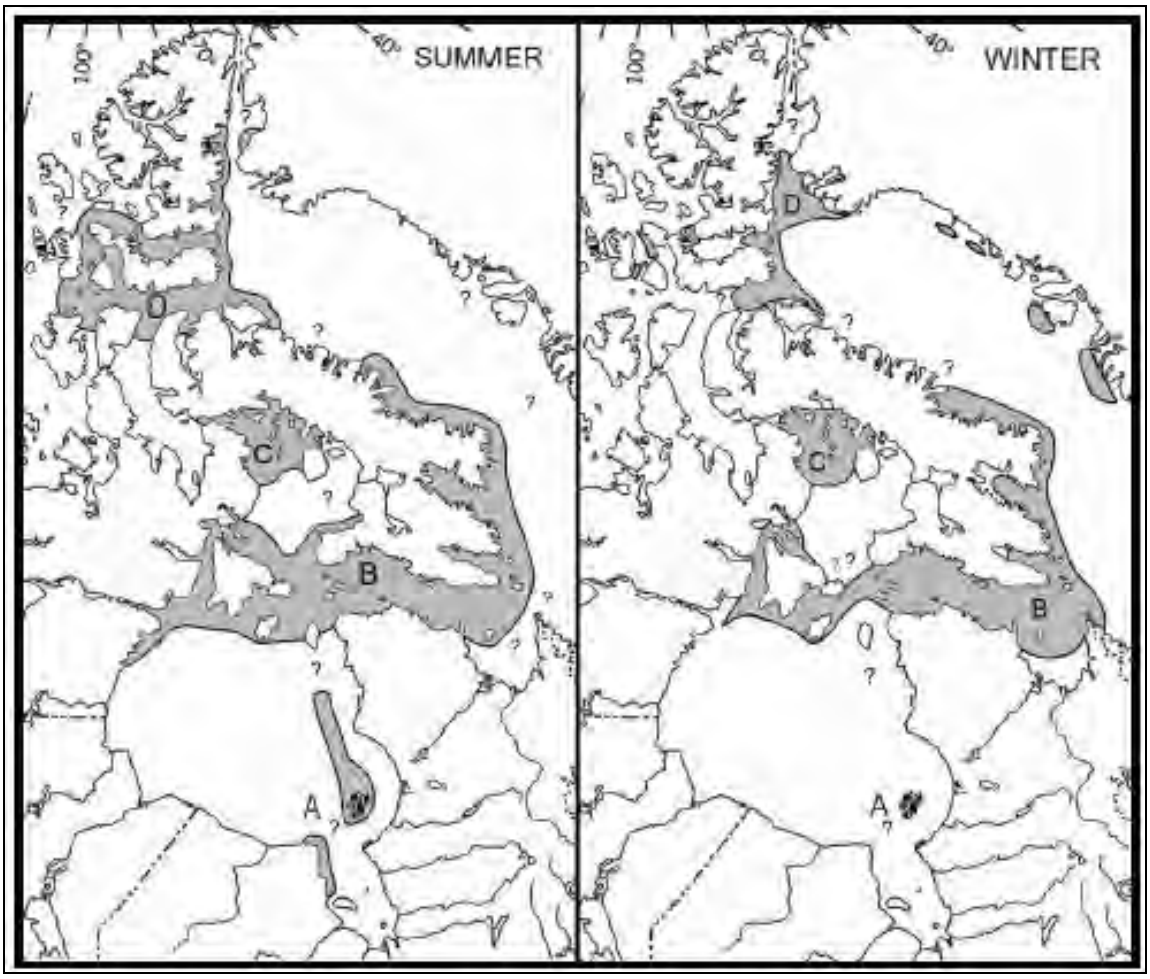

Figure 24. Approximate summer and Winter Distributions of Atlantic Walrus Populations in Canadian Waters South and East Hudson Bay (A), Northern Hudson Bay - Davis Strait(B), Foxe Basin (C), and Baffin Bay (High Arctic) (D) populations. Question marks indicate uncertainty with respect to distributions and/or movements (COSEWIC 2006).

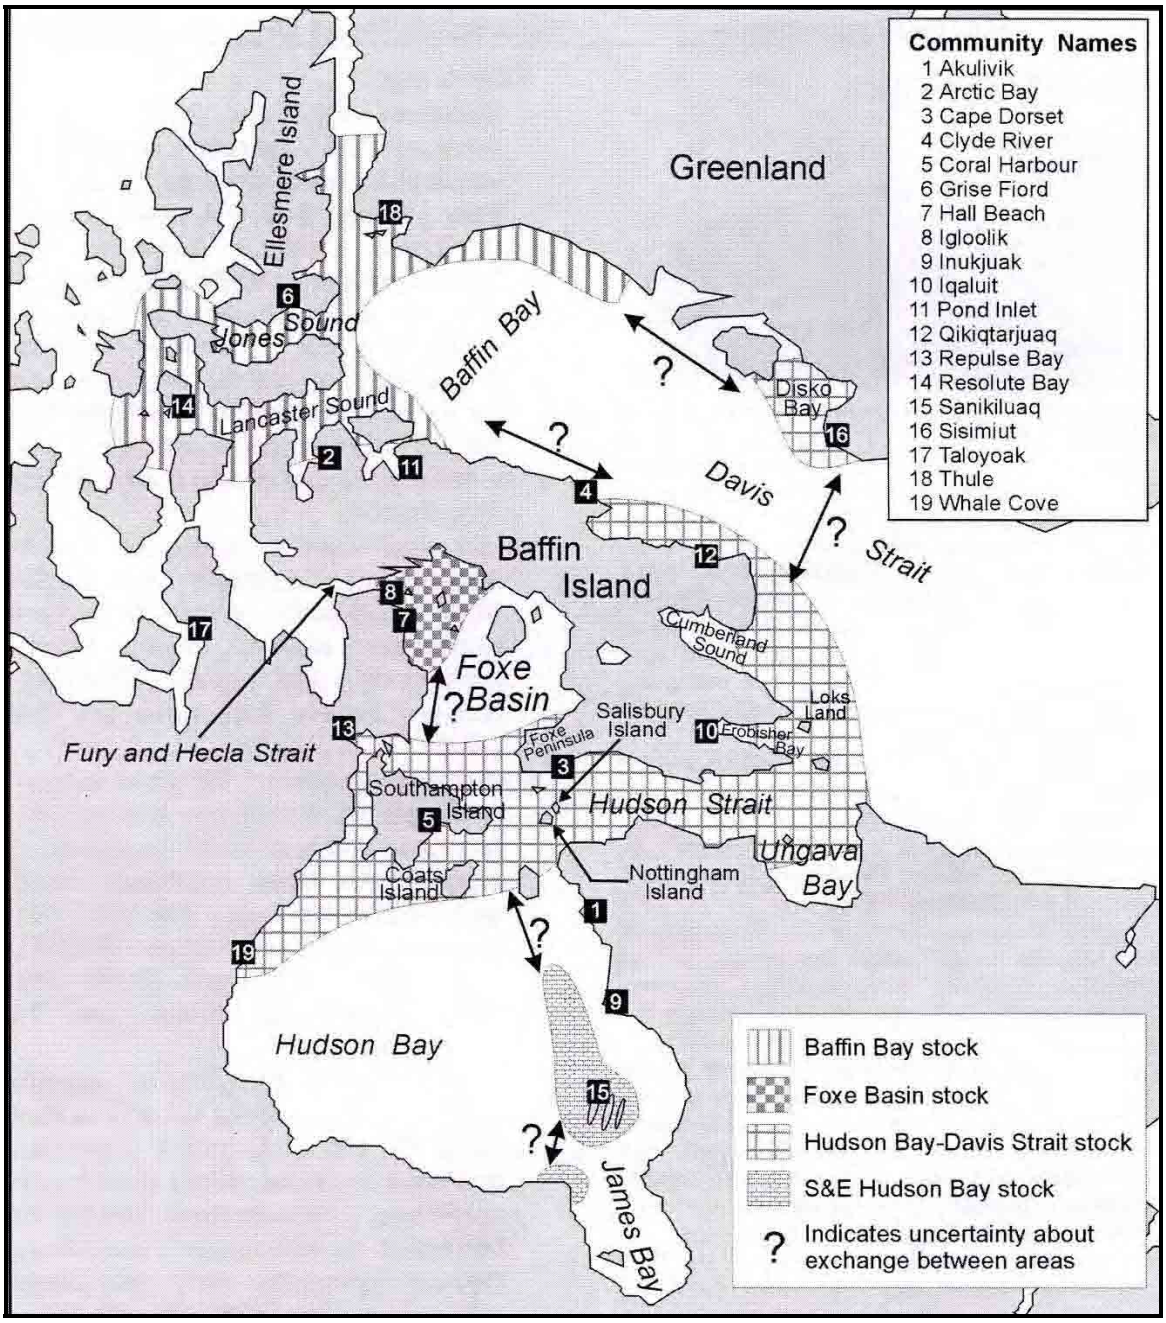

Figure 25. Map of the range and distribution of Atlantic walrus stocks in eastern Canadian waters (from DFO 2000).

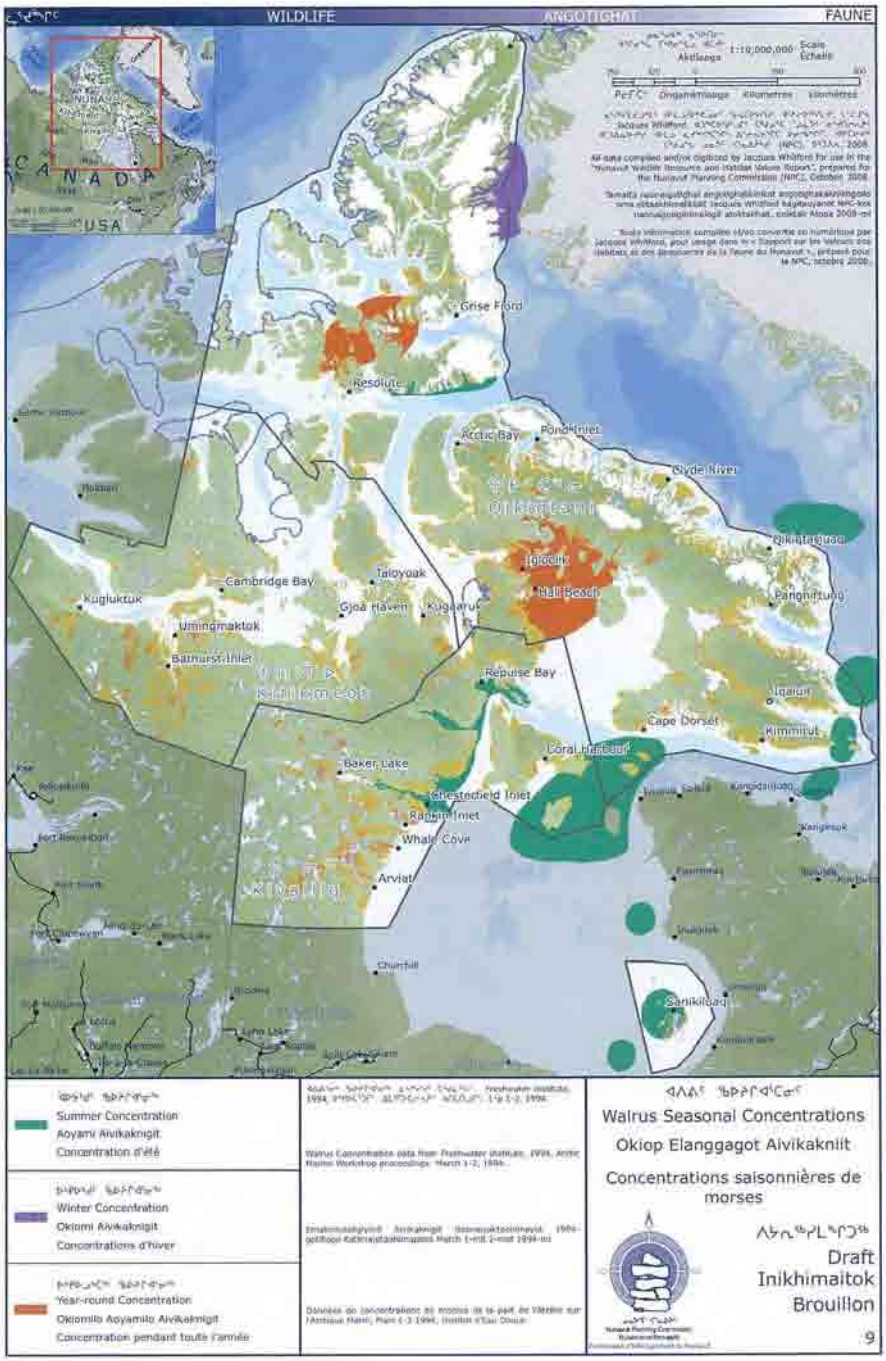

Figure 26. Walrus seasonal concentrations within Nunavut

4.6 CETACEANS

Toothed Whales

4.6.1 Killer Whale (*Ornicus orca*)

The killer whale, *Ornicus orca*, frequents the eastern Canadian Arctic Davis Strait and Baffin Bay Region in summer (MacLaren, 1978a, 1978b, Dunbar and Moore 1980, COSEWIC 2008). Current detailed information on their distribution within Nunavut is lacking. Killer Whales tend to be seen inshore during the spring and summer, likely searching for prey such as seals (Leatherwood et al., 1976) and juvenile bowhead whales (Finley, 2001). Information regarding use of offshore habitat by killer whales is lacking. Inuit are reporting increases in killer whale presence within coastal Nunavut waters. Killer whales are not actively hunted by the peoples of Nunavut. Killer whale distribution and range is shown in Figure 27.

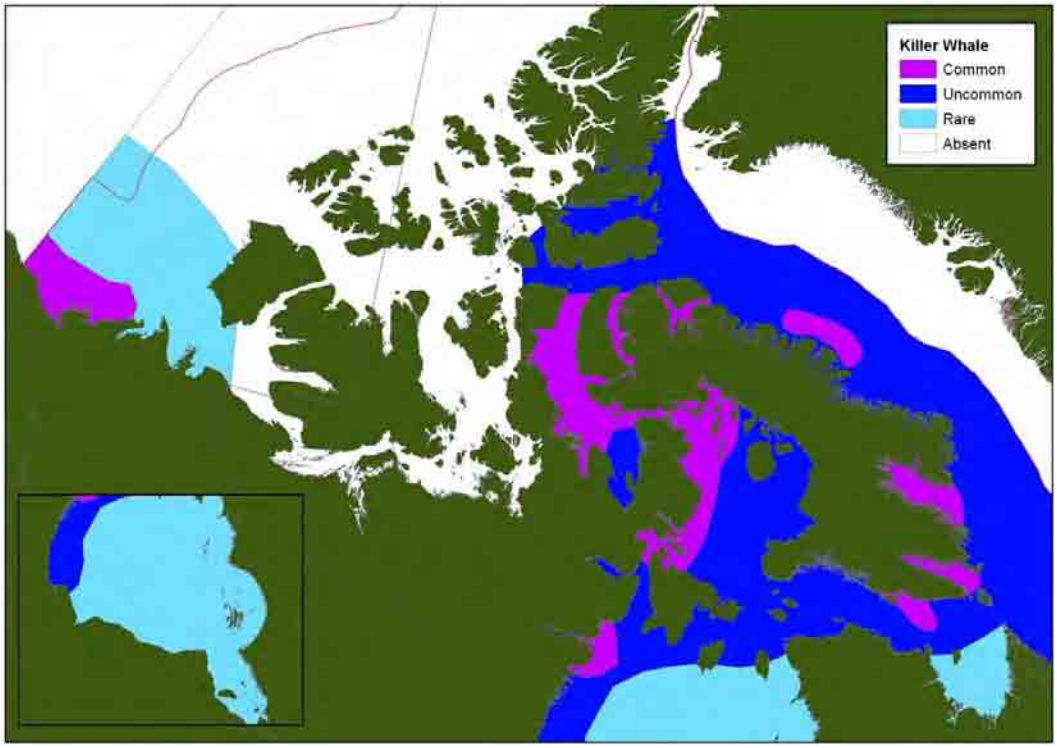

Figure 27. Distribution of Killer Whale (*Orcinus orca*) in the Canadian Arctic (Stephenson and Hartwig 2010)

4.6.2 Beluga Whale (*Delphinapterus leucas*)

Beluga whales (*Delphinapterus leucas*) are circumpolar in distribution. In the summer, it can be found in the warm shallow bays and estuaries of large rivers, whereas in the fall (mid-September) it migrates south to over-winter amongst the pack ice, in leads and polynyas, where open water provides access to air (Doidge and Finley, 1993; DFO 2002; NAMMCO, 2005). Their general distribution and range is shown in Figure 28. The highest concentrations of Beluga Whales in the Canadian Arctic waters are found in Hudson Bay especially in the Nelson River area in summer (Stephenson and Hartwig

2010). This population is called the Western Hudson Bay population (WHB) and they migrate to the Hudson Strait area in winter (Stephenson and Hartwig 2010).There is also an Eastern Hudson Bay population (EHB) that summer around the Nastapoka River of eastern Quebec (Stephenson and Hartwig 2010). In general, Beluga over-winter in highly productive areas like Baffin Bay, Hudson Strait and Davis Strait (Stephenson and Hartwig. 2010.), (DFO 2010), (Hammill and Lesage 2009, Hammill et al. 2009), (Gosselin et al. 2009). Both SARA and COSEWIC (2004) have identified that the Cumberland Sound beluga population with a "Threatened" status and the Eastern Hudson Bay Beluga population assigned a status of "Special Concern". Their distributions are shown in Figure 29.

Due to the beluga's summertime preference for shallow warm estuarine waters, it is unlikely that it would be encountered offshore at this time where the majority of the seismic activity will take place. Beluga is harvested by members of the Nunavut community on a year round basis (Table 7).

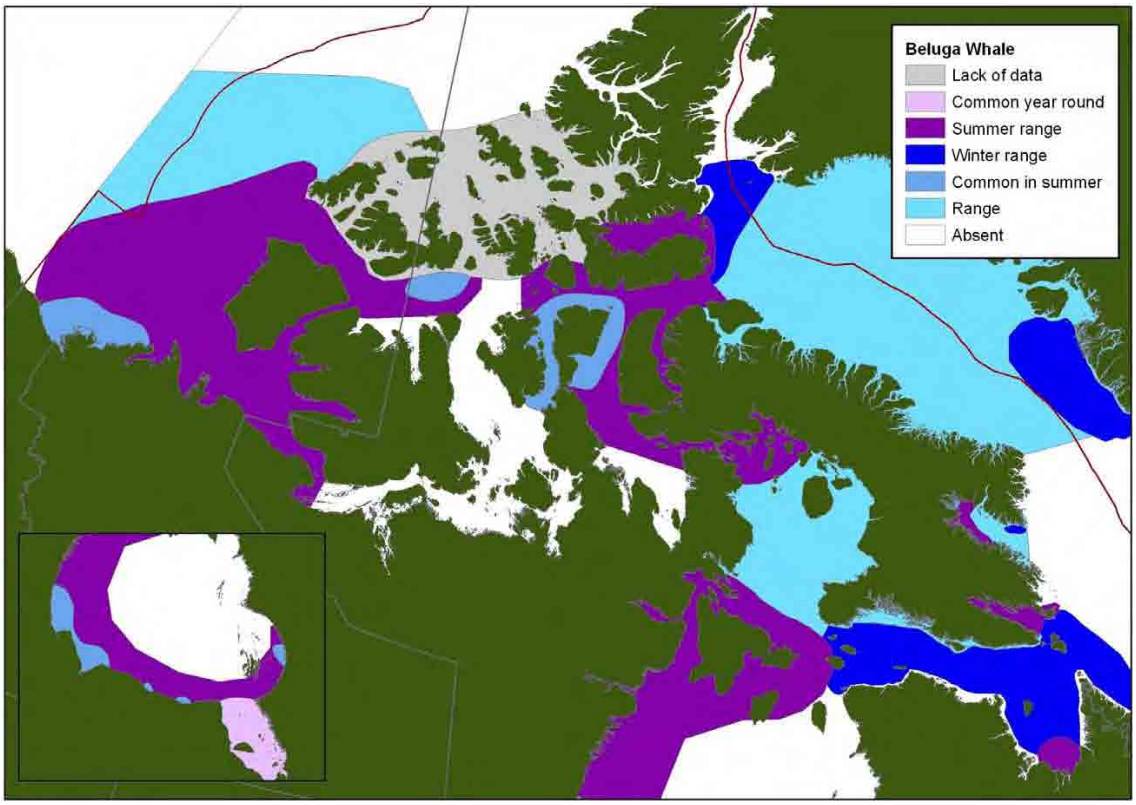

Figure 28. Distribution of Beluga Whale (*Delphinapterus leucas*) in the Canadian Arctic. (Stephenson and Hartwig 2010)

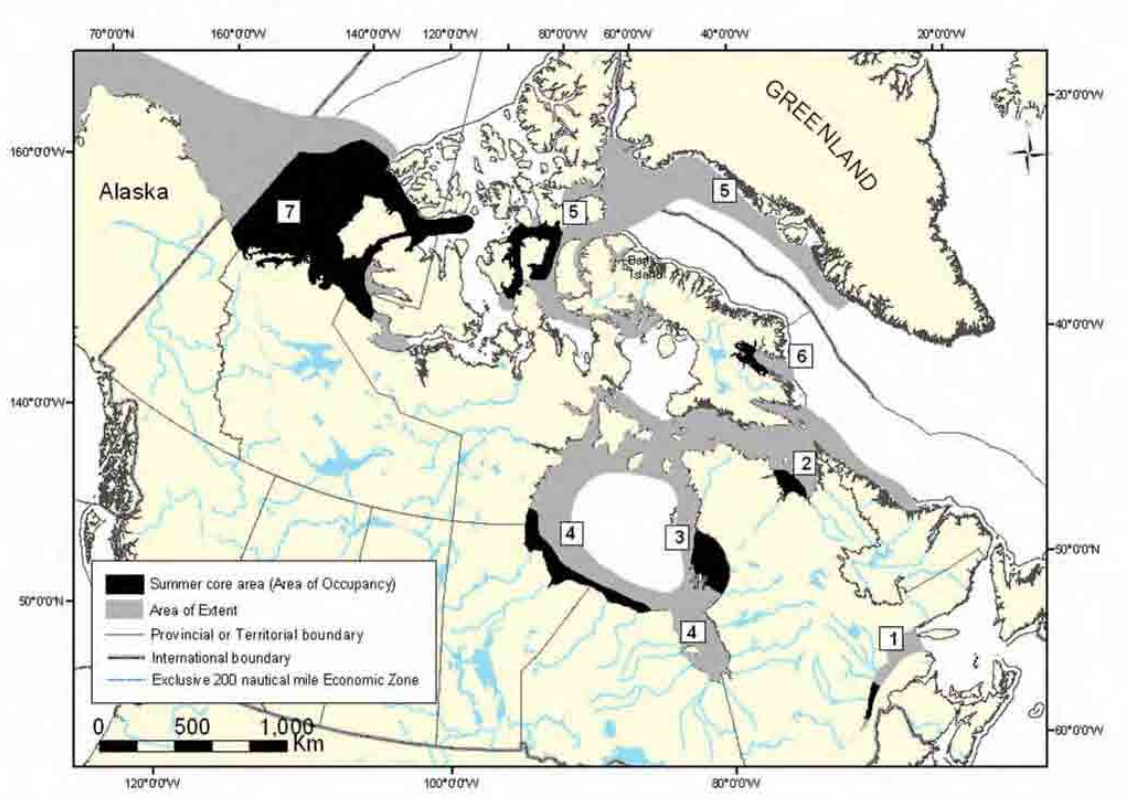

Figure 29. Location of Canadian Beluga Populations: (1) St. Lawrence Estuary population (2) Ungava Bay population (3) Eastern Hudson Bay population (4) Western Hudson Bay population (5) Eastern High Arctic – Baffin Bay population (6) Cumberland Sound population (7) Eastern Beaufort Sea population (COSEWIC 2004).

4.6.3 Narwhal (*Monodon monoceros*)

The narwhal, *Monodon monoceros*, is a toothed whale and its distribution and range in the Canadian Arctic is shown in Figure 30. The Narwhal also is common in coastal areas (Figure 31 and Figure 32) (COSEWIC, 2004). Most animals are believed to over-winter in Baffin Bay, Davis Strait, and Hudson Strait. When the pack ice breaks up in Davis Strait these whales move up the leads into Pond Inlet and Lancaster Sound. (Mansfield et al. 1975).

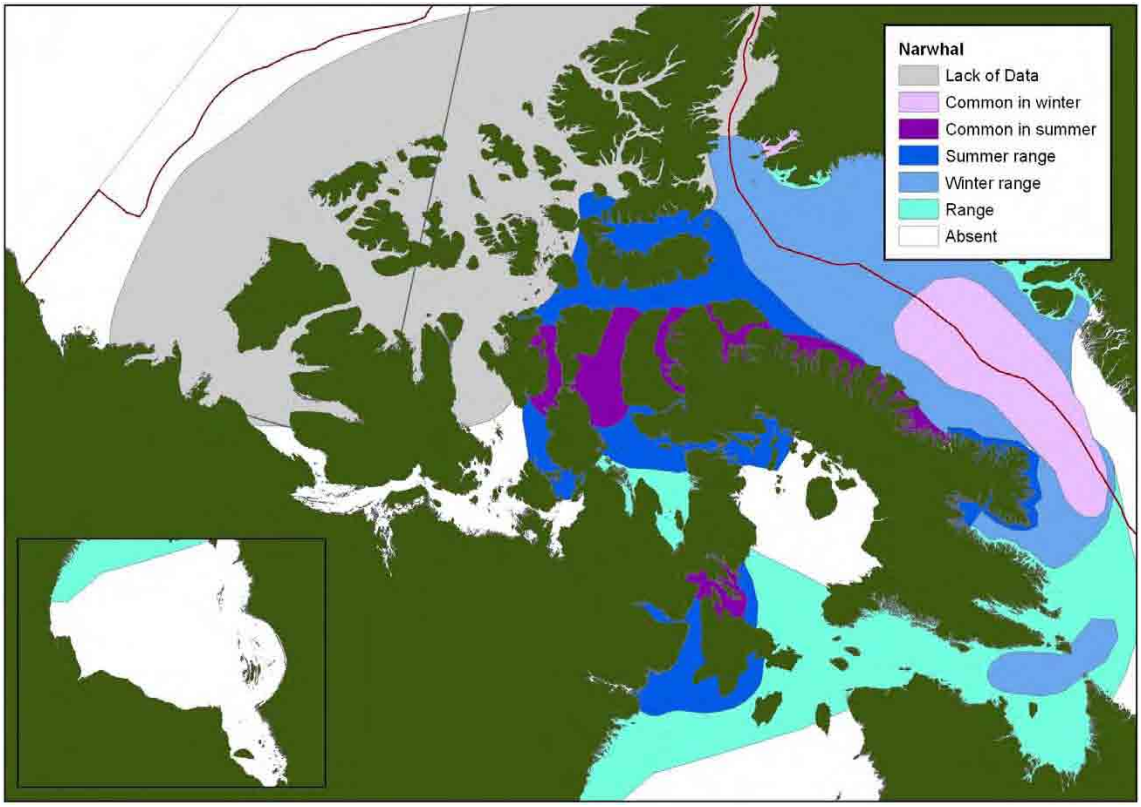

Figure 30. Distribution of Narwhal (*Monodon monoceros*) in the Canadian Arctic. (Stephenson and Hartwig 2010)

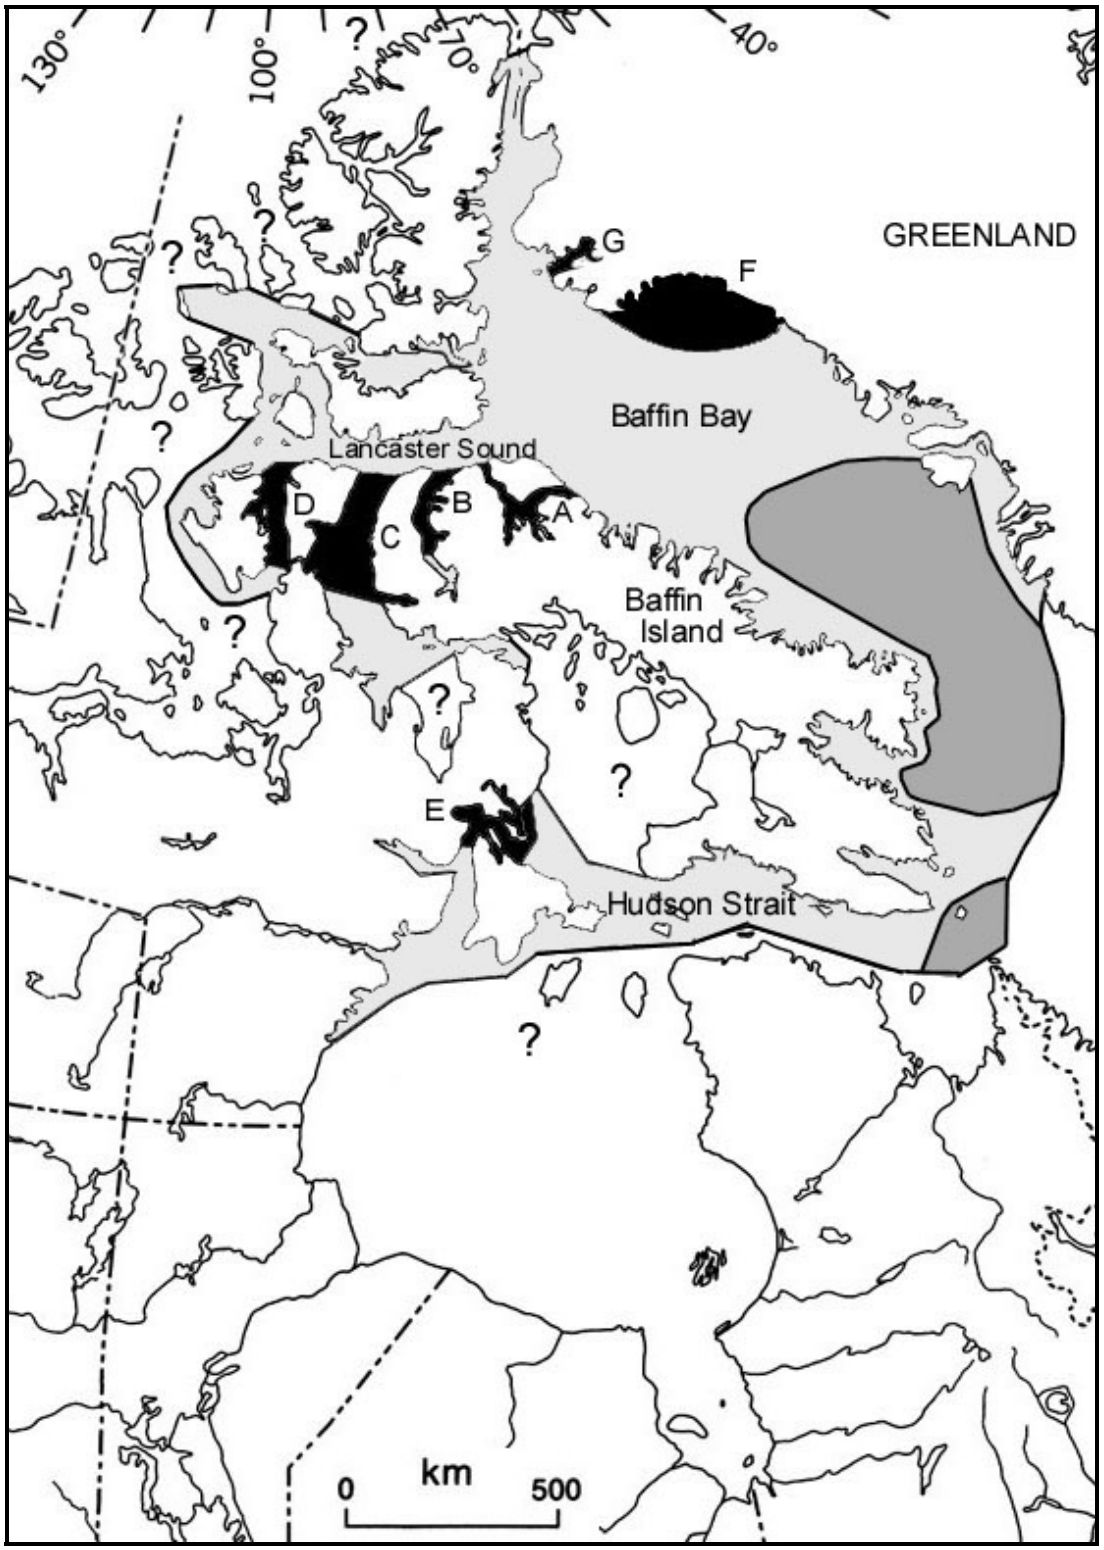

Figure 31. Narwhal summer concentrations in solid black include: A. Eclipse Sound/Navy Board Inlet, B. Admiralty Inlet, C. Prince Regent Inlet,D. Peel Sound, E. Foxe Channel, F. Melville Bay, and G. Inglefield Bredning. Wintering concentrations are shown in medium grey and known range in pale grey. Question marks indicate areas where the extent of the narwhal's distribution is uncertain. (Stephenson and Hartwig 2010).

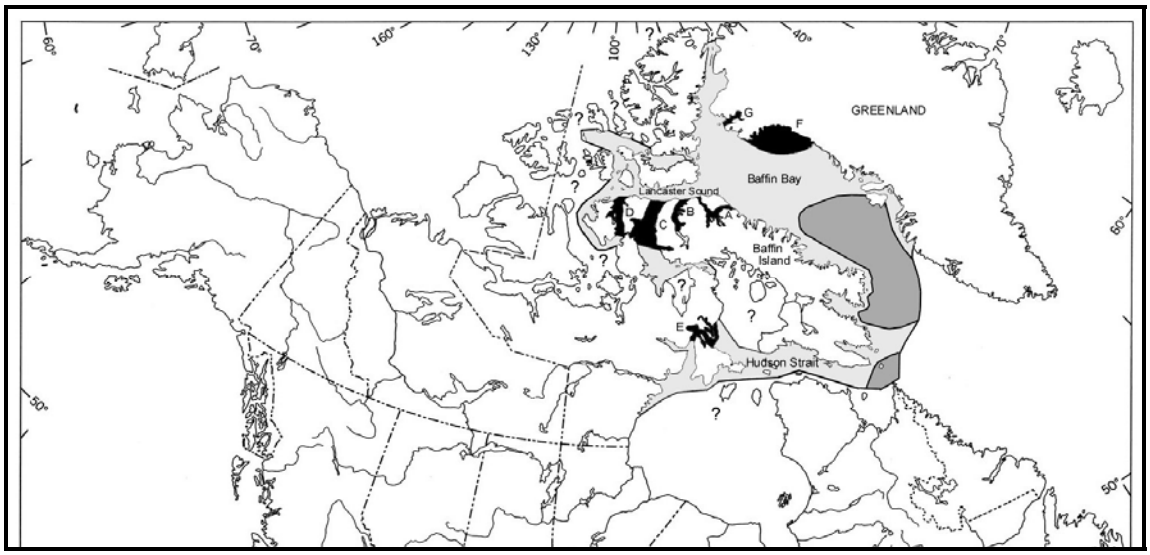

Figure 32. Distribution of Narwhals in Northern Canada

Summer concentrations in are shown in solid black, wintering concentrations in medium grey, and known range in pale grey (COSEWIC, 2004).

Narwhal research in Nunavut waters is conducted primarily by the Department of Fisheries and Oceans. Studies on summer and fall movements of narwhals, as determined through satellite telemetry, suggested that Narwhals showed a preference for deep fjords and for the continental slope (1,000-1,500 m) along eastern Baffin Island Figure 33 (Dietz et al., 2001, Dietz and Heide-Jørgensen, 1995). Within Nunavut narwhal are hunted from May through September Table 9, Priest and Usher (2004). COSEWIC (2005) and SARA have identified that Narwhal, in the Canadian Eastern Arctic are of “Special Concern” with respect to their population stability.

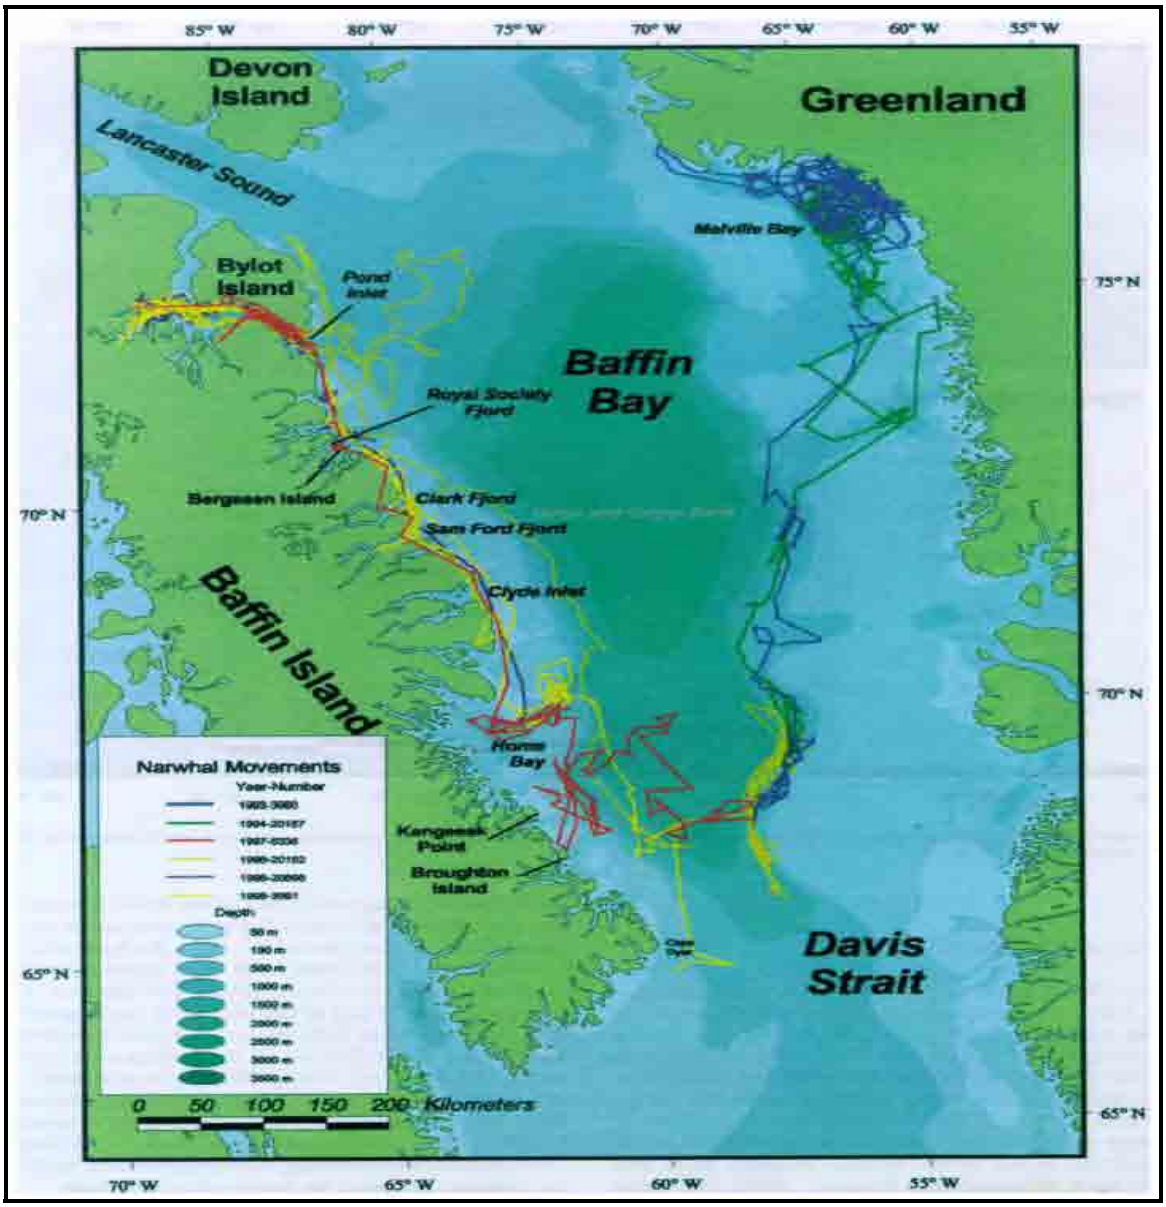

Figure 33. Map of Narwhal Movements (Dietz et al., 2001)

4.6.4 Bowhead whale (*Balaena mysticetus*)

The bowhead, *Balaena mysticetus* (or Greenland right whale), was once common and abundant in the region (Leatherwood et al., 1976, COSEWIC 2005). The present general distribution/range is shown in Figure 34. This whale is often associated with the edge of the pack ice and moves closer to shore during the summer months (MacLaren 1977 1978a and 1978b; Moshenko 2003). Both SARA and COSEWIC (2005) have identified that both the Hudson Bay/Foxe Basin and Davis Strait /Baffin Bay population of Bowhead whale populations are “Threatened”. Seasonal distribution of this species as well as general ranges are presented in Figure 34 to Figure 39. Inuit TEK for this species is shown in Figure 40.

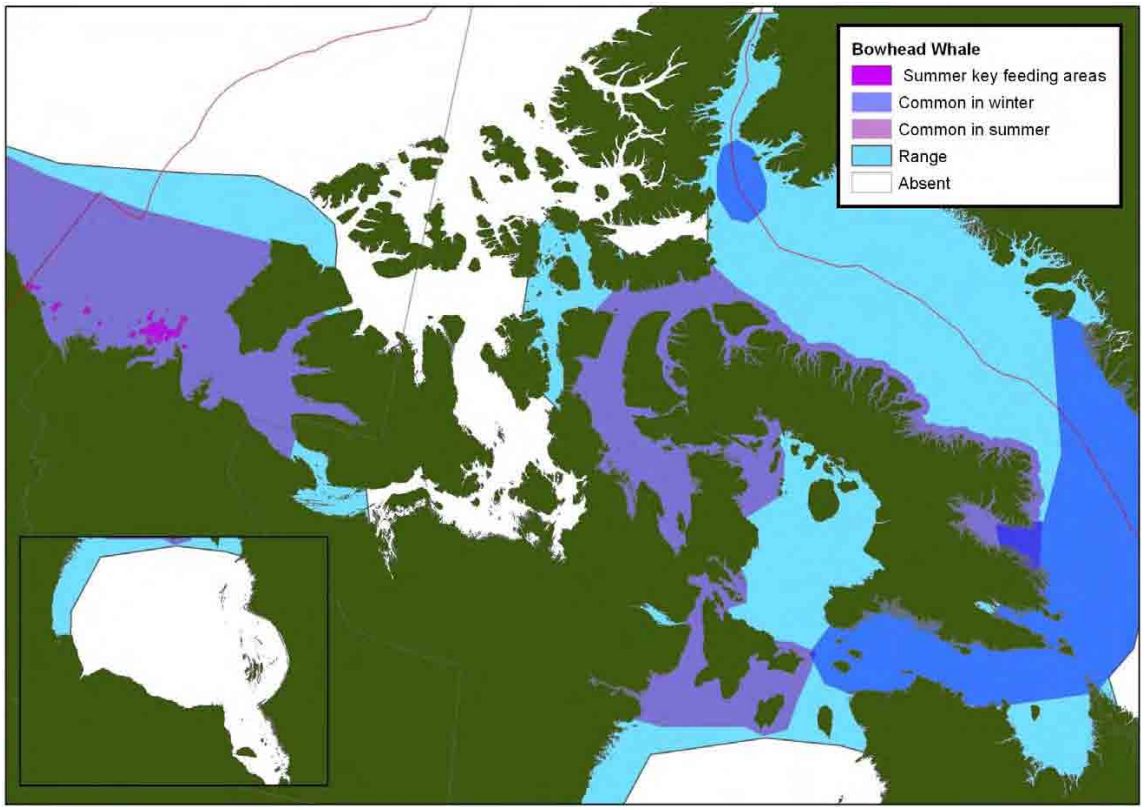

Figure 34. Distribution of Bowhead Whale (*Balaena mysticetus*) in the Canadian Arctic. (Stephenson and Hartwig 2010)

In the high Canadian Arctic the understanding of bowhead movements within Baffin Bay and Davis Strait has been refined through the use of satellite-linked telemetry combined with habitat modeling techniques (Dueck et al. 2006, Husky 2008). Remote telemetry studies show that bowheads migrate large distances throughout the eastern Canadian Arctic from both Foxe Basin and Baffin Bay regions Figure 35, COSEWIC 2005, Cosens et al. 2006). Some satellite tracking information of bowheads in the proposed study area is summarized in Figure 36 (Heide-Jorgensen et al, 2003, COSEWIC 2005). This figure demonstrates that migrating bowheads may be encountered in offshore regions and perhaps with higher likelihood east of Bylot Island, although the bowhead habitat near Bylot Island will likely not be impacted by the project due to temporal differences (i.e. bowhead's use this habitat primarily in June and surveys here will be conducted later in the season). Bowheads using the east coast of Baffin Island in August and September may however be encountered during this period. Bowheads using the offshore habitat due east of the Clyde Inlet region will also be potentially encountered during seismic surveys. Migration within Davis Strait of whales tagged in west Greenland indicated a general westward movement across Davis Strait using leads in the ice in the spring to the Lancaster Sound and northern Baffin Island region in the summer (Dueck et al., 2006). Tagged whales in Baffin Bay and Davis Strait migrated southward along the east coast of Baffin Island using bays and fiords in late summer and early fall (Dueck et al., 2006). Please note that the number of whales tagged was only 19 in Canadian and 25 in Greenlandic waters.

Habitat modeling of known bowhead locations with environmental and geographic variables suggests that at least one discrete area of highly suitable bowhead habitat may exist along the coastal region (within approximately 30 kilometres from shore) of the eastern shore of Baffin Island. Positions from satellite-tagged bowheads have been recorded in this coastal area during the summer (Dueck et al., 2006).

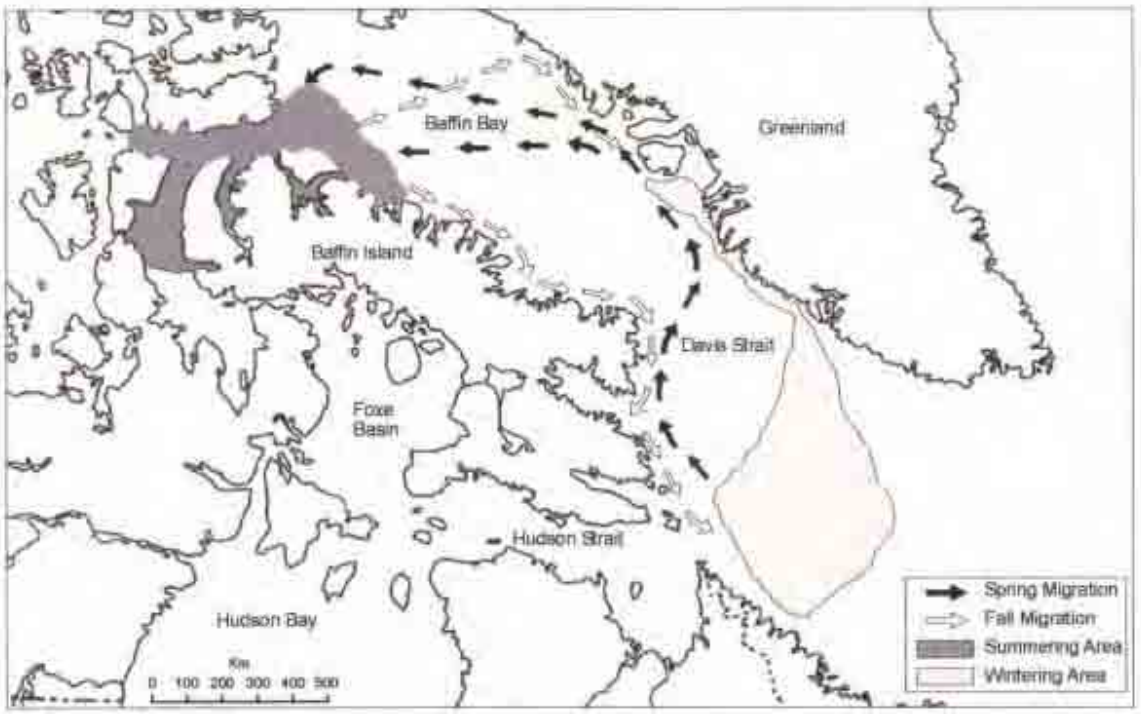

Figure 35. . Generalized seasonal occurrence and migration corridor for the Davis Strait-Baffin Bay population of bowhead whales (COSEWIC 2005).

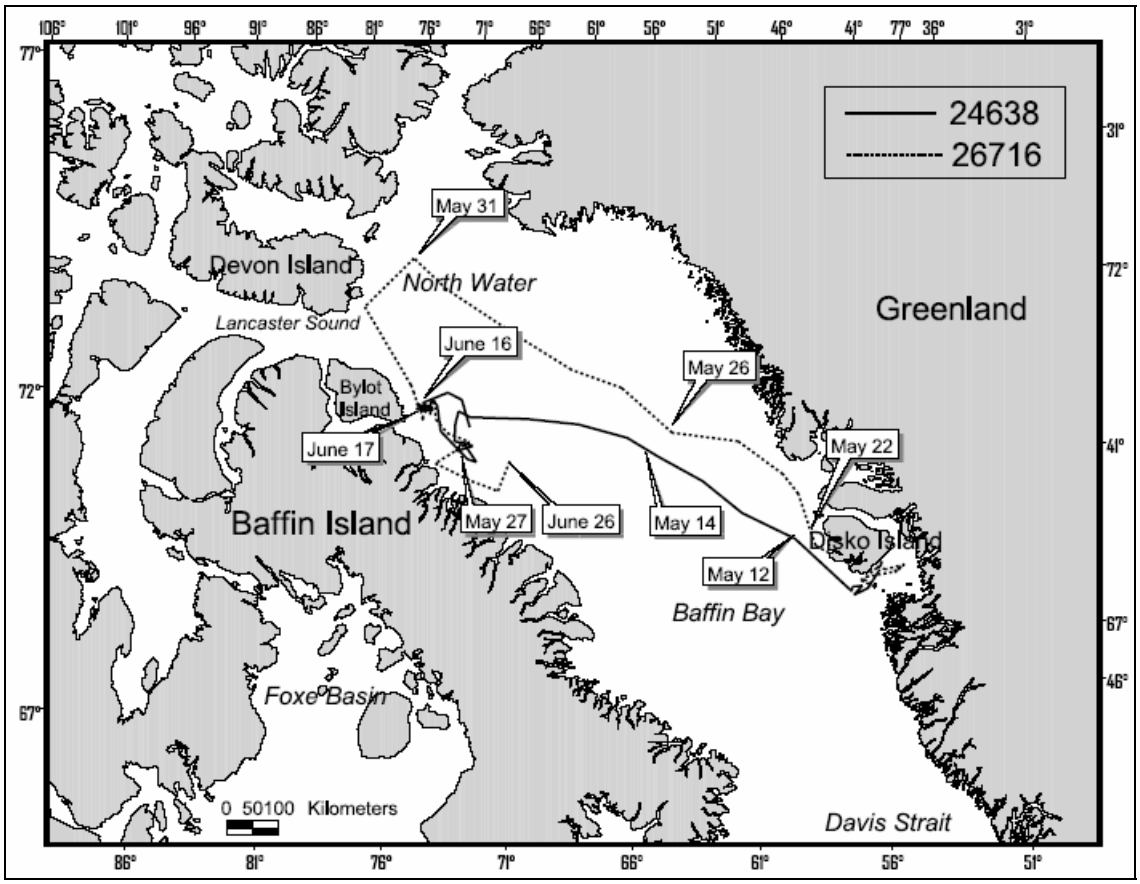

Figure 36. Satellite Tracks of Bowhead Whales (Heide-Jorgensen et al., 2003)

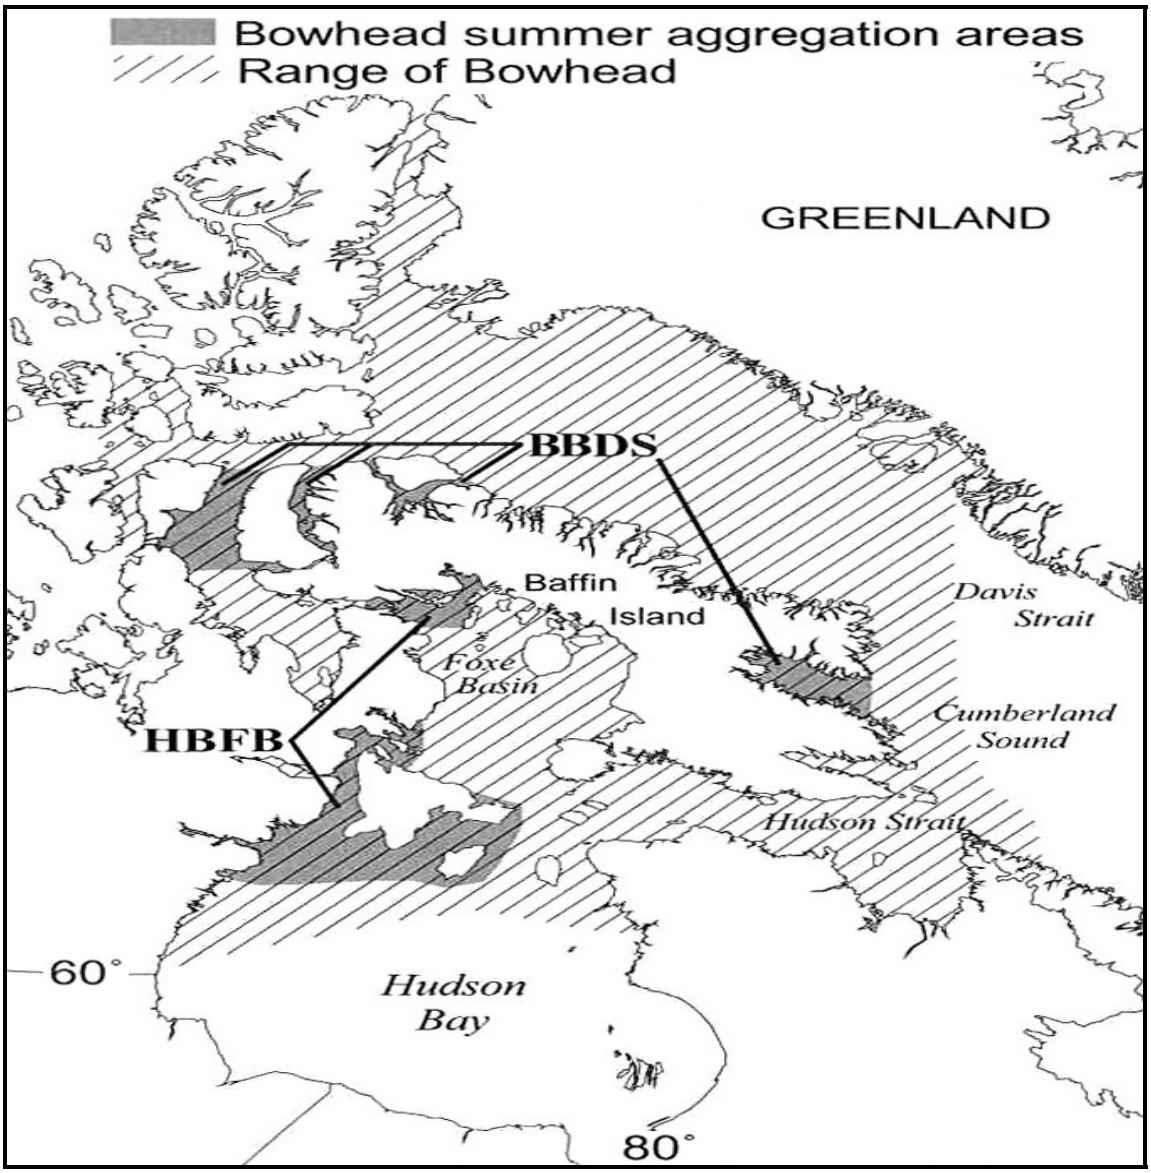

Figure 37. Ranges and summer aggregation areas of the two putative stocks of bowhead whales in eastern Canadian Arctic waters (modified from Reeves and Cosens 2003:284). BBDS = Baffin Bay-Davis Strait stock; HBFB = Hudson Bay-Foxe Basin stock) (Stephenson and Hartwig 2010).

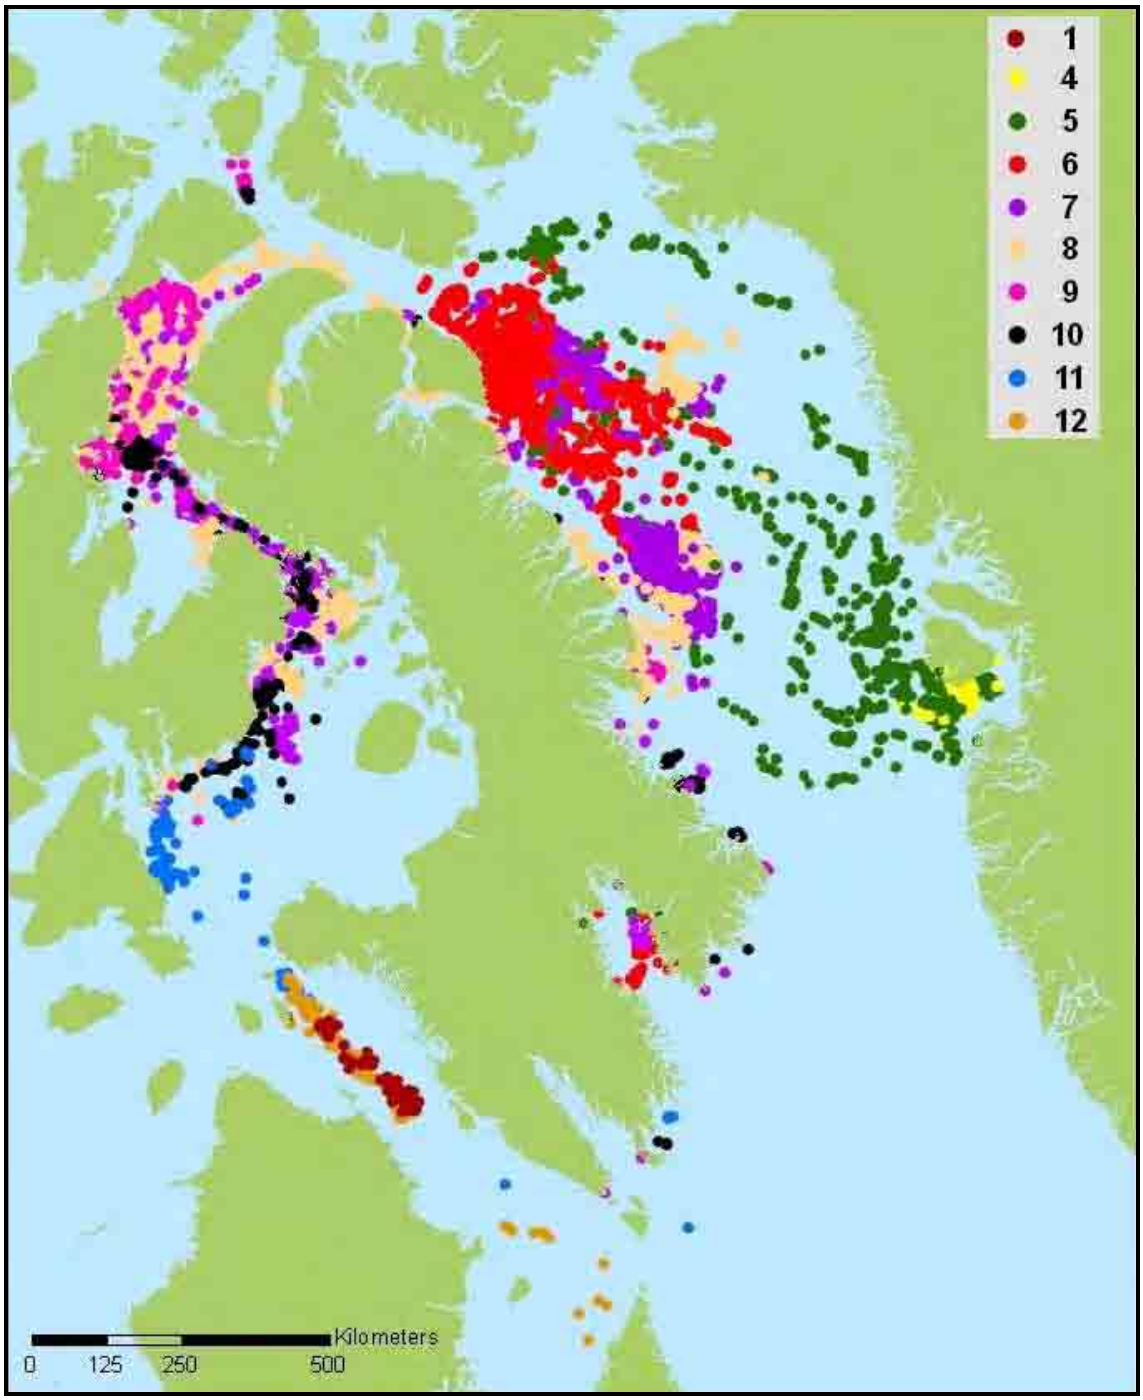

Figure 38. Seasonal Distribution of Bowhead Whale Locations Based on satellite-linked telemetry; results for whales tagged in Canada (n = ~19) and west Greenland (n = ~25); numbers for colour codes refer to calendar month (Dueck et al., 2006 including Mads Peter Heide Jørgensen's unpublished data).

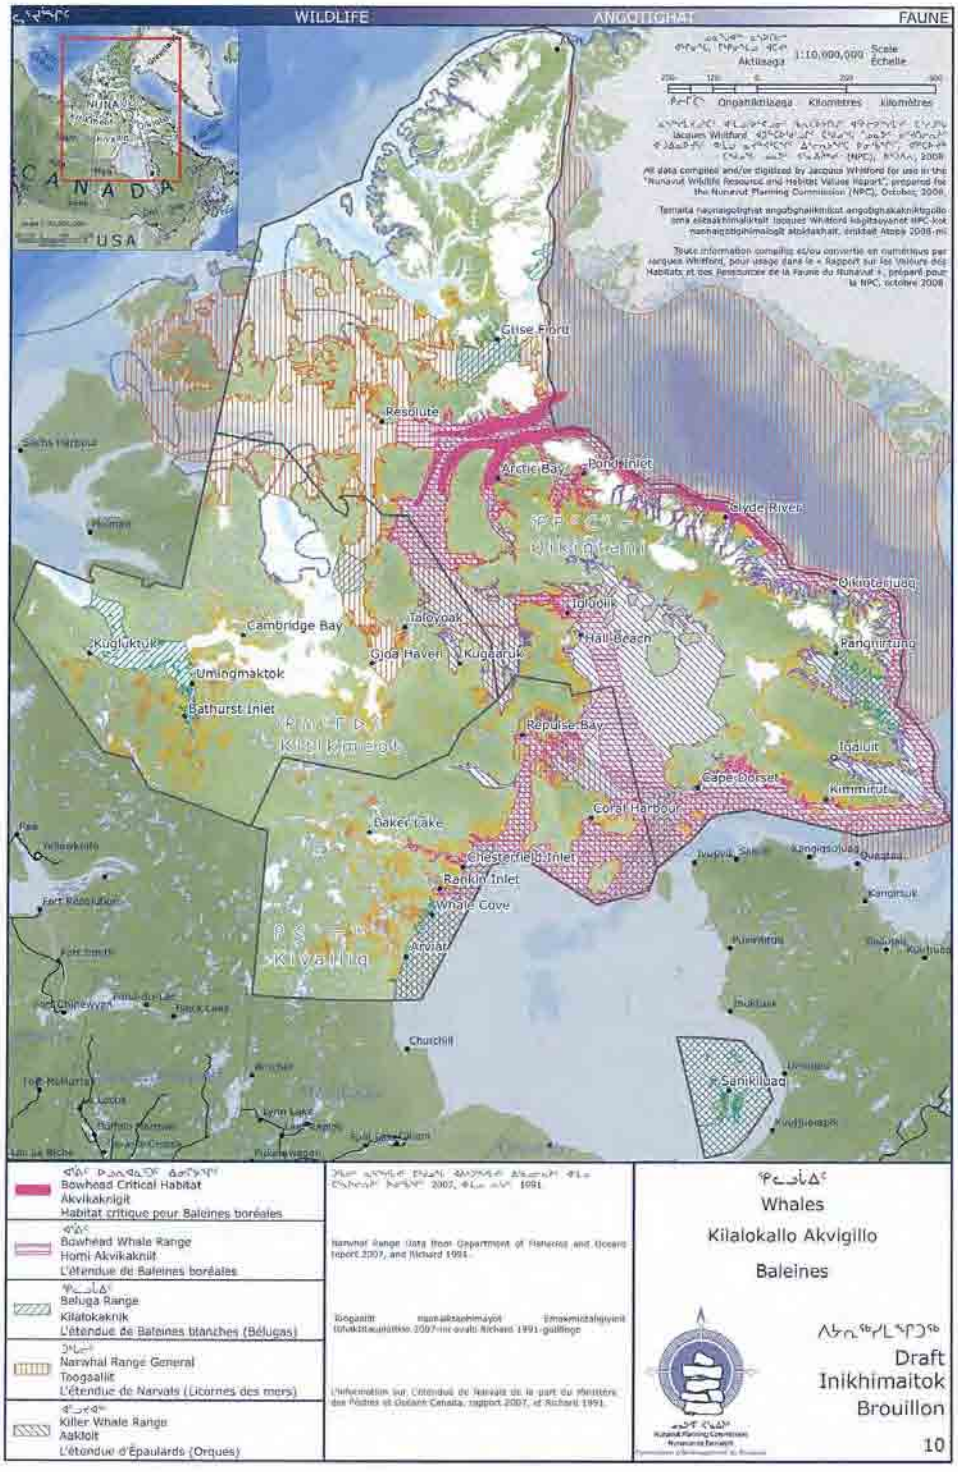

Figure 39. Whale distributions

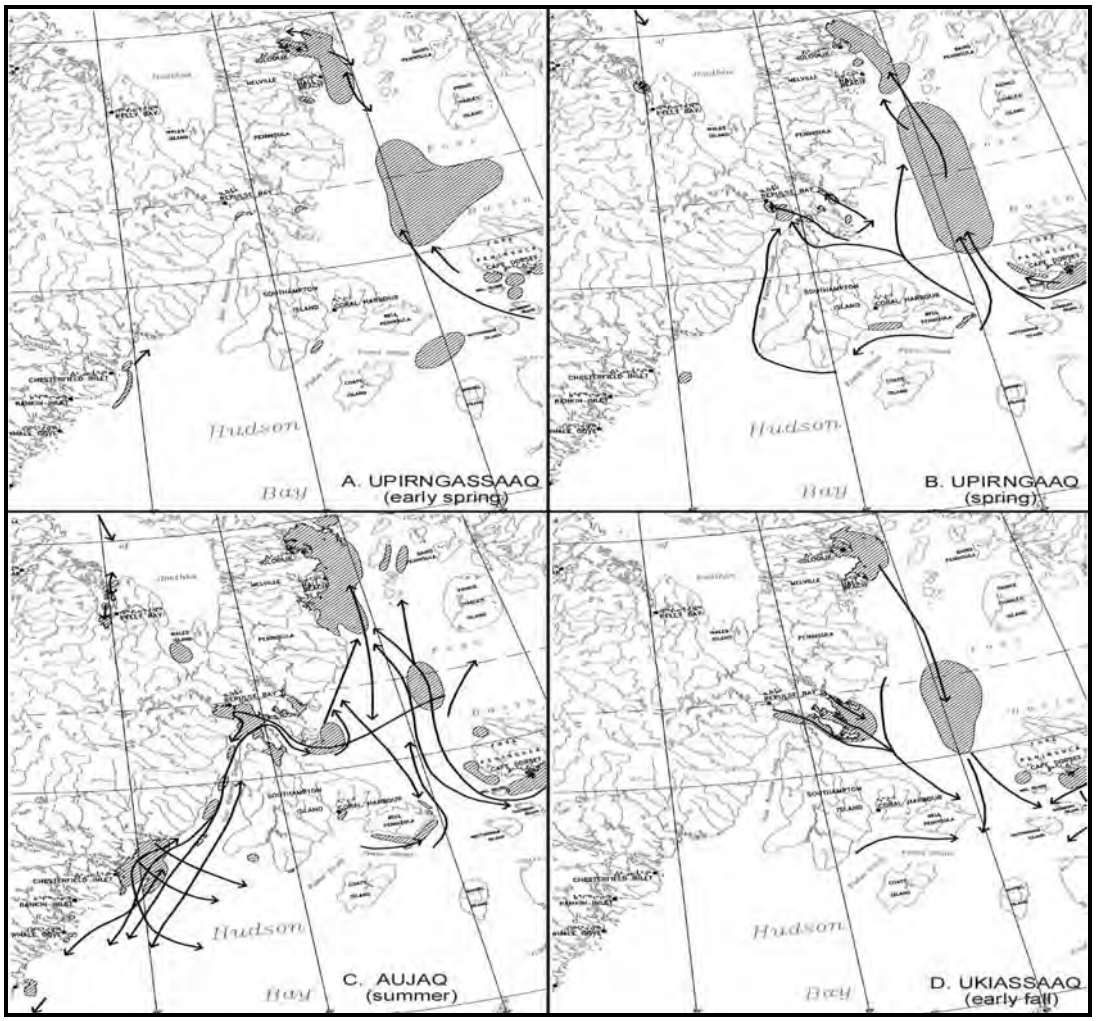

Figure 40. Inuit knowledge of the seasonal movements of bowheads in Hudson Bay and Foxe Basin from A. UPIRNGASSAAQ (early spring) to D. UKIASSAAQ (early fall) (adapted from NWMB 2000) (Stephenson and Hartwig 2010).

4.6.5 Harbour Porpoise (*Phocoena phocoena*)

There are three sub-populations of harbour porpoise (*Phocoena phocoena*) in Atlantic Canadian waters. There is the Newfoundland and Labrador, the Gulf of St. Lawrence and the Bay of Fundy-Gulf of Maine population. Harbour porpoise are most commonly occurring in association with continental shelves, where they frequent bays and harbours. No dedicated harbour porpoise surveys have been conducted in the study area (COSEWIC 2006). It is assumed that harbour porpoise winter along the coast of the US, as far south as North Carolina, and very little is known about the movements of harbour porpoise sub-populations in the far north (COSEWIC 2006, Figure 41). As they are not commonly found in deep oceanic waters, it is unlikely that they will be measurably influenced by the project if they are seen at all. SARA and COSEWIC (2006) have classified the Northwest Atlantic population of Harbour porpoise as a population that is of “Special Concern”.

Figure 41. Distribution of harbour porpoises in eastern Canada. Dashed lines indicate approximate delineations of the three subpopulations. (COSEWIC 2006).

4.6.6 Polar Bear (*Ursus maritimus*)

Polar bears (*Ursus maritimus*) are year-round inhabitants of the Arctic. There general arrange and distribution is shown in

Figure 43. Two populations overlap within the study area; the Baffin Bay population and the Davis Strait population (Figure 42,

Figure 43, Figure 45 COSEWIC, 2002/2008). By in large the most important factor influencing the seasonal distribution pattern as well as movement is the seasonal variation in sea-ice condition (Stephenson and Hartwig 2010).

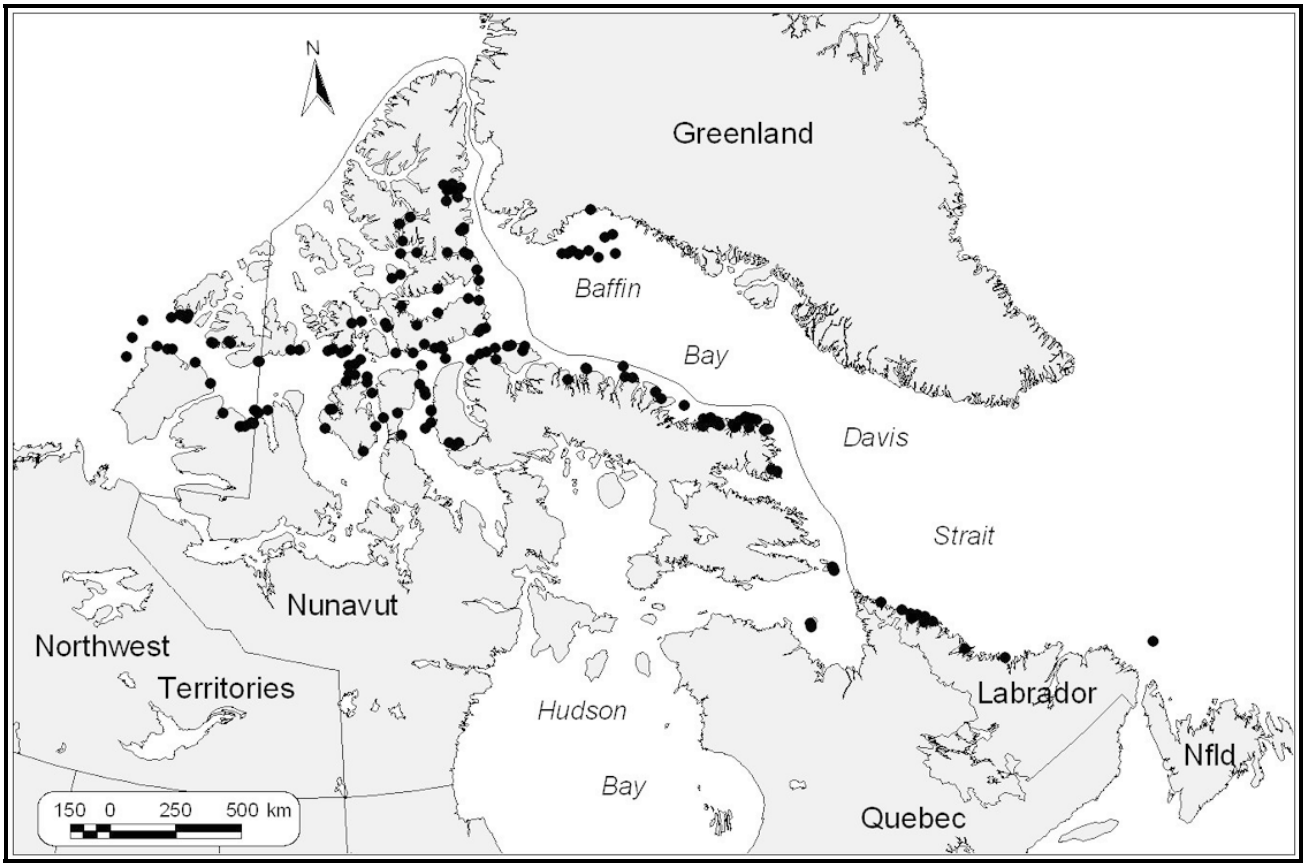

Figure 42. Initial Capture Locations for Adult Female Polar Bears Fitted with Satellite Radio Collars
(Taylor et al. 2001)

Polar bears are often associated with flow edges and pack ice where they can forage. For ringed seals, their main prey. Polar bears readily traverse this pack ice and can travel over large distances (Taylor et al., 2001). When large swells from autumn storms begin to wash over the remaining ice, individuals within Baffin Bay retreat from the offshore pack ice to live on land in late August and early September (Taylor et. al., 2001). In Davis Strait, most bears seek land as the ice retreats in early July (Taylor et. al., 2001). Both of these populations spend the open-water season on Bylot Island and the windward shores of Baffin Island (Taylor et al., 2001). SARA and COSEWIC (2008) have determined that the Polar Bear is a species of "Special Concern". A distribution/range map for Nunavut based on traditional ecological knowledge is presented in
Figure **43**. As the seismic program will take place offshore in the summer and fall when there is no pack ice over the proposed seismic survey area, it is unlikely that polar bears will be encountered.

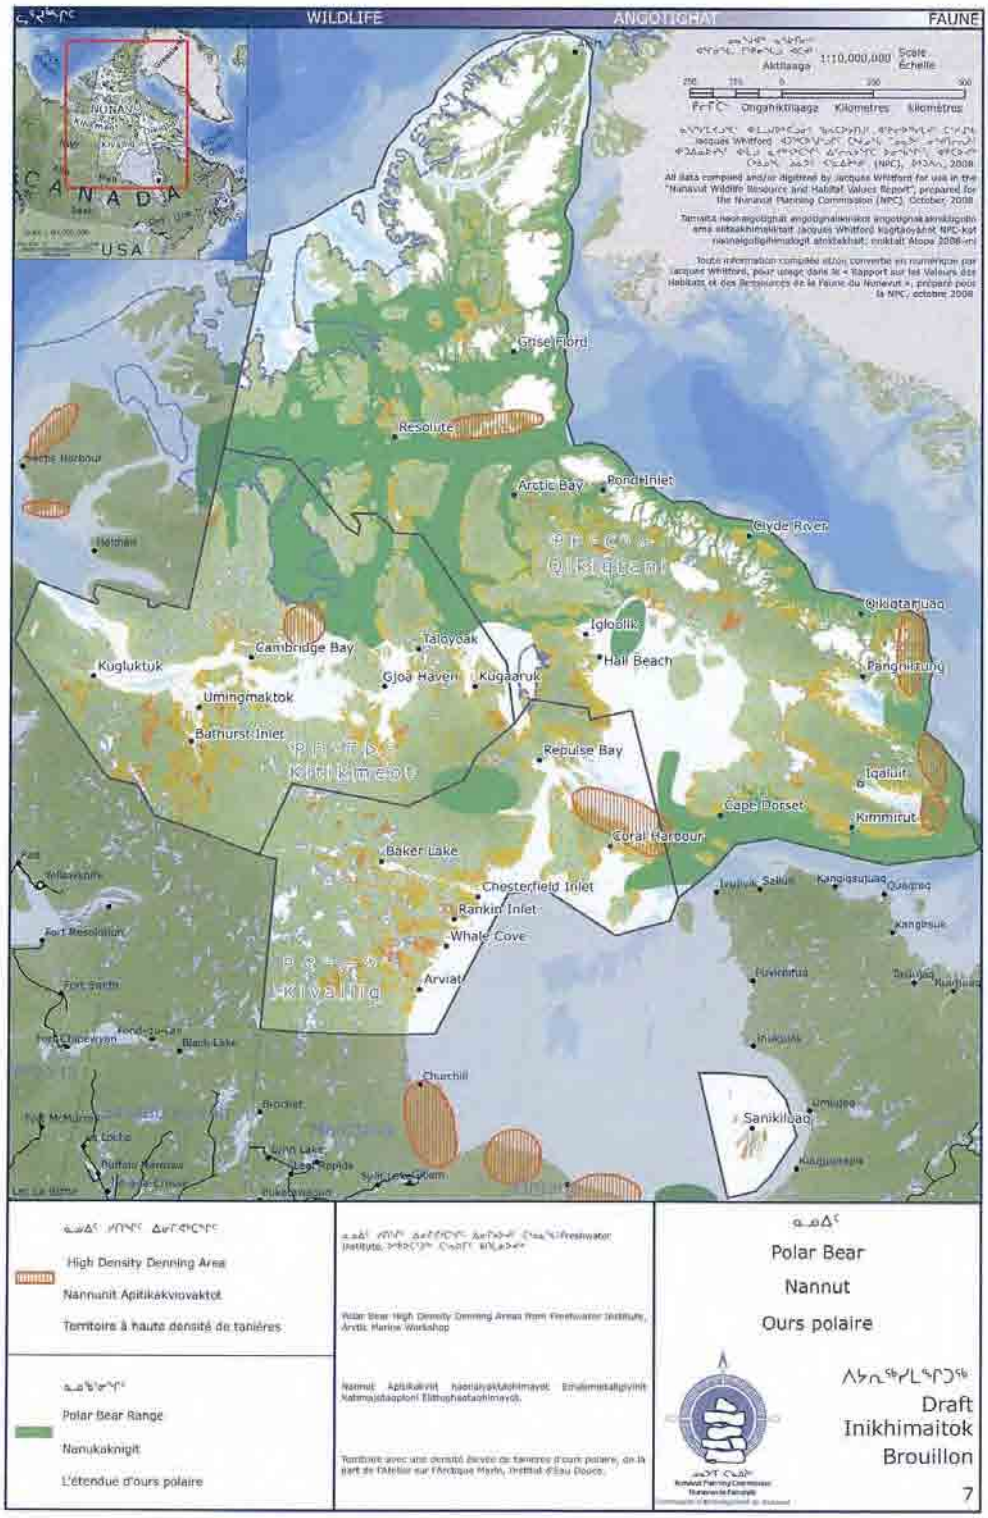

Figure 43. Polar Bear distribution according to Inuit traditional ecological knowledge.

.

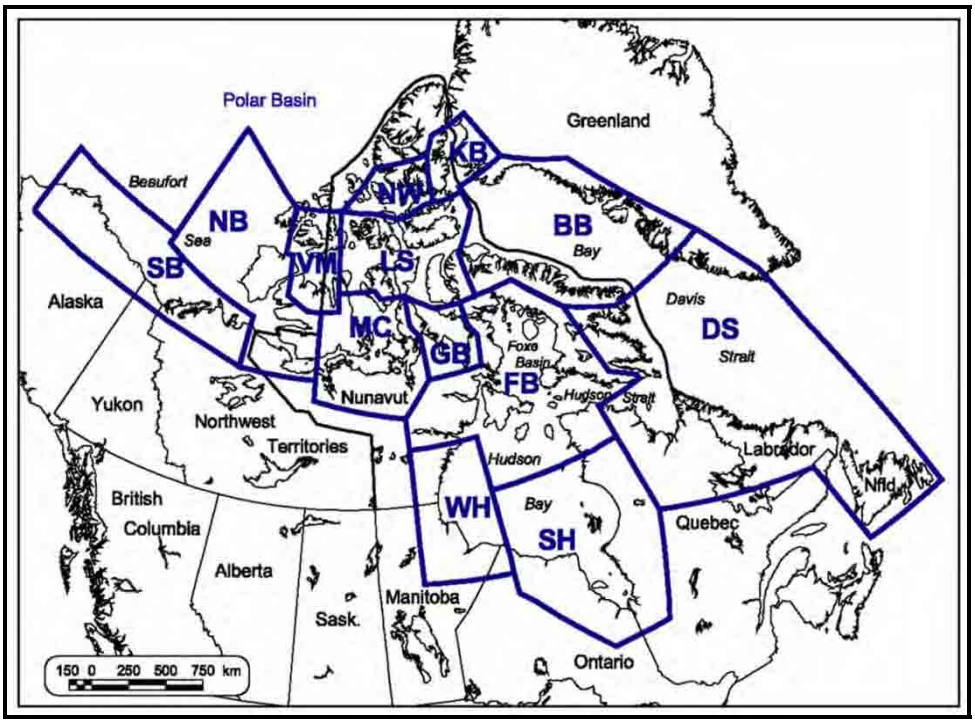

Figure 44. Initial Capture Locations for Adult Female Polar Bears Fitted with Satellite Radio Collars (Taylor et al. 2001)

Figure 44 shows a map of the boundaries of Canadian Polar Bear Populations (1996).These boundaries have been determined from analyses of movements of bears in mark-recapture studies, returns of tags from bears killed by Inuk hunters, and the movements of adult females with satellite radio collars (Taylor et al., 2001; reproduced from COSEWIC, 2008).

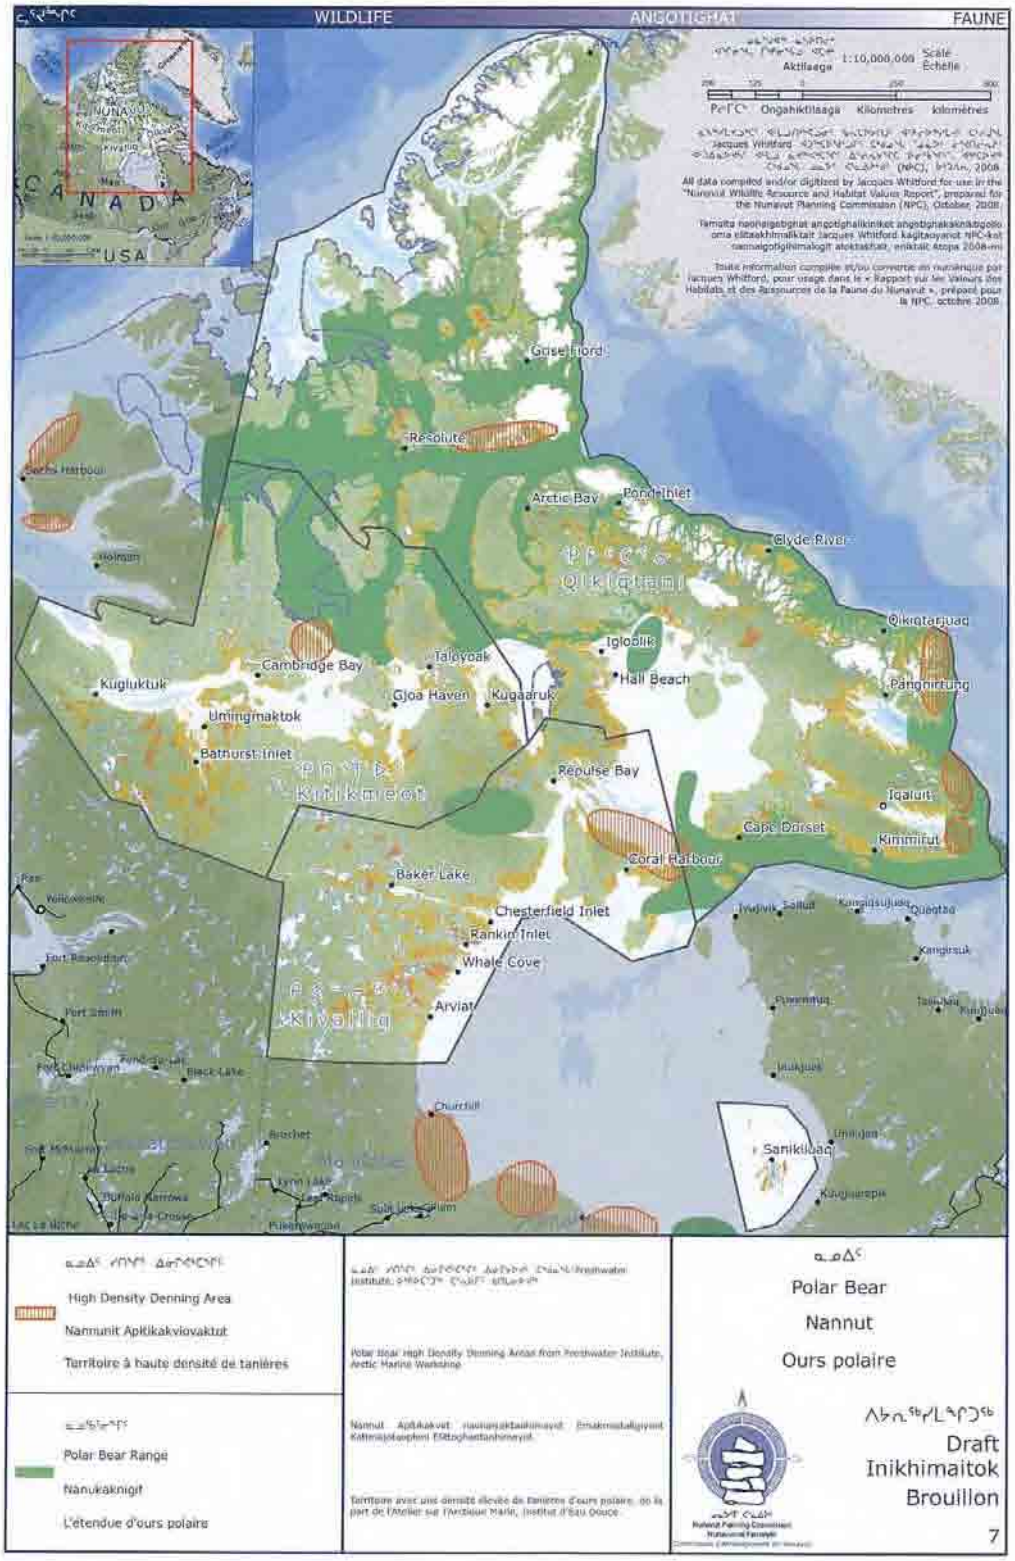

Figure 45. Map Polar Bear distribution according to Inuit traditional ecological knowledge.

4.6.7 Marine Reptiles

There is only one marine reptile that may be encountered in the North Atlantic, the leatherback sea turtle (*Dermochelys coriacea)*. The leatherback has been recorded off Labrador by Bleakney (1965), and Goff and Lein (1988) determined from survey studies that this species is found off Labrador and may occur further north during July to September when seawater temperatures are seasonally high. This species has been relegated to a Species at Risk category of Endangered. Figure 46 illustrates the distribution of the leatherback turtle in Canadian waters (COSEWIC, 2001). Note that the extent of the leatherback sea turtle is not in the vicinity of the presently proposed survey area; therefore, no further discussion is presented.

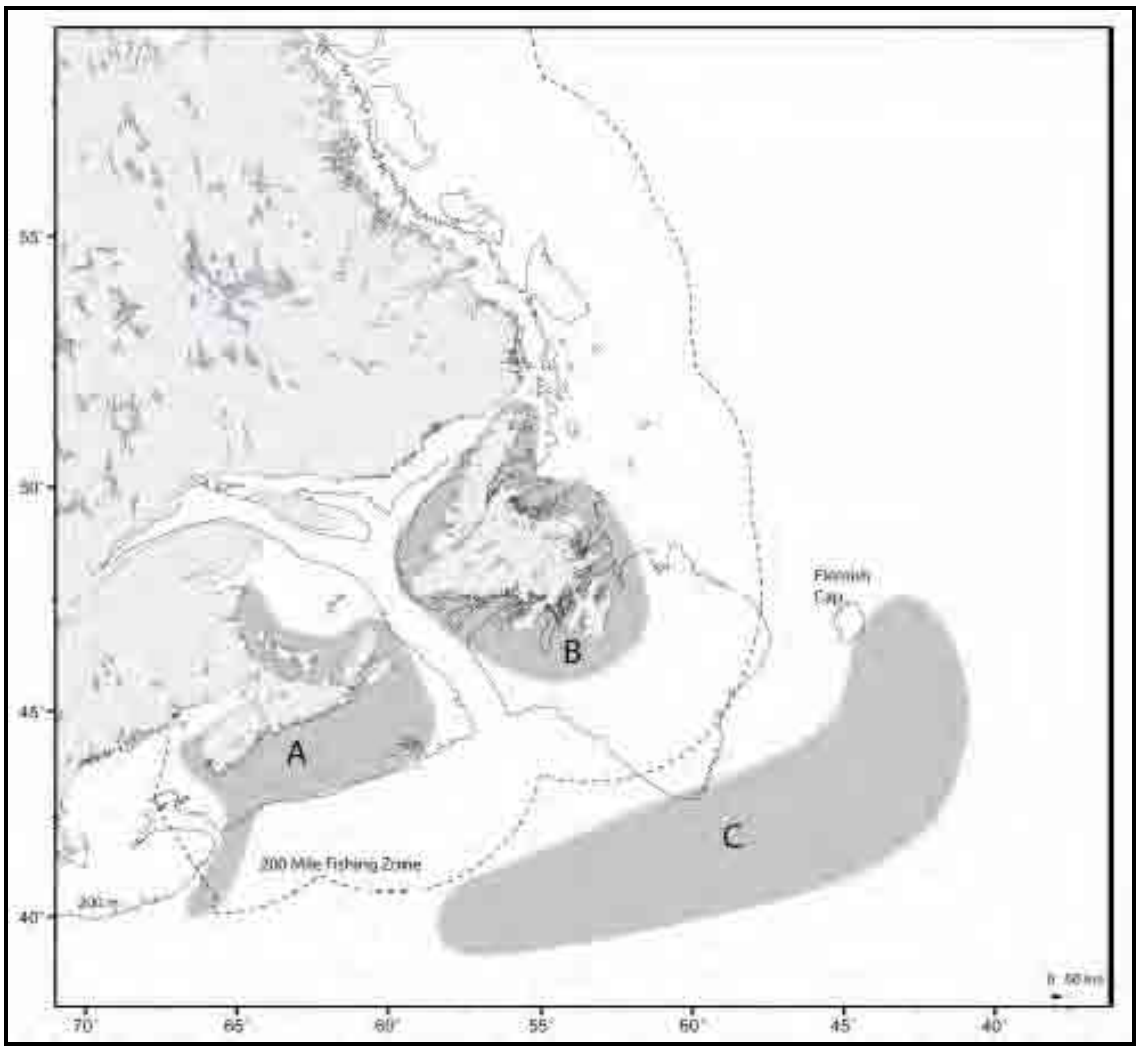

Figure 46. Distribution of the Leatherback Turtle in Canadian Waters
(COSEWIC, 2001)

4.7 SPECIES AT RISK

Canada's Species at Risk Act (SARA) received Royal Assent on December 12th, 2002, and took full effect on June 1st, 2004 when the prohibitions and enforcement provisions came into effect. The overall goal of the SARA is to prevent wildlife species from extinction and to help in the recovery of species at risk, and will confer legal standing on the species listed by the Committee on the Status of Endangered Wildlife in Canada (COSEWIC). The Act also builds on other laws and programs, such as the Fisheries Act, the National Parks Act, the Migratory Birds Convention Act, and the North American Waterfowl Management Plan, as well as other legislation and programs.

The Act incorporates measures to protect species and their environment and prohibits the killing, harming, harassing, capturing, or taking of species protected under the Act (Schedule 1) which are listed as threatened, endangered, or extirpated, and the destruction of their residences. Once identified, critical habitat will be protected by conservation agreements, provincial or territorial legislation, or federal prohibitions. No critical habitat has yet been identified under SARA.

Initially, 233 species were included on Schedule 1 (Wildlife Species at Risk) of the Act, under the designations of Extirpated, Endangered, Threatened, and Special Concern.

In January 2005, the Schedules were revised and 73 additional species were added to Schedule 1 (SOR 2005-14). Some of the species added to Schedule 1 had been on Schedules 2 and 3, and others were added from the current COSEWIC listings. As with the original 233 species, recovery strategies and action plans must be developed for SARA species listed as Endangered or Threatened, and management plans must be established for those of Special Concern.

The SARA species that might be within or adjacent to the north project are listed in the following **Table 8** and discussed in sections that follow.

Table 8 also identifies "Species at Risk" that could be found within the Study area during the scheduled survey period.

Table 8. Month with Species

Species	Risk Category	Comment	Source
Marine Mammals			
Beluga whale (Eastern Hudson Bay Population)	Endangered	Not in survey area during seismic activity	COSEWIC (2004a)
Bowhead Whale (Davis Strait Population)	Threatened	Late fall wintering area north tip off Labrador , unlikely to be in study area	COSEWIC (2005)
Narwhal	Special Concern	Potentially in study area	COSEWIC (2004b)
Harbour Porpoise	Special Concern	Potentially in study	COSEWIC (2006a)

		area	
Atlantic Walrus	Special Concern	Potentially in study area and coastal	COSEWIC (2006b)
Polar Bear	Special Concern	Potentially in study area	COSEWIC (2002)
Birds			
Ivory Gull	Endangerd	Potentially in study area	COSEWIC (2006c)
Marine Fish	See note below		
NOTE: According to the SARA Registry, there are no marine fish within the Nunavut Region that have a SARA or COSEWIC status rating.			

4.7.1 Cetaceans and Pinnipeds

The Bowhead whale (East Canada – West Greenland) was listed as a Threatened species until April of 2009. It is presently listed as a species of Special Concern. Although the population was severely depleted by whaling, recent trends indicate an increase in their numbers, thus downgrading it to special concern status (COSEWIC, 2009).

The Narwhal is presently listed as a species of Special Concern. The Baffin Bay population appears to be large, however, this population could be affected if hunting in Greenland is not effectively managed (COSEWIC, 2004a).

The Atlantic Walrus has been assigned the status of Special Concern, as the total size of the Northern Hudson Bay – Davis Strait population could be as small as 4,000 to 6,000 individuals. The population's ability to sustain minimum current removals is questionable, as some portion of this population is hunted in Greenland waters (COSEWIC, 2006b).

Additional marine mammal species that have the potential to occur, but are not likely to be encountered during the survey, include the Blue and North Atlantic Right Whale, with SARA Endangered status designation, nor are the Nova Scotia populations of the Northern Bottlenose Dolphin. SARA has assigned the Fin Whale to a status of Special Concern, but these species are not known in the area where seismic activity will occur. COSEWIC has assigned Special Concern to other marine mammals, including the Polar Bear and Sowerby's Beaked Whale, however, as survey activity will commence at a distance of 12 nautical miles offshore (from the shoreline and Outer Land Fast Ice Zone), the survey will unlikely measurably impact those species that may be in the region.

The mitigation measures proposed for this seismic survey will ensure that any potential interaction with marine mammals of any designation is kept to a minimum. It is unlikely that any individual will be measurably impacted by the program if encountered during the survey considering the mitigation methods adopted.

4.7.2 Marine Birds

There have been no studies on the effect of seismic airgun exploration on seabirds (Davis et al., 1998), although Stemp (1985) made observations on the reactions of seabirds to seismic exploration programs in Davis Strait over three summer periods, and no distributional or mortality effects were detected.

The Ivory Gull is considered a species of Special Concern by SARA. This species spends summers in the extremely high Arctic (Ellesmere Island area) and winters in the Baffin Bay and the northern Davis Strait region. This species is not expected to be in the region at the time of the seismic survey.

4.7.3 Fish

Three wolfish species may occur in the most southern regions of the survey area. However, all species are at the limits of their northern extents in Canadian waters off the north of Labrador. It is unlikely that any individual will be measurably impacted by the seismic program.

In summary, by adopting all industry mitigation standards, as well as more stringent measures discussed below, no anticipated measurable environmental impacts are predicted on SARA species for this seismic exploratory research field program.

4.8 SENSITIVE AREAS

4.8.1 Niginganiq (*formerly Igaliqtuuq*) National Wildlife Area

The Niginganiq (*formerly Igaliqtuuq*) National Wildlife Area, near Clyde River in Isabella Bay, represents a sensitive marine area adjacent to the project area (Figure 47). This marine wildlife area extends from the coast to 12 nautical miles (approximately 22.2 kilometres, 13.8 statute miles). As the survey area does not commence until the 12 nautical mile limit, the project area does not encroach into this area. Furthermore, the closest survey line is approximately 28 kilometres from the seaward limit of this area, and approximately 60 kilometres from the entrance to Isabella Bay.

Note that a Proposed Biosphere Reserve also exists around this area, and its seaward limit is approximately defined by the limit of land-fast ice. As described in Section 3.2, only a very small portion of the survey area exists within the Outer Land Fast Ice Zone. Within this zone approximately 245 line kilometres of 2D data are proposed to be acquired, which represents approximately 2.2% of the total line kilometres for the survey (10,970 kilometres).

The mitigation measures that will be adopted during the survey will ensure minimal, if any, measurable interaction with local marine related wildlife that may be in the area at the time of the survey.

Other (terrestrial) wildlife areas / parks on the eastern coast of Baffin Island include:

- Qaqulluit National Wildlife Area (also known as Cape Searle, near Qikiqtarjuaq)
- Akpait National Wildlife Area (near Qikiqtarjuaq)
- Bylot Island Migratory Bird Sanctuary (Pond Inlet)
- Nirjutiqavvik National Wildlife Area (Grise Fiord)

The figure below illustrates the Niginganiq (*formerly Igaliqtuuq*) National Wildlife Area and Proposed Biosphere Reserve (New Parks North, 2004).

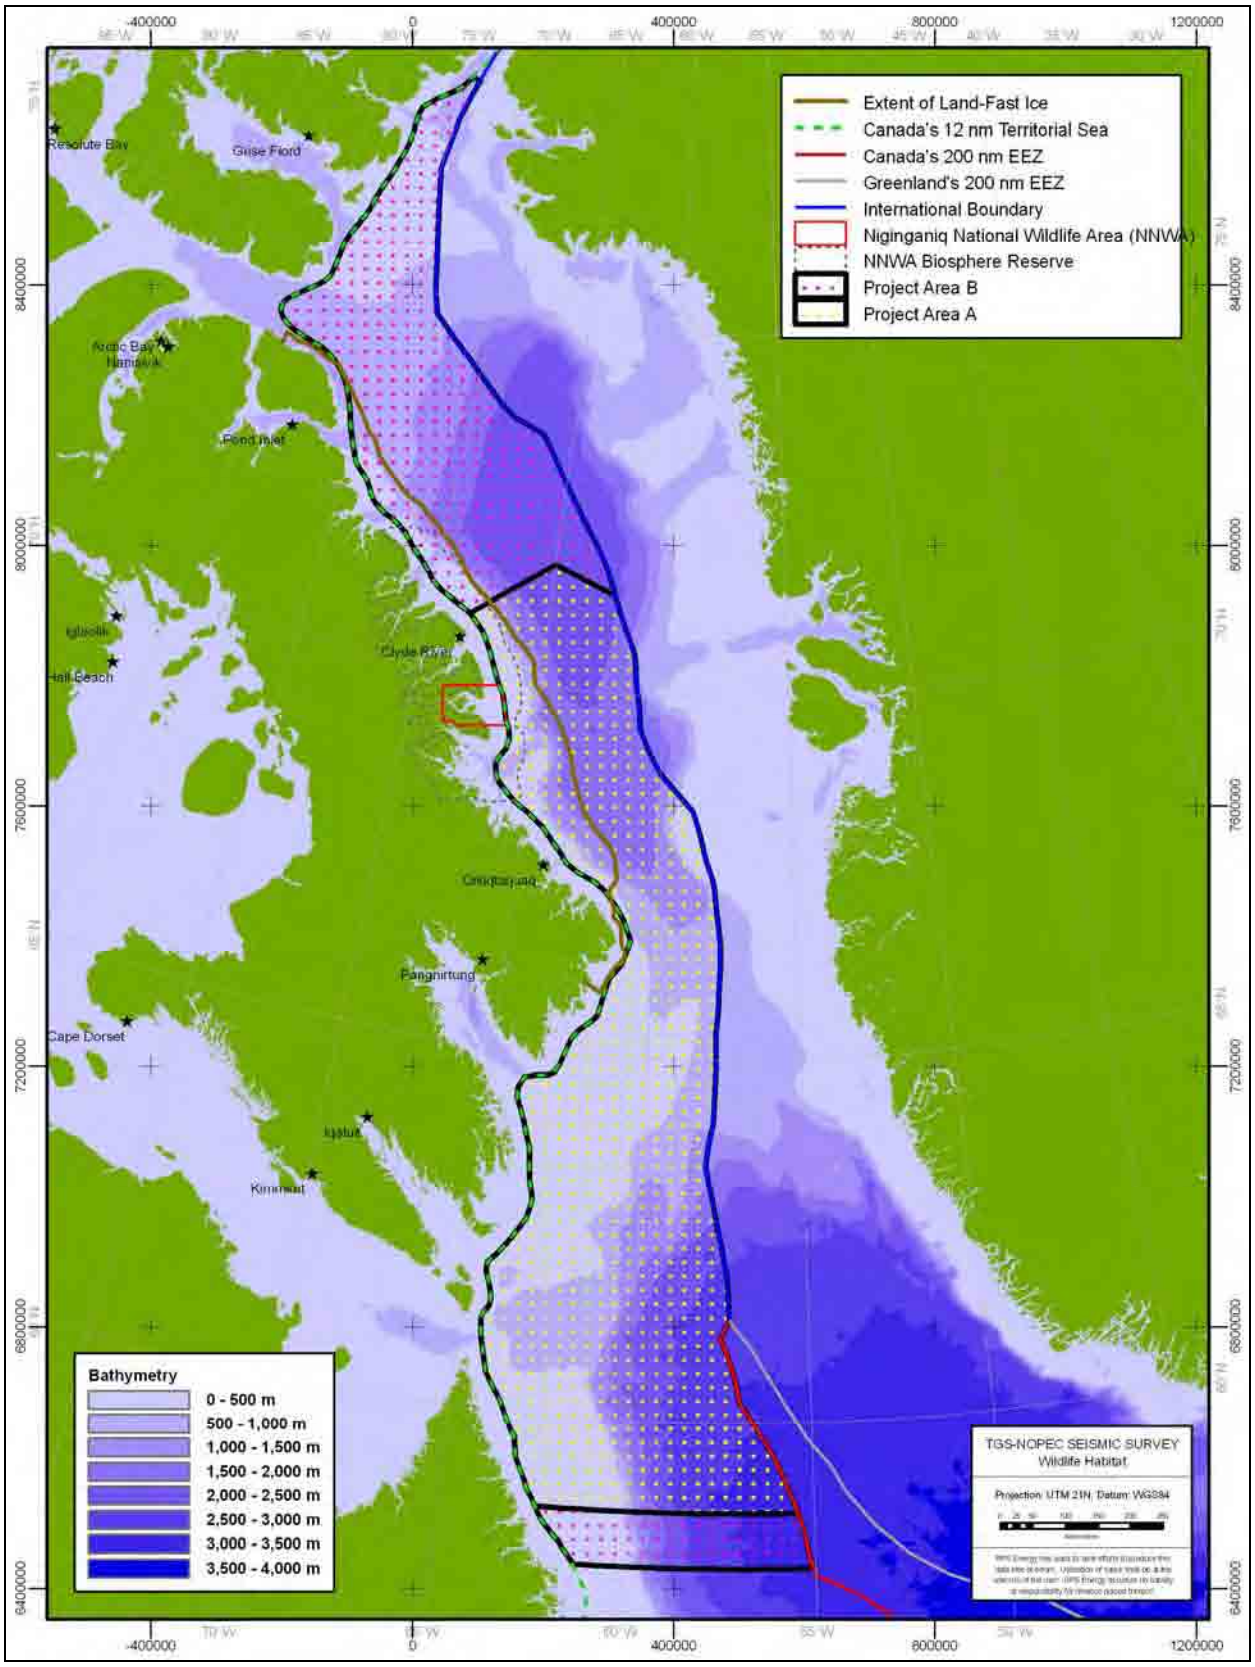

Figure 47. Niginganiq (*formerly Igaliqtuuq*) National Wildlife Area

4.8.2 Narwhal Over-Wintering Area

Since 1998, fishing effort restrictions have been in place to limit the time spent by vessels fishing for Greenland halibut (turbot) in an area identified as a narwhal over-wintering area in Davis Strait.

In April 2006, DFO Fisheries Management decided that a large portion of the narwhal over-wintering grounds should be closed to all Greenland halibut fishing. Reasons for this decision included the status of “special concern” of the narwhal that use this area, the importance of halibut in its diet during the winter, concerns over entanglement in gillnets, and the presence of deep-sea corals (see below), which may play an important role in this ecosystem (Fisheries and Oceans Canada, 2007). The closed area was described and included in the draft 2006-2008 Fisheries Management Plan NAFO SA0, and DFO is currently developing related policies (Fisheries and Oceans Canada, 2007).

The northern narwhal over-wintering area is illustrated in Figure 48, and overlap with the proposed 2011 survey lines; however, narwhals do not tend to occupy this area until November (Dietz et al., 2001; Mosbech et al., 2000). The survey will not take place in the area during this critical period; consequently, it is unlikely that narwhals will be in the area during active surveying.

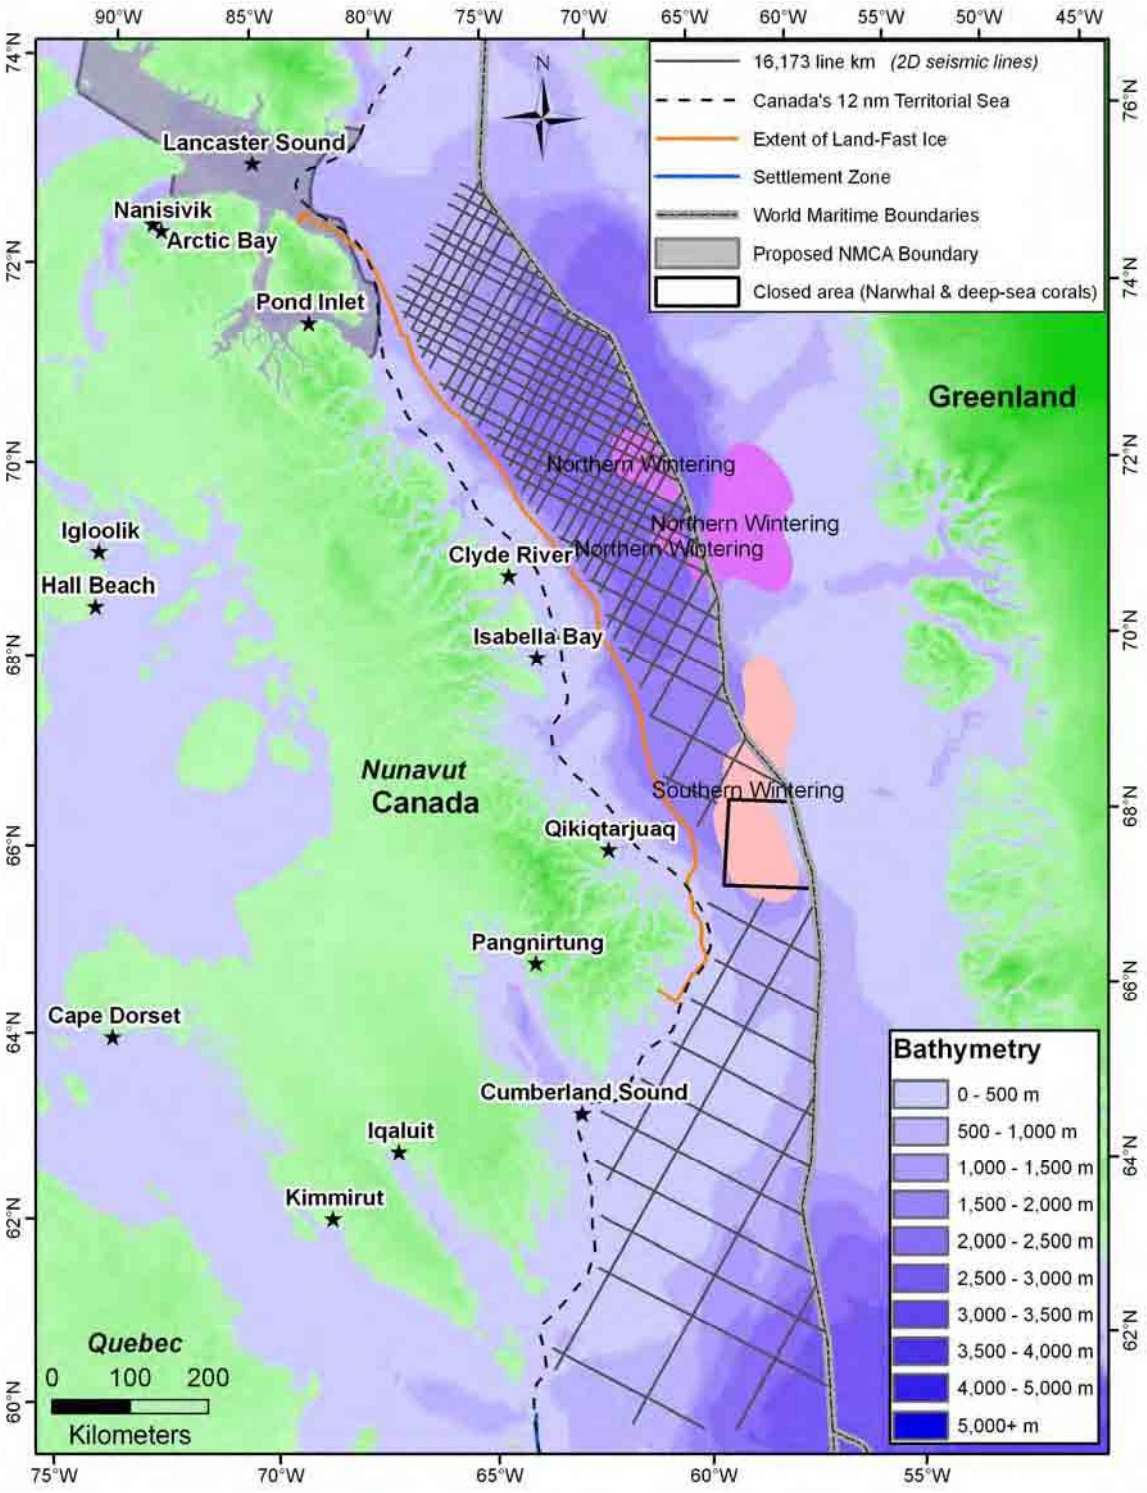

Figure 48. Location of Narwhal Over-wintering Areas Relative to the 2011 Survey

4.8.3 Deep-Sea Corals

There are more than 27 species of deep sea corals identified off the coast of Atlantic Canada but their distribution is largely unknown. The coral have been identified along the edge of the continental shelf from the Gulf of Maine to the Davis Strait by DFO fisheries observers and local fishermen (Gass and Willison 2005). A personal communication from K. MacIsaac (DFO) confirms that deep sea corals are present in Baffin Bay.

Deep-sea corals, by the nature of their physiology (i.e. having no pressure sensitive or sound detecting organs such as swim bladders and ears), are extremely unlikely to be impacted by seismic array activity. Also, the acoustic source is towed at a fixed depth (<7 metres) during seismic surveying, well above the coral that grow on the seafloor.

4.8.4 Lancaster Sound

Ottawa, Ontario, December 6, 2010 – John Baird, Canada's Environment Minister, John Duncan, Minister of Indian Affairs and Northern Development, Christian Paradis, Minister of Natural Resources, and Leona Aglukkaq, Minister of Health, all today proudly announced the Government of Canada's position on a potential future boundary for a national marine conservation area (NMCA) in Lancaster Sound, Nunavut. Today's announcement represents a key step in Canada's commitment to protect the marine waters and wildlife of Lancaster Sound, a globally-significant ecological treasure that has been referred to as the "Serengeti of the Arctic". Ministers also announced that the government will immediately begin consultations to finalize the boundary. (Reference: CP2010-01348 Government of Canada presents boundary proposal for Lancaster Sound National Marine Conservation Area), shown in Figure 50. This present survey will not encroach more than 180km from the mouth of Lancaster Sound.

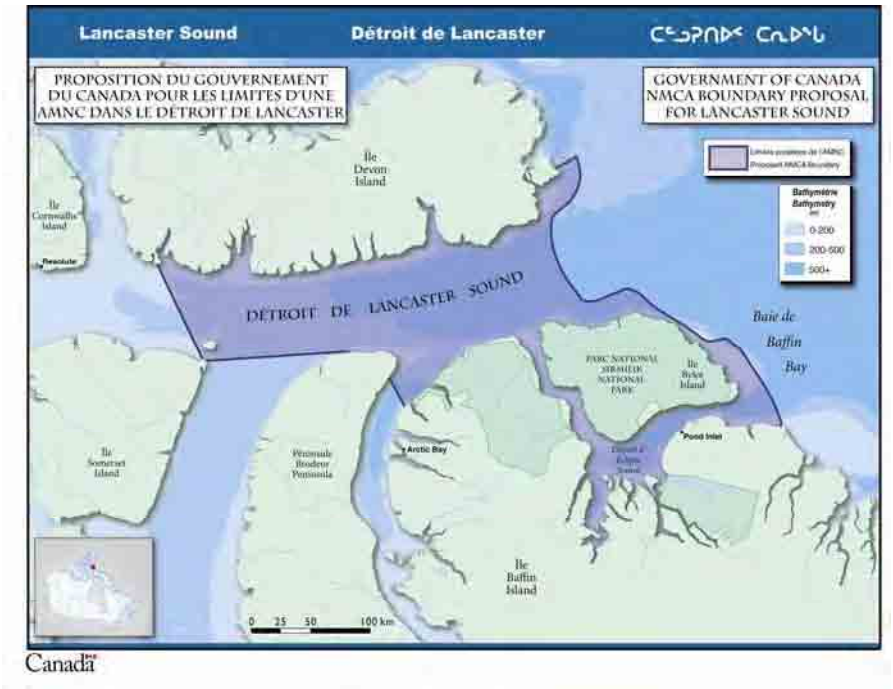

Figure 49. NMCA Boundary Proposal for Lancaster Sound

4.9 COMMERCIAL FISHING

There are two major commercial fisheries in the Baffin Bay – Davis Strait area; the Greenland halibut, also known as the Greenland turbot, (*Reinharditus hippoglossoides*), and shrimp (*Pandalus borealis*).

4.9.1 Greenland halibut (*Reinharditus hippoglossoides*)

Bowering and Nedreaas (2000) note that "Greenland halibut spawning in the western Atlantic has long been postulated to occur in Davis Strait during the late fall-early winter near the submarine ridge between Baffin Island and Greenland at about 67° N." More recently, spawning Greenland halibut have been sampled at various times of the year throughout the range of its offshore distribution along the continental slope from Davis Strait to the Flemish Pass (Morgan and Bowering, 1997). Junquera and Zamarro (1994) studied turbot spawning in the Flemish Pass and observed peak spawning in winter and another in summer. These spawning differences might be the result of a change in fish behaviour associated with a shift in distribution pattern (Bowering and Power, 1995). This could represent normal behaviour observed as a result of now obtaining samples from very deep water (1,250 to 1,800 metres) compared to earlier years. The only recognized major nursery area is near the northern end of its distribution, west of Disko Bay, approximately 69°N (Smidt, 1969; Jørgensen, 1997a, 1997b; in Bowering and Nedreaas, 2000). The fishing methods used in this area include long-lines, gill nets, and bottom trawls.

The turbot fisheries occur from August to November and peak in the months of August and September. Turbot catches in 2007 were near the survey area but were concentrated within extent of the land-fast ice and along the Canada – Greenland international boundary (Figure 50); this represent the farthest extents of the survey. Interactions with this fishery are not expected to be significant.

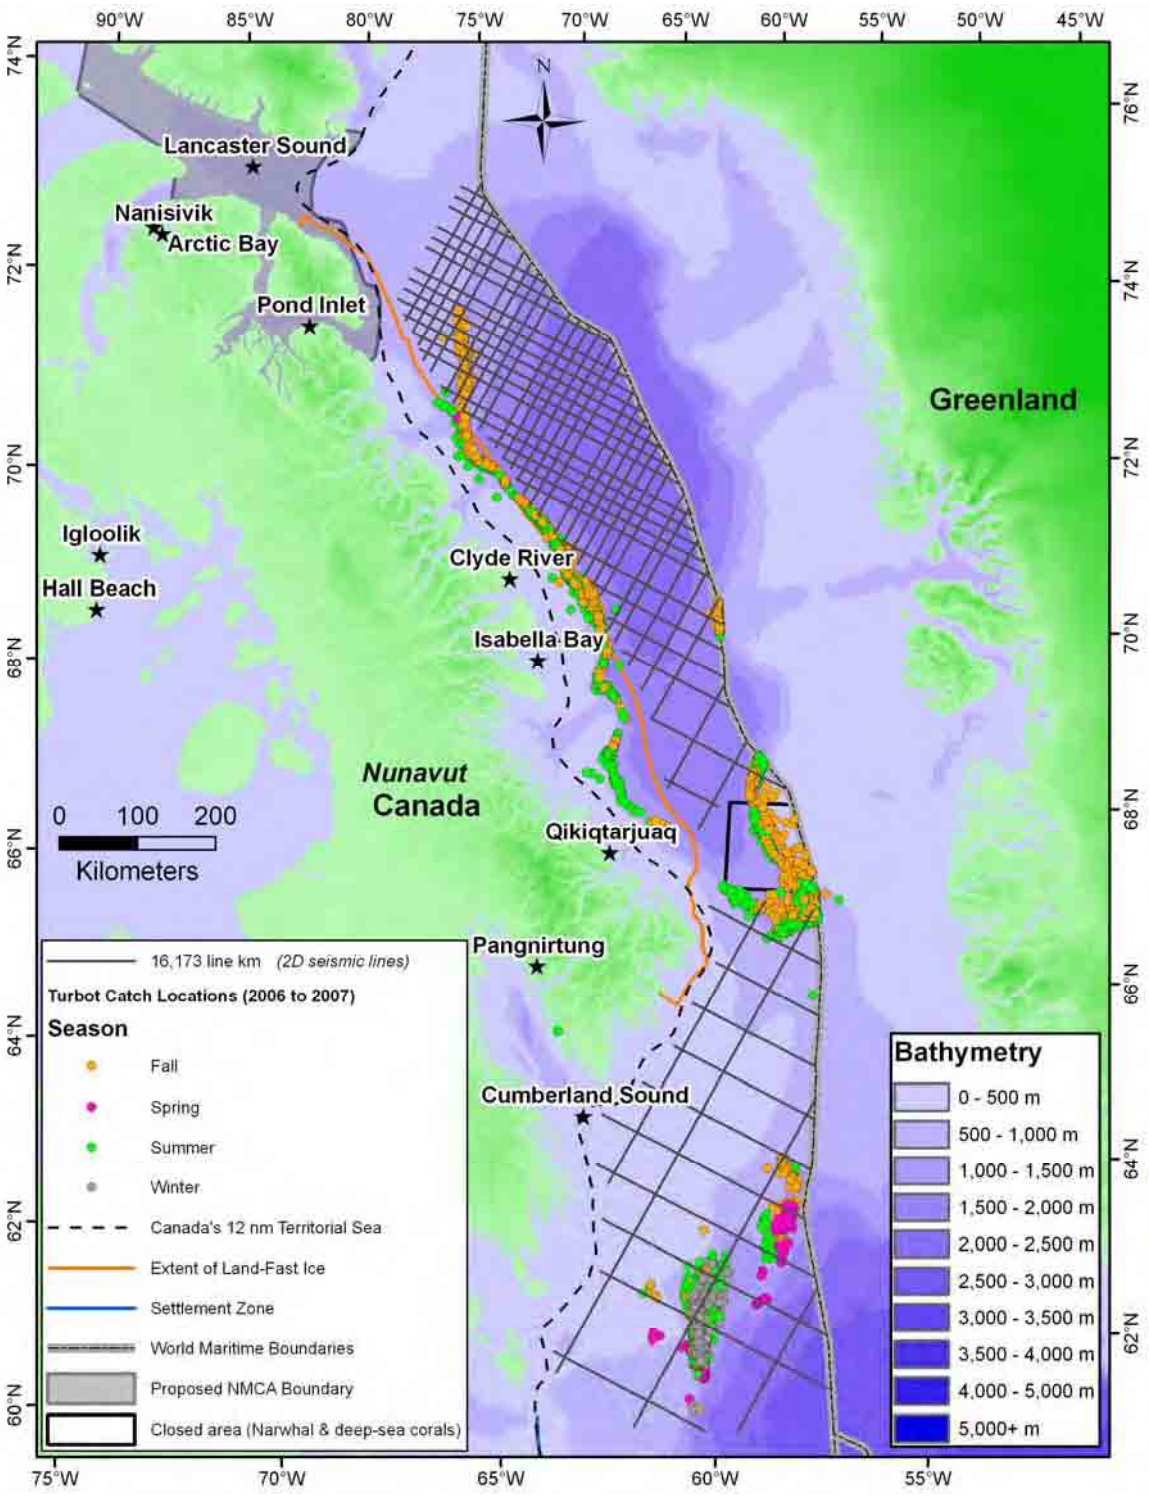

Figure 50. Turbot Fisheries Catch Data for 2006 – 2007 by Season

4.9.2 Northern Shrimp (*Pandalas borealis*)

The Northern Shrimp (*Pandalas borealis*) is the most important commercial invertebrate species within the project area. They are generally found in deep depressions and capture using trawl nets. Northern shrimp spawn during late summer and fall, with the eggs remaining attached to the female until spring. Females with eggs move inshore in late autumn and winter to release the eggs (Parsons, 1993). The proposed 2011 survey lines do not occur in an area of shrimp fishing, which is active south of the survey area from May through December, with peak activity in September and October.

The shrimp are caught from trawlers, which are mobile, whereas turbot are caught in gill nets, which are fixed in position. Gill nets may be anchored to the seabed to keep the gear stationary or positioned in varying water depths, depending on the location of the species, and are marked by buoys on each end, which float on the sea surface. Gill nets may be joined together to increase the efficiency of the operation.

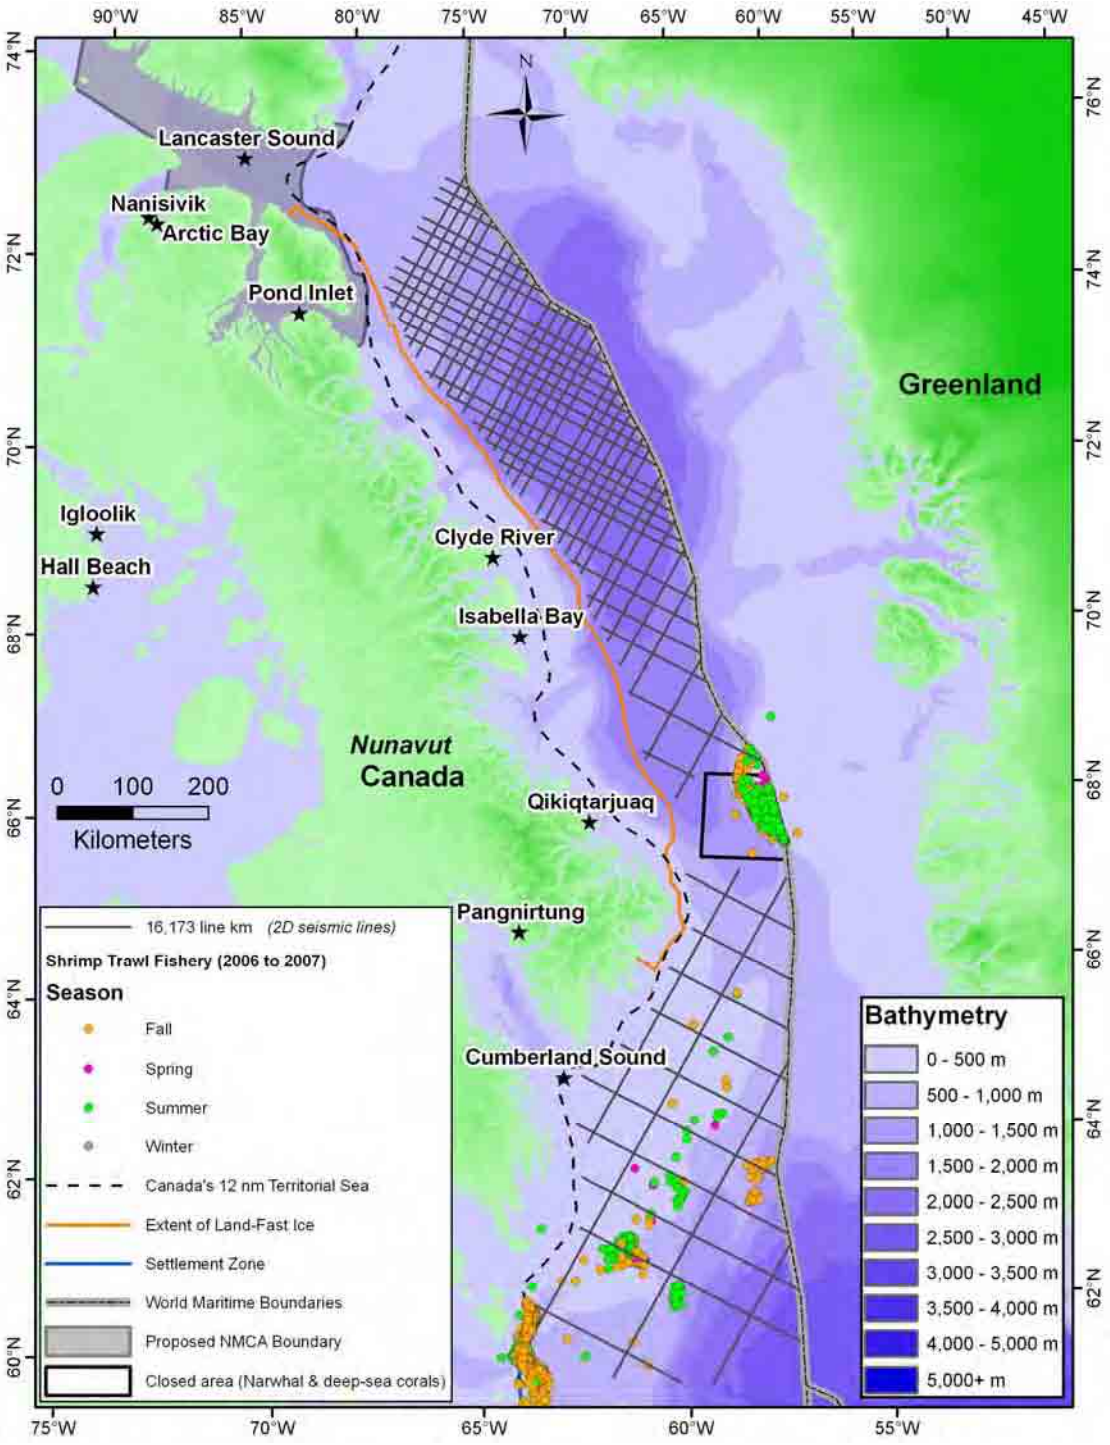

Figure 51. Harvest Data – Shrimp

4.9.3 Fishing Gear

Avoiding fishing gear is a very important component of seismic operations and fixed gear historically is more of a hazard than mobile gear due to the fact that direct communication is maintained between trawlers (using towing mobile gear) and seismic vessels at sea. Refer to Section 5.2.4 for additional discussion on potential fishing gear conflict management.

4.9.4 Fisheries Liaison Officer

The operator will provide a Fisheries Liaison Officer for the duration of the survey to facilitate communications with the fishing industry. The operator will provide a single point of contact in the event of a suspected conflict with fishing gears or vessels during the 2011 program.

4.10 HUMAN AND SOCIOECONOMIC ENVIRONMENT

The seismic survey will take place entirely in marine waters no closer than 12 nautical miles (approximately 22.2 kilometres, 13.8 statute miles) from the Canadian coastline, as defined by the limit of Canada's territorial sea. No Geophysical data will be collected within the Land Fast Ice Zone. Therefore, no survey work will be performed in fjords, inlets, or bays and the survey will be well removed from harvesting areas.

The largest consideration related to the human and socioeconomic environment is with respect to traditional harvesting activities. An appreciation of the traditional knowledge was obtained by consulting two major studies: The Nunavut Wildlife Harvest Study (Nunavut Wildlife Management Board, August 2004), and the Final Report of the Inuit Bowhead Knowledge Study (Nunavut Wildlife Management Board, March 2000). In addition, the operator will employ an Inuit Observer to advise the crew of local knowledge.

Both of these reports are available on the Nunavut Wildlife Management Board website:

http://www.nwmb.com/english/resources/harvest_study/NWHS%202004%20Report.pdf

http://www.nwmb.com/english/resources/Bowheadreport.pdf

Of particular importance are the harvesting activities related to marine species from coastal communities (including Iqaluit, Pangnirtung, Qikiqtarjuaq, Clyde River, and Pond Inlet). The figures below show these data for the Davis Strait and Baffin Bay, and illustrate that harvesting occurs within coastal areas well removed from the proposed survey lines.

The following harvesting data are presented in the figures below:

- Figure 52. Harvest Data – Marine Mammals
- Figure 53. Harvest Data – Fish
- Figure 54. Harvest Data – Big Game
- Figure 55. Harvest Data – Waterfowl
- Figure 56. Harvest Data – Eggs

These harvesting data represent the most comprehensive study completed regarding harvesting levels and patterns of Inuit use of wildlife resources, and are the results of five (5) years of harvest data. The raw data from this study were transposed from the study report to the EIA GIS files and project maps for this assessment purposes. Subject to funding constraints, the NWMB intended to continue to gather, review, and analyze such data into the future, and to report on the results of its efforts, however at this time the data presented in the EIA represent the most recent data published.

The Nunavut Wildlife Harvest Study (NWHS) was mandated by the Nunavut Lands Claim Agreement (NLCA) and carried out under the direction of the Nunavut Wildlife Management Board (NWMB). Harvest data were collected monthly from Inuit hunters for a total of five (5) years covering the harvest months from June 1996 to May 2001. The

Harvest Study covered the entire Nunavut Settlement Area (NSA) involving participants from 28 communities, in all of the three administrative regions: Baffin, Kitikmeot, and Kivalliq regions.

5. ENVIRONMENTAL IMPACT ASSESSMENT

5.1 VALUED ECOSYSTEM COMPONENT (VEC) SELECTION

This assessment uses a valued ecosystem component (VEC) approach to define and focus the issues and factors considered in this assessment. These include components that are important for a variety of reasons, such as their economic or social value, their status (e.g. at-risk species), or their importance to/as habitat. The selection of VEC's is limited, however, to those components that have some reasonable potential for interaction with, or sensitivity to, the planned project activities, most notably the Field Data Acquisition Program during the period of active profiling. This approach was also used in the '*Environmental Impact Assessment for Marine 2D Seismic Reflection Survey, Baffin Bay / Davis Strait / Labrador Sea, Offshore Canada*', also prepared by RPS Energy (April 2007), as commissioned by TGS.

5.1.1 Impact Definitions and Criteria

The Canadian Environmental Assessment Agency's Practitioner's Guide states that "the criteria for determining significance include magnitude, geographic extent, duration and frequency, irreversibility, ecological context" and that the assessment considers the likelihood of an adverse impact occurring. Significant adverse environmental effects are those that will cause a change in the VEC, such that its status or integrity is altered beyond an acceptable level. In other words, a significant adverse anthropogenic environmental effect may alter the assigned VEC in terms of its physical, chemical, or biological quality or extent to such a degree that there is a detrimental change in its ecological integrity beyond which natural mechanisms would not return that VEC to its former level of ecological integrity within the system. The following Table 9 describes the criteria applied for this project within the ecological context described in this report. Residual impacts are determined after application of applicable mitigation measures.

Table 9. Impact Definitions and Criteria

Magnitude	LOW > within natural variation/less than one generation
	MEDIUM > temporarily outside natural variation / 1 to 2 generations
	HIGH > permanently outside natural variation / whole population affected
Geographic Extent	LOW > localized
	MEDIUM > sectoral
	HIGH > widespread
Duration	LOW > less than one month
	MEDIUM > one to two months
	HIGH > greater than two months
Frequency	LOW > one time event
	MEDIUM > several events low duration
	HIGH > continuous

Reversible / Irreversible	Reversible > by natural processes and / or mitigation
	Irreversible > permanent regardless of mitigation
Limits of Confidence	LOW > high degree of scientific uncertainty
	MEDIUM > medium degree of scientific uncertainty
	HIGH > low degree of scientific uncertainty (conclusions are accurate)
Significance Characterization Post-Mitigation	No Significant Residual Impact Significant Residual Impact Positive Residual Impact

The assessments for each VEC considered: impact pathways, a review of relevant literature / research, evaluation of potential effects, and identification of specific appropriate mitigation. Table 10 shows which potential VEC's are considered in this document. Explanation of why phytoplankton, zooplankton, and invertebrates are not considered is discussed in Section 5.1.2.

5.1.2 Fish Eggs, Zooplankton, and Invertebrates

While it is recognized that fish eggs, zooplankton (*including icthyoplankton and pelagic / benthic invertebrates*), and their larvae could be killed or damaged at distances up to or less than 5 metres from a large array, various studies have indicated that the impact would be indistinguishable from natural mortality, given the extent of exposure and the numbers of organisms involved.

Sætre and Ona (1996), in a worst-case risk analysis, estimated the total mortality from a typical 3D seismic survey (conducted in a tight, close grid over a relatively small area) on a typical larval population in the North Sea and calculated an effective mortality radius. Their results showed that the maximum population mortality from a large 3D seismic survey would be just 0.45% of the fish larvae, or 0.18% of the total population in the area per day. They note that since natural mortality for eggs and larvae is estimated at 5-15% per day, the effects of the array on fish larvae would be impossible to differentiate from natural mortality, and well within natural variability.

A workshop with oil industry, Fisheries and Oceans Canada, and fisheries participants from Nova Scotia and Newfoundland (sponsored by Environmental Studies Research Funds (ESRF)) took place in Halifax in 2000. During the workshop, LGL Griffiths Muecke (Thomson et al., 2001) noted that studies of seismic effects on fish eggs and larvae were of low priority and were not considered further at the workshop.

In addition, the 1998 seismic Scotian Shelf class screening assessment (Davis et al., 1998) calculated that, a volume of water equivalent to about 1% of the volume of water in the study area would contain impulses lethal to fish larvae, but not all types of fish larvae would be affected by the seismic pulses and those that have the potential to be affected would not be within range at all times. For example, herring spawning occurs close to shore in very shallow water and eggs would not be affected by seismic exploration. During the day, few pollock, redfish, flatfish, and mackerel larvae would be found in surface waters and they tend to be found at or below the thermocline. At night, the larvae of mackerel and redfish and other species do rise in the water column and are found in surface waters. Lethal ranges for flatfish larvae, which have no swim bladders, would be considerably less than those with swim bladders. Therefore, considerably less than 1% of fish larvae, in the potentially affected water mass, would be affected by seismic pulses. The assessment concluded that “Impacts on fish eggs and larvae, including those in nursery areas, would be minor, sub-local and short-term and likely to occur’. Authors concluded that “Direct physical impacts on invertebrates and their larvae are likely to be negligible”.

In another study, Kostyuchenko (1973) concluded that damage to fish eggs would likely be limited to within 5 metres. Dalen and Knutsen (1986) exposed Atlantic cod eggs, larvae, and fry to airguns, with no effects seen on eggs, larvae, and fry at a distance of 1 metre from a seismic energy source where received levels were 222 dB re 1 µPa. Fry that were 110 days old were also exposed to received levels of 231 dB re 1 µPa from a seismic energy source and all survived. Booman et al. (1996) conducted a study of close-range exposure of fish, fish larvae, and eggs (cod, pollock, plaice, turbot, and herring) to seismic sounds from an airgun cluster (242-220 dB re 1 µPa). Mortality and reduction in hatching success were not measurable beyond a few metres from the cluster. The report concludes that the existing mortality and injuries are near distance incidents with highest mortality rates and most frequent injuries observed out to 1.4 metres distance, while low and no mortality rate and more infrequent injuries were observed out to 5 metres distance.

Studies of invertebrate species show similar results. Pearson et al. (1988) reports that stage II zoeae of the Dungeness crab (*Cancer magister*) were not affected by exposure up to 231 dB re 1 µPa. They concluded that exposure did not affect survival, development, or behaviour.

With regard to phytoplankton, Kosheleva (1992; cited in Turnpenny and Nedwell, 1994) reported that arrays with source levels of 220-240 dB re 1 µPa had no effect on phytoplankton or benthos at distances of 1 metre or more. Studies by the Minerals Management Services of the United States Department of the Interior have indicated that, in general, seismic surveys are expected to have little or no effect on plankton, since the energy source (the airgun array) does not appear to have any effect on this group of organisms. Seismic activities are, therefore, considered to elicit little or no effect on lower trophic level organisms (MMS, 1998).

In 2004, Fisheries and Oceans Canada concluded a detailed review of scientific information on impacts of seismic sound on fish, invertebrates, marine turtles, and marine mammals (Fisheries and Oceans Canada, 2004b). It concluded, in relation to zooplankton, eggs, and larvae of fish and invertebrates, the following:

1) Few studies of the effects of seismic sound on eggs and larvae or on zooplankton were found. A number of these studies provided inadequate description of experiment design; properties of the sound applied as treatments, or had methodological shortcomings.
2) Data are generally insufficient to evaluate the potential damage to eggs and larvae of fish and shellfish (or other planktonic organisms) that might be caused by seismic sound under field operating conditions.
3) From the experiments reported to date, results do show that exposure to sound may arrest development of eggs, and cause developmental anomalies in a small proportion of exposed eggs and/or larvae; however, these results occurred at numbers of exposures much higher than are likely to occur during field operation conditions, and at sound intensities that only occur within a few metres of the sound source.
4) Effects of seismic sounds on behavioural functions and sensory perception of fish and invertebrate eggs and larvae are unknown.
5) In general, the magnitude of mortality of eggs or larvae that models predict could result from exposure to seismic sound would be far below that which would be expected to affect populations. However, special life history characteristics such as extreme patchiness in distribution and timing of key life history events in relation to the duration and coverage of seismic surveys may require case-by-case assessment.
6) No studies were found which specifically investigated the role of seismic sounds in recruitment variation of marine fish or invertebrates. There have been a large number of research studies on causes of variation in recruitment of marine fish or invertebrates, and none has considered that there are recruitment anomalies (positive or negative), which might be linked in space or time to seismic survey operations. This negative evidence applies at the scale of stocks, but does not provide information about the potential for effects on local-scale recruitment dynamics.

Given the above findings and since the exposure for most such organisms would be a “one time” occurrence, environmental elements such as phytoplankton, zooplankton, invertebrate (pelagic and benthic), their associated larvae, as well as fish eggs and larvae were not directly assigned VEC status (Table 10).

Studies by Payne et al. (2007) have indicated that adult American lobsters may experience physiological effects from intense seismic sound / pressure. American lobsters are not found in the proposed seismic study area and consequently will not be potentially impacted by seismic operations. Payne et al. (2007) further indicate that the damaging exposure levels could reach a depth of 100 metres. Most of the seismic survey will take place in deeper waters and there are no commercially exploited benthic macro-invertebrates within the study area. Thus it is unlikely that the seismic survey will measurably impact benthic macro-invertebrates within the study area. Furthermore, although there are commercially exploited pelagic macro-invertebrates within the study

area, there are no scientific studies that address the potential impact of seismic exploration practices on them. There has been considerable seismic activity within the region historically, and no measurable effects have been identified and documented for either benthic or pelagic macro-invertebrates of the region.

Furthermore, since the impacts on eggs, larvae, and juveniles are expected to be insignificant, no specific mitigations are required. The proposed survey does not adversely impact critical or unique spawning grounds, including those of Species at Risk, and the majority of the survey is not on the upper shelf or banks (i.e. shallower than 200 metres). Line spacing, frequency of exposure (effectively 1 time event), location, and water depths, reduce the likelihood of impacts on any areas of concentration. Furthermore, the survey will be conducted progressively by a single vessel, the area occupied by the survey at any given time will be a moving “point” in deeper waters away from the near shore, and there will be no continuing ensonification in any one area.

5.2 SELECTED VEC ASSESSMENT

5.2.1 Impacts on Marine Fish

Marine fish species differ widely in their ability to hear or identify sound. Fish, such as herring, in which the swim bladder is connected directly to the inner ear, appear to perceive sounds more acutely than those that do not. Herring, for example, have the upper frequency limit of hearing ranges from 4,000 to 13,000 Hz, whereas the upper limit in fish without the swim bladder connection to the inner ear is about 1,000 to 1,200 Hz (Enger, 1967). While herring are relatively sensitive to sound, cod do not have a direct connection between swim bladder and inner ear, and, therefore, are less sensitive (Olsen, 1969).

Finfish held in cages and unable to avoid an approaching array have shown physical damage to their hearing, and fish held immediately under an array may be killed (Thomson et al., 2001). For instance, Falk and Lawrence (1973; cited in Davis et al., 1998) exposed adult Arctic cisco and other small *coregonids* with swim bladders to a 300 cubic inches source unit operating at 2,000 to 2,200 psi. While no mortalities were observed, some fish sustained damage to their swim bladder. Based on the damage observed, they concluded that the lethal radius of the airgun was between 0.6 and 1.5 metres (at 226-234 dB re 1 µPa). Weinhold and Weaver (1982) tested effects on salmon smolts (130 millimetres, 25 grams). Nineteen of twenty fish survived exposure to pressures of 70 to 166 psi (234 dB re 1 µPa) at a distance of 1 metre from airguns. Studies by Enger, (1981) and Hastings et al. (1996) suggest that exposure to continuous sounds of 180 dB re 1 µPa RMS for 1 to 5 hours can cause damage to the sensory hair cells that are the fundamental sound receptors in fish, McCauley (2000b c.f. Thomson et al, 2001) found some damage to fish hearing organs after 10 exposures to seismic sounds at received energy levels of 132-182 dB re 1 μPa^2.

In general, under normal circumstances, most fish would be expected to swim away to avoid the source as it approaches. Gausland (2000), in a review of known impacts on marine organisms, concluded that airgun operations cause little direct physical damage to fish at distances greater than 12 metres from the source. Nevertheless, it is evident that fish respond to sounds emitted from airguns. Reactions to the sound impulses are reported at levels from 180 dB re 1 µPa, but the full extent of the reactions is unknown. Due to the avoidance behaviour by free-swimming fish, they should not suffer physical damage from the airguns. However the immediate catch rate near surveys can be affected, but the reduction in catch rates is not expected to be long lasting. The reason for reduced catches is probably because fish dive to the bottom or disperse when exposed to high-level sound. For mitigation it is standard industry practice to ‘ramp-up’ airguns when starting a survey to ‘warn’ fish and marine mammals in the area.

Similarly, the Western Australian Department of Minerals and Energy’s “*Guidelines on minimising acoustic disturbance to marine fauna”* (2001, Section 5) state that the effects of seismic surveys on fish are generally observed to be transitory, except at close range. Seismic shots are known to elicit a startle response in fish, resulting in a movement away from the source of the noise, and changes in schooling behaviour. Behavioural changes are observed to cease during the exposure period, sometimes within minutes of commencement of surveying, indicating habituation to the noise. Fish are considered to have good low frequency hearing and so are likely to be able to hear seismic shots for up to several kilometres from the source. Disturbance of fish is believed to cease at

noise levels below 180 dB re 1µPa (Western Australian Department of Minerals and Energy, 2001).

Davis et al. (1998) also concluded that adult fish on the Scotian Shelf would not be physically injured by seismic arrays unless immediately adjacent to an airgun and direct impacts of seismic exploration on adult fish should be negligible.

McCauley et al. (2000a) investigated physiological stress indicators in several species of caged finfish exposed to airgun arrays by measuring changes in cortisol levels. They report, for all species studied, there were no significant increases in stress measurements, which could be definitively associated with airgun exposure. They concluded that there had been no significant physiological stress increase as a result of exposure.

The recent 2004 Fisheries and Oceans Canada review of potential seismic impacts (Fisheries and Oceans Canada, 2004b) in relation to physical effects on marine fish concluded the following:

1) There are no documented cases of fish mortality upon exposure to seismic sound under field operating conditions. With regard to the detect ability of fish kills, if they occurred, it was noted that in Canada seismic surveys have frequently, but not always, included follow-on vessels instructed to watch for fish kills, and none have been observed. It was also noted that fish kills are not necessarily cryptic events, and kills caused by anoxic events, toxic spills etc are often readily detected. However, it was also argued that the efficiency of detecting fish kills by the follow-on vessels was not tested independently, so the possibility of undetected fish kills cannot be eliminated.
2) Under experimental conditions one study found that some subjects from three of four species tested suffered lethal effects from low-frequency (<500 Hz) tonal sounds, under exposure levels of 24 h at >170 dB. Participants noted that the experimental regime differed greatly from field operating conditions of seismic surveys, so extrapolation of the results to seismic surveys was not warranted. However some participants argued that the result indicates that risk of direct fish mortality from sounds with some characteristics of seismic sound cannot be discounted completely.
3) One anecdotal report of fish mortality upon exposure to an airgun less than 2 metres away was discussed and found to be inconclusive when considered relative to field operating conditions. Overall, exposure to seismic sound is considered unlikely to result in direct fish mortality.
4) Under experimental conditions, sub-lethal and/or physiological effects, including effects on hearing, have sometimes been observed in fish exposed to an airgun. The experimental design made it impossible to determine to the satisfaction of all experts what intensity of sound was responsible for the observed damage to ear structures, nor the biological significance of the damage that was observed. Simulated field experiments attempting to study such effects have been inconclusive. Currently, information is inadequate to evaluate the likelihood of sub-lethal or physiological effects under field operating conditions. The ecological significance of sub-lethal or physiological effects, were they occur, could range from trivial to important depending on their nature.

Considering the limited duration that the survey will be in any particular area and expected distances from the array based on fish avoidance, physical impacts on fish, including sub lethal and chronic impacts (e.g. permanent effects on hearing), are not expected. Nevertheless, to avoid potential impacts on fish the survey will employ a "ramp-up" procedure (i.e. starting with low energy array components and slowly increasing the volume) each time it starts the array. This will allow finfish (and other non-planktonic organisms such as marine mammals and turtles) to move away from the area before they can be exposed to the full array energy. The ramp-up procedures will begin prior to the use of seismic equipment in accordance with the Statement of Canadian Practice (Appendix A) and will progress continuously until recording starts. Ramp-up will begin with a single low cubic inch airgun firing singly, followed gradually by other airgun units in the array.

Overall, seismic operations will not measurably impact marine fish within the profiling area (Table 11).

5.2.2 Impacts on Marine Mammals

Many species of marine mammals, such as cetaceans, depend on sound to communicate, forage, avoid danger, and navigate. Increases in anthropogenic noise levels can result in the masking of these sounds or a decrease in the distance over which they can be detected. The likelihood that an animal would be impacted by a noise is dependent on its intensity, frequency, duration of exposure, and the distance between the animal and the source. It is also dependent on the frequency of the noise being emitted relative to the hearing sensitivity of the marine mammal.

Because of the potential affects of seismic surveys on marine mammals, with close proximity to the seismic array, a marine mammal observer (MMO) will be employed on the seismic vessel and an additional MMO onboard the supply vessel during the proposed survey. MMO's are used to detect cetaceans and pinnipeds in the survey area and advise the crew to take corrective action and shut down operations if marine mammals enter the exclusion zone. They will keep a daily log of wildlife sightings, observation location, and effort data using the forms associated with the guidelines. The MMO will be a trained observer, preferably with experience working in the Arctic.

As a group, marine mammals have a functional hearing range of 0.01 to 200 kHz. However, different species of marine mammals have different acoustic abilities and sensitivities. Toothed and baleen whales, for instance, are known to be sensitive to different frequencies of noise. Toothed whales are less sensitive to low frequency sounds (<500 Hz), but have good sensitivity at up to 100 kHz or more (Evans and Raga, 2001). In contrast, baleen whales are thought to be sensitive to the low frequency sounds (<500 Hz), the frequencies at which they vocalize (Evans and Raga, 2001). If man-made noises occur within these frequencies there is the potential to negatively affect marine mammals either physiologically or behaviourally.

The potential effects of acoustic emissions on marine mammals can be divided into four categories:

- Permanent threshold shift (PTS): Long-term hearing damage due to physical injury to a marine mammal's hearing apparatus. Occurs when an animal is exposed to high peak pressure sound impulses (Richardson et al., 1995).
- Temporary threshold shift (TTS): Temporary reduction in hearing sensitivity. Occurs when an animal is exposed to a strong sound that results in a non-permanent elevation of the hearing sensitivity threshold (Richardson et al., 1995).
- Masking: Failure to distinguish the signal when both the signal and masking noise have similar frequencies and either overlap or occur very close to each other in time (NRC, 2003); and
- Changes in the behaviour and/or distribution (i.e. habitat avoidance) of a marine mammal that is of sufficient magnitude to be "biologically significant" (Richardson et al., 1995; NRC, 2005).

The noises emitted during seismic operations have higher peak source levels than other man-made noises including drilling, construction, and vessel activity. However, seismic exploration sounds tend to be short, discontinuous pulses, which are separated by quiet periods.

The energy from seismic activity varies; however, airgun arrays and other "high energy" sources are generally between 20 and 1,500 Hz. As a result, it is likely below the hearing sensitivities of toothed whales. This may explain why there is no known seismic data on the behaviour of toothed whales exposed to seismic noise. However, overall received levels of airgun pulses are often ≥ 130 dB re 1 µPa, a level that is potentially audible to toothed whales. Therefore, despite the toothed whales poor low-frequency hearing, it has been suggested that they may be able to hear seismic noise out to a radius of 10-100 kilometres.

In contrast to toothed whales, the low hearing sensitivity of baleen whales makes them much more sensitive to seismic noise. Baleen whales have been seen slowing, turning away, and increasing respiration rates as a result of airgun noise (Richardson et al., 1995). These behavioural observations have been detected in bowheads 5-10 kilometres away from the sound source and in humpbacks at ranges of up to 3.2 kilometres away (Richardson et al., 1995).

A scientific review on what is known regarding marine mammals and acoustic noise is presented in Appendix I (Fisheries and Oceans Canada, 2004b). This document, titled *Review of Scientific Information on Impacts of Seismic Sound on Fish, Invertebrates, Marine Turtles and Marine Mammals*, forms the basis of the *Statement of Canadian Practice on the Mitigation of Seismic Noise in the Marine Environment* described in Section 5.3 of this document (Fisheries and Oceans Canada, 2004a), and is available on the Fisheries and Oceans Canada website:

http://www.dfo-mpo.gc.ca/csas/Csas/status/2004/HSR2004_002_E.pdf

Based on current knowledge on hearing sensitivities, it is possible that seismic activity related to the project may affect marine mammals, particularly baleen whales. However, because the project will be following the Statement of Canadian Practice on the Mitigation of Seismic Noise in the Marine Environment, the more serious PTS and TTS effects are unlikely. Impacts to marine mammal behaviour, particularly habitat

avoidance, are possible (e.g. bowheads at the Isabella Bay sanctuary may hear the seismic operation and temporarily alter their behaviour), but overall these impacts are expected to be limited due to the short term and periodic nature of the proposed seismic activity. The survey acquisition plan (i.e. order of survey lines to be acquired) is intended to maximize separation between marine mammals and the survey vessel, and includes starting acquisition in the south and progressing north. This detailed survey acquisition plan will be prepared prior to project initiation.

5.2.3 Impacts on Bowheads and Baleen Whales

Oil and gas exploration in the Arctic has prompted considerable research to investigate the potential effect of seismic noise on bowhead whales. Early studies on the effects of seismic noise indicate that bowheads show behavioural changes when seismic noises are within 8.2 kilometres, a range where received levels would be 142-157 dB re 1 µPa. In addition, whales will move away from the noise when it is within 3 to 7.2 kilometres (152-178 dB) (Richardson et al., 1986). These responses result in the whales being displaced by approximately 2 kilometres and their behaviour being altered for up to 1 hour (Ljungblad et al., 1988).

Findings from a more recent study by Richardson et al. (1999) suggest that these early sensitivity estimates may be an underestimate. Richardson et al. (1999) reported bowheads avoiding areas within 20 kilometres of seismic sources, corresponding to received noise levels of 120-130 dB re 1 µPa. The presence of this large avoidance zone was supported by the observation that areas outside of the zone had significantly higher densities of whales.

Other changes in behaviour that have been associated with seismic activity include reduced surface interval and dive duration, lower numbers of blows per surfacing, and longer intervals between successive blows. These effects have been detected at distances of up to 5-10 kilometres (Richardson, 1995).

Thresholds for temporary threshold shift (TTS) and permanent threshold shift (PTS) in baleen whales are unknown (Davis et al., 1998). It is not prudent to assume that the measured TTS thresholds for bottlenose dolphins apply to baleen whales, which seem to be much better adapted for low frequency hearing. TTS threshold levels could be important for assessing effects on baleen whales because individuals of some species of baleen whales occur quite close to ships and to seismic operations. McCauley et al. (1998) found that some individual humpback whales approached an operating seismic airgun to within 100-400 metres. Thus, the received levels that induce TTS may be particularly relevant for baleen whales such as the bowhead. The US National Marine Fisheries Service uses the threshold received level of 180 dB when considering potential TTS and PTS to marine mammals.

Based on United States National Marine Fisheries Service, available bowhead and acoustic impact information, they are likely to be disturbed only temporarily when encountered by the survey vessel. This disturbance is unlikely to result in auditory damage (i.e. TTS and PTS), especially given that professional marine mammal observers will ensure operations are suspended if marine mammals are identified within 500 metres of the arrays (see the following mitigation section for details). The most significant behavioural reactions are likely to consist of mid-range avoidance movements

(Davis et al., 1998), and it is not presently possible to quantify the overall long-term biological significance of such disturbances, however the proposed survey is well-removed from the continental shelf region, in particular from the Niginganiq (formerly Igaliqtuuq) National Wildlife Area (Isabella Bay). Bowheads are closely associated with pack-ice (possibly for feeding, protection, or other reasons), hence survey lines approaching summer pack-ice regions may potentially induce temporary habitat displacement, but will likely return after several hours. It is unlikely that this temporary disturbance will significantly reduce the overall value (i.e. feeding, resting) of this habitat.

5.2.4 Impacts on Narwhals and Toothed Whales

There is very little information about the behavioural responses of *odontocetes* to seismic exploration (Davis et al., 1998); this is especially true for responses of narwhals. The narwhal, in particular, is poorly studied and no scientific reports addressing hearing sensitivity and reactions to noise are available. However, it is known that narwhals are very sensitive to vessel activity and exhibit “freeze” or “flight” responses similar to those seen in beluga whales (Richardson et al., 1995). Their acute responsiveness has been linked to their confinement to heavy ice and the associated good sound propagation conditions. Goold (1996a) found that common dolphins (conceivably having comparable hearing sensitivity to narwhals) were tolerant of the noises from an array at distances of over 1 kilometre. The threshold levels for behavioural responses by bottlenose dolphins to single 1-second pulse ranged from 178 to 186 dB re 1 µPa for frequencies from 75 to 3 kHz (Finneran et al., 2002).

It is concluded that the effects of seismic pulses on narwhals would be minor, sub-local, short-term, and likely to occur. The use of professional marine mammal observers onboard the survey vessel will ensure operations are suspended if marine mammals are identified within 500 metres of the array (see the following mitigation section for details). The possibility of non-auditory physiological effects cannot be evaluated with present data, however if they occur they would be limited to animals very close to the operating array.

The situation for sperm whales is less clear, as the available data limited. Nevertheless the initial results of a major MMS study in the Gulf of Mexico involving the tagging and tracking of endangered sperm whales suggests that these whales may not significantly alter their behaviour when seismic arrays are active (Biers, 2003), and the US National Marine Fisheries Service (1995, 2000) has advised that whales in general should not be exposed to impulse noise at received levels exceeding 180 dB re 1 µPa (RMS), and have established a 500 metre radius precautionary safety zone for seismic arrays.

With the proposed mitigation methods in place the predicted effects for this study in the proposed study area are negligible to minor, local, short-term, and therefore not considered significant.

5.2.5 Impacts on Pinnipeds

Preliminary results of a radio telemetry study by Thompson et al. (1998; cited in Anderson Resources 2001) suggest that pronounced (but short-term) behavioural changes can occur in harbour seals and gray seals exposed to airgun pulses. They

stated that normal foraging dives were interrupted and that avoidance reactions usually occurred. The seals returned to their previous foraging areas after airgun operations ceased. The USNMF Service has also set a safety limit of 190 dB for seals.

Overall, on the basis of the above information, as well as implementation of appropriate mitigation measures, no measurable impact on marine mammals is anticipated during the period of seismic acquisition in the Baffin Bay region (Table 11).

5.2.6 Impacts on Marine Birds

There are many species of seabirds and related species that can be found associated with the waters of proposed survey area. Not all are breeding populations and may only contact water or the shore area for brief period in the summer. There are no endangered or threatened species within the seismic survey area according to the latest information on the Species at Risk (SARA) Registry, however, the Ivory Gull is designated a species of special concern by COSEWIC. Environment Canada protocols for seabird observations will be used for seabirds for this project.

In general, there is little scientific information about impacts of seismic array sounds on birds. Davis et al. (1998) reports, “Stemp (1985) made observations on the reactions of birds to seismic exploration programs in southern Davis Strait over three summer periods. No distributional or mortality effects were detected. Evans et al. (1993b) made observations from operating seismic vessels in the Irish Sea. They noted that, when seabirds were in the vicinity of the seismic boats, there was no observable difference in their behaviour, birds neither being attracted nor repelled by seismic testing.

Many of the birds that might forage in the project area are divers, such as the Dovekie, Thick-billed Murre, and Atlantic Puffin that dive quite deeply and may spend considerable time under water. Murres regularly dive to depths of 100 metres and have been recorded underwater for more than three minutes (Gaston and Jones, 1998; cited in LGL, 2003).

Since the array will be gradually ramped-up at each start, and the array will generate impulses every 13 seconds, seabirds will be warned as they approach the ship and array. This will reduce or remove the likelihood that birds will choose to come close enough to the array to experience hearing damage or other physical harm.

In terms of risk to birds from pollutants, oil slicks, or wastewater, the survey vessel will comply with all applicable regulations concerning discharges of materials into the marine environment, as described above. The vessel is equipped to minimize risk of any spills and has an emergency response plan in place.

With respect to seabird interaction with surface oil, Lehoux and Bordage (2000) present deterrent techniques and a bird dispersal approach for oil spills that could be applied to any significant spill of oil of any variety. By utilizing the proposed mitigation measures, no measurable contribution of hydrocarbons is anticipated to enter the marine environment and impact marine life.

Onboard lights are known to attract birds, though the situation on the survey vessel is not expected to be any different than for any other similar-sized cargo or fishing ship, and the survey vessel will not typically be stationary.

In general, considering the small impact of seismic sounds in the air and the brief time the survey vessel will be in specific areas, the presence of the survey vessel should pose little risk and no measurable impact is predicted on seabirds within the area of survey (Table 11).

Table 11. Matrix of Potential Environmental Effects of the Project Components on Value Ecosystem / Environmental Components

Valued Ecosystem Component (VEC)		Magnitude	Geographic Extent	Duration	Frequency	Reversible / Irreversible	Limits of Confidence	Significance Level Post-Mitigation
Marine Mammals	Whales	LOW	LOW	MED	LOW	Reversible	MEDIUM	No Significant Residual Impact
	Seals	LOW	LOW	MED	LOW	Reversible	HIGH	No Significant Residual Impact
	Walrus	LOW	LOW	MED	LOW	Reversible	HIGH	No Significant Residual Impact
	Polar Bear	LOW	LOW	MED	LOW	Reversible	HIGH	No Significant Residual Impact
Sea Turtle		LOW	LOW	MED	LOW	Reversible	HIGH	No Significant Residual Impact
Birds		LOW	LOW	MED	LOW	Reversible	HIGH	No Significant Residual Impact
Fish		LOW	LOW	MED	LOW	Reversible	MEDIUM	No Significant Residual Impact
Fishing Gear Conflict		LOW	LOW	MED	LOW	Reversible	HIGH	No Significant Residual Impact

Key:

Magnitude	LOW	Within natural variation/less than one generation
	MEDIUM	Temporarily outside natural variation / 1 to 2 generations
	HIGH	Permanently outside natural variation / whole population affected
Geographic Extent	LOW	Localized
	MEDIUM	Sectoral
	HIGH	Widespread

Duration	LOW	Less than one month
	MEDIUM	One to two months
	HIGH	Greater than two months
Frequency	LOW	One time event
	MEDIUM	Several events low duration
	HIGH	Continuous
Reversible / Irreversible	Reversible	By natural processes and or mitigation
	Irreversible	Permanent regardless of mitigation
Limits of Confidence	LOW	High degree of scientific uncertainty
	MEDIUM	Medium degree of scientific uncertainty
	HIGH	Low degree of scientific uncertainty (conclusions are accurate)
Significance Level Post-Mitigation	No Significant Residual Impact	
	Significant Residual	
	Positive Residual Impact	

5.2.7 Fishing Gear Conflict

All proposed activity associated with this project will occurs offshore, fishing vessels and their associated in-sea gear represent the main group that could be potentially affected by the physical presence of the survey vessel and in-sea equipment. In order to manage this effectively, Fisheries Liaison Officers (FLO) familiar with the survey area's fisheries will be employed on the vessel during the proposed survey as means of facilitating inter-industry communications, advising on fisheries issues, and avoiding fishing / gear conflicts. It is anticipated that the FLO individuals will be hired based on the recommendation of the local fishing industry (FFAW), and personnel with experience working in the Arctic are appropriate for this type of project. The FLO will provide dedicated marine radio contact for all fishing vessels in the vicinity of the survey vessel to discuss potential interactions and solutions. These persons, knowledgeable about local fishing, will assist the vessel's bridge personnel with information about established fishing activities and harvesting methods.

As discussed in Section 4.9 of this report, commercial fish harvesting activities may occur throughout the survey period within some parts of the survey area, though the timing of specific fisheries varies. The fixed-gear (gill nets and long lines) of the turbot fishery poses the highest potential for gear conflict if they are concurrent and co-location with seismic survey operations. Historically, such gear conflicts have occurred in other areas, typically 2-3 times annually throughout Atlantic Canada. All incidents have involved fixed gear (typically crab or lobster pots, gill nets, or large pelagic long lines). When these events occur, they are assessed on a case-by-case basis and compensation paid for determined losses.

Mitigation plans to avoid active fishing areas are presented below. These focus on reducing the likelihood of conflicts. With precautions and compensation plans in place, the economic impacts on fishers would be negligible, and thus not significant.

5.2.8 Avoidance

As discussed above, potential impacts on fishing gear will be mitigated by avoiding active fixed gear fishing areas. The FLO, good at-sea communications, and mapping of fishing locations have proven effective in the past at preventing such conflicts.

5.2.9 Fisheries Liaison Officer (FLO)

As described above, the onboard fisheries industry FLO will provide a dedicated marine radio contact for all fishing vessels in the vicinity of the survey vessel to help identify gear locations, discuss potential interactions and find solutions, and provide essential guidance to the Bridge.

5.2.10 Communications with Fishing Industry

Good communications are the best way to minimize interference with fishing activities. Maintaining good communication with fishers is important before and during the survey.

The Operator (through its consultants) will communicate with appropriate fisheries organizations to inform them of planned survey activities and to facilitate information exchange with fisheries participants.

Relevant information about the survey will also be publicized using established communications mechanisms, such as the Notices to Shipping and CBC Radio's Fisheries Broadcast, as well as direct communications between the survey vessel and fishing vessels via marine radio at sea.

5.2.11 Single Point of Contact

The operator will arrange for the services of a Single Point of Contact (SPOC) with the fisheries industry. The SPOC role will include updating vessel personnel (i.e. the FLO, the Captain, and the Party Manager) about known fishing activities in the area, and will relay relevant information from Fisheries and Oceans Canada.

5.2.12 Fishing Gear Compensation

In case of accidental damage to fishing gear, the operator will have available a gear damage compensation contingency plan to provide appropriate and timely compensation to any affected fisheries participants. The Notices to Shipping filed by the vessel will also inform fishers that they may contact the SPOC, if they believe that they have sustained survey-related gear damage.

The Operator is familiar with the C-NLOPB / CNSOPB Compensation Guidelines Respecting Damages Related to Offshore Petroleum Activity (C-NLOPB / CNSOPB, 2002), and with programs developed jointly by the fisheries industry and offshore petroleum operators (e.g. by the Canadian Association of Petroleum Producers and other Operators) as alternatives to claims through the courts, to address all aspects of compensation for attributable gear damage. These programs include provisions for paying compensation for lost or damaged gear, and any additional financial loss that is demonstrated to be associated with the incident. The programs include mechanisms for claim payments and dispute resolution. The operator will implement similar procedures to settle claims promptly for any gear damage that may be caused by survey operations, including the replacement costs for lost or damaged gear, and any additional financial loss that is demonstrated to be associated with the damage, as recommended under the C-NLOPB Guidelines. The operator will provide the NEB with the details of any compensation to be paid.

By adopting the above mitigation measures it is unlikely that a significant impact on fishing gear will occur during the seismic program (Table 11).

5.3 MITIGATIONS

The operator will follow the 'Statement of Canadian Practice on the Mitigation of Seismic Noise in the Marine Environment' developed by Fisheries and Oceans Canada in order to minimize the negative effects of its activity on the environment (Fisheries and Oceans Canada, 2004a). This document is available for review online:

http://www.dfo-mpo.gc.ca/oceans-habitat/oceans/im-gi/seismic-sismique/pdf/statement-enonce_e.pdf

This Statement of Canadian Practice was created to formalize and standardize the mitigation measures used in Canada with respect to the conduct of seismic surveys in the marine environment. Based on current knowledge and experience, seismic surveys conducted with the mitigation measures contained in the Statement of Canadian Practice are not expected to cause significant adverse environmental effects. A copy of this document is provided in Appendix A.

A scientific review on what is known regarding marine mammals and acoustic noise is also presented in Appendix I. (Fisheries and Oceans Canada, 2004b). This document, titled 'Review of Scientific Information on Impacts of Seismic Sound on Fish, Invertebrates, Marine Turtles and Marine Mammals', forms the basis of the 'Statement of Canadian Practice on the Mitigation of Seismic Noise in the Marine Environment', and is also available on the Fisheries and Oceans Canada website:

http://www.dfo-mpo.gc.ca/csas/Csas/status/2004/HSR2004_002_E.pdf

No residual environmental impacts are expected on the marine resources in the survey area. A seismic energy source for this type of survey produces about 230 db re 1 µPa @ 1 m. Note this is a theoretical level and is not actually reached the array is not a point source. At a distance of about 1 kilometre from the sound source the received sound is in the order of 170 db re 1 µPa. The Department of Fisheries and Oceans has concluded that exposure to seismic sound is considered unlikely to result in direct fish or invertebrate mortality (Fisheries and Oceans Canada, 2004a).

For marine mammals a safety zone distance of 500 metres from the sound source will be established. At this distance the received sound level (180 dB re 1 µPa) is similar to the vocalization sounds made by Humpback, Bowhead, Right, Blue, Fin, as well as other large marine mammals (175-190 dB). Furthermore, vessel traffic in the area, such as commercial fishing, produces sound levels in the order of 154 dB (Richardson et al., 1995). As a note, rain will increase the background noise by up to 35 dB above ambient.

All standard and industrially related mitigation measures pertaining to the use of seismic airgun arrays for exploration will be adopted and followed. For marine mammals, especially whales, the safety radius or zone of 500 metres from the sound generating source will be adopted to reduce received sound levels in the order of 180 dB at the maximum (LGL, 2005). Note that this sound level is about the same sound production level that is produced by cracking and breaking pack ice that is prevalent in this high Arctic environment, and represents a background noise level. Further mitigation measures with respect to potential marine mammal interaction with the project will also be adopted. These include the following:

1) Alteration of vessel speed / course providing it will not compromise operational safety requirements.
2) Airguns will be shut down if any marine mammal enters or is anticipated to enter the 500 metres safety zone through observations by a trained marine mammal observer on the seismic vessel.
3) Airgun start-up procedures will not commence unless a full 500 metres safety zone is clear of any marine mammal by visual inspection by a trained marine mammal observer for a continuous period of at least 30 minutes.
4) The airgun array will be "powered down" during transit from one seismic line to another. All guns will be turned off except for one gun, which will function as a signal intended to alert marine mammals of the presence of the vessel.
5) Total shut down of all airgun activity will occur and not resume until all marine mammals have cleared the 500 metres safety zone.
6) Airgun start-up procedures will include a "ramping-up" period.
7) The location of the seismic activity associated with this project will not take place in the vicinity of any native harvest area.
8) Notice to mariners posting where and when surveying will occur.
9) Adherence to recent Fisheries and Oceans Canada guidelines for conducting seismic surveys in Canadian waters (Appendix A).

With respect to polar bears, it is highly unlikely that the sub-sea sound produced will impact bears if they are encountered. If seen by the trained marine mammal observer within the 500 metres safety zone, all of the above mitigation measures will be applied to ensure that no project interaction occurs.

For marine fish and invertebrates, federal Department of Fisheries and Oceans and other scientific studies have indicated that no fish kills have taken place that can be directly attributed to seismic exploration activity, and no measurable impact on populations of phytoplankton, zooplankton, as well as fish eggs, larvae, or juveniles have been reported at distances of 8 metres from the seismic sound source.

Overall, by adopting all industrial mitigation standards as well as more stringent measures discussed above, no anticipated measurable environmental impacts are predicted for this seismic exploration research field program in the Davis Strait project area.

5.3.1 Ramp-Up

"Ramping-up" (i.e. starting with low energy array components and slowly increasing the volume) will allow marine mammals to avoid the survey area if they choose to. The survey vessel will gradually ramp-up (soft-start) the energy of the airgun array to warn away marine mammals and finfish before they can be exposed to the full array energy.

As specified in the Statement of Canadian Practice, the ramp-up procedures will begin after a 30-minute observation period (see below), at least 20 minutes prior to the use of seismic equipment, and be continuous until recording starts. Ramp-up will begin with a

single air-source unit firing singly followed by other source units in the array. The array will then increase intensity, either through adding units or increasing pressure (or both), at a planned rate until the full intensity of the array is achieved.

5.3.2 Start-Up and Shutdown Procedures

Guidelines for the mitigation of seismic noise in the marine environment established DFO in 2004 (Mitigation of Seismic Noise in the Marine Environment – Statement of Canadian Practice; Appendix A) will be adopted. A designated observer for the presence of marine mammals and/or sea turtles will conduct a visual inspection of the area 30 minutes prior to commencement of the soft start.

The operator undertakes not to commence the array start-up, or to recommence firing the array if stopped, if any marine mammal is sighted within 500 metres of the survey vessel during this period. During ramp-up, if a marine mammal is sighted within 500 metres of the array, the array will be shut down.

If for any reason the array is shut down, ramp-up procedures will be followed prior to recommencing survey operations. Outside daylight hours, or in periods of low visibility, visual observations may not be practicable. In these situations, a soft-start approach will still be employed, and the reasons for “no observations” will be recorded.

Employing these mitigation methods, no measurable impact is anticipated for the leatherback sea turtle that could potentially enter the area of seismic profiling (Table 11).

5.3.3 Mitigations with Respect to Seabirds

The array will be gradually ramped-up and the array will generate impulses approximately every 15 seconds. Seabirds will therefore be warned as they approach the ship and array, which will reduce the likelihood that birds will choose to come close enough to the vessel or array to experience any measurable deleterious interaction.

Onboard lights are known to attract birds, although the situation on the survey vessel is not expected to be any different than that for any other similar sized cargo vessel or fishing ship. Nevertheless, the measures adopted to address stranding of *Storm Petrels* as described by Williams and Chardine will be adopted. A copy of this document is provided within Appendix J.

5.4 ACCIDENTS AND MALFUNCTIONS

All safety measures established on the research vessel will be enforced while seismic data are collected. Dedicated safety officers and crew of the research vessel will be fully briefed on the procedures required by the scientific staff for deployment, data collection, and instrument retrieval. No instrument deployment / data collection will occur at any time without the knowledge of the vessel Captain or designate. The vessel carries

trained personnel and applies specific protocols to deal with equipment malfunctions that may lead to the spill of toxic materials.

5.5 EFFECTS OF THE ENVIRONMENT ON THE PROJECT

Sea and ice conditions are the primary sources of potential effects of the environment on the project. If sea states exceed a Beaufort wind scale value of 7, with sea waves in excess of 3-4 metres in height, seismic activity cannot take place. Additionally, if pack-ice is covering the proposed survey area, no seismic data can be acquired in that region and another ice-free survey area must be visited.

As described in detail in Section 5.3.2, airgun start-up procedures will not commence unless a full 500 metre safety zone is clear of any marine mammal by visual inspection by a trained marine mammal observer for a continuous period of at least 30 minutes. Outside of daylight hours, or in periods of low visibility, visual observations may not be practicable. In these situations, start-up procedures (including a soft-start approach, described below) will still be employed, and the reasons for "no observations" will be recorded.

This gradual ramp-up / soft-start of the seismic array commences by firing a single source (preferably the smallest source in terms of energy output and volume), and then continuing to active additional sources in ascending order of size over a 20 minute period until the desired operating level is attained.

5.6 CUMULATIVE ENVIRONMENTAL EFFECTS

Environmental effects resulting from individual projects may accumulate and interact within the environment to result in cumulative environmental effects. Potential cumulative effects due to accumulation and/or interaction of the seismic program's activities are considered below. In this regard, the evaluation of cumulative environmental effects considers the nature and degree of change from baseline environmental conditions as they pertain to the proposed program, the program in combination with past and ongoing projects, and the program in combination with future planned projects and activities.

With regards to future activities, a critical step in the assessment process is determining what other projects or activities have reached a level of certainty (e.g. reasonable foreseeable) that they will be undertaken. Within the study area, other projects / activities that meet this level of certainty include: commercial fishing, commercial vessel / shipping (both domestic and international), scientific research surveys, and mineral resource exploration and development.

Seismic surveys are of particular interest since cumulative impacts from seismic impulses within the marine environment are significantly harder to quantify than effects attributed to other activities. This is because the acquisition of seismic data requires the temporary creation of sound / pressure waves (airgun-derived) that dissipate and soon disappear when the sound energy source is stopped. Unlike other mineral resource

exploration / extraction activities that are tangible in nature, such as the production and deposition of drilling muds on the seafloor, or other industrial related cumulative impacts, such as deposition of mine tailings and contaminant loading, any cumulative impact that maybe attributed to a seismic energy source is intangible and can only be measured as impacts associated with organisms in the environment.

Specifically, the energy source produces sound / pressure that, in it, do not “accumulate” in the physical environment from one project to another. There is no bioaccumulation of sound / pressure within the food chain as there can be with contaminants and noxious materials. However, there may be a relatively temporary additive effect if sounds from one activity coincide and overlap spatially and temporally with another concurrent activity. In any case, the “added sound” dissipates and is removed from the receiving environment once one or the other sound-generating source ceases or passes out of the area of concern.

To our knowledge, there have been no historical or current documented measurable cumulative physical environmental effects on any marine organism that can be attributed to, in part, a seismic energy source operating within the survey region. Thus, any cumulative impacts from a seismic survey energy source would have to be measured as behavioural impacts caused by repeated exposure to the energy source in conjunction with other sound sources.

Within the study area there may be many sound generating sources present when the seismic energy source is active. Commercial fishing occurs within the proposed survey area. Concurrent with fishing activity is domestic and international shipping. Propeller noise from these vessels combines to make the ocean a very noisy place, especially near and at primary fishing and commercial ports. Since the proposed seismic survey will not be concentrating efforts in areas of major commercial shipping activity for any extended period of time, it is not anticipated that the relatively small seismic survey vessel, with its associated propeller noise, will contribute a significant addition to the overall domestic / international vessel traffic noise within the region. This conclusion also applies to government research survey vessels that may occur within the proposed seismic survey area.

The behaviour of marine mammals and birds may be influenced by noise. Existing marine activities within the study area that contribute to background noise include: commercial fishing, general marine traffic (domestic and international shipping), government research surveys, as well as recreational boaters. In addition, there is considerable naturally occurring background noise, such as that cause by the cracking and breaking of sea ice. When combined, this combination of routine and naturally occurring sounds make the underwater environment considerably noisy. It is anticipated that the additional noise generated as a result of the present proposed seismic survey activities will be minimal, in part due to the broad area that is to be surveyed over an extended sampling time, and not concentrated in a particular area over a short period of time. Mitigation measures are in place to protect marine mammals and reptiles thus reducing the potential for impacts.

As noted in Appendix C, a considerable number of seismic studies have been undertaken in the region (190 seismic reflection surveys (2D and 3D), seismic refraction surveys, and shallow seismic / seabed surveys) and no measurable cumulative impact

on any fishery, nor other marine resource, has been identified that can be attributed to seismic exploration; therefore it is unlikely that cumulative impacts will result from the proposed program. Potential cumulative impact related to seabirds may primarily be related to accidents and malfunctions that may release hazardous materials, such as oils, into the marine environment that would combine with other materials already present. Mitigation methods are in place to address these issues. Furthermore, lights from several vessels operating in close proximity may cause cumulative impacts relating to stranding of birds on the vessels. However, due to the nature of the seismic survey method, where the seismic apparatus is towed up to several kilometres behind the survey vessel, no other vessel is likely to be in close proximity. Therefore, the likelihood of cumulative accidents / malfunctions releasing hazardous materials from the seismic survey vessel and another vessel is low, as is the attraction of seabirds to multiple vessels in close proximity to each other at night.

Commercial fishing and domestic / international shipping, as well as government research surveys, will continue to occur. However, no measurable cumulative impacts / effects associated with past or current activities have been identified despite over 1.5 million line kilometres of seismic survey data having been collected in the region. Overall, the proposed seismic survey is not projected to measurably contribute to residual cumulative environmental effects within the proposed survey area

5.7 CONSULTATIONS

As mentioned early in this document, in person meetings were held with HTO groups in the communities, meetings with Federal and territorial groups in Iqaluit prior to the commencement of the EA development. A copy of these meetings can be found in Appendix B. It is anticipated that RPS Energy will return to some communities for public meetings in late May 2011. These meetings were scheduled for May 1-6th but negative feedback due to it being election week, resulted in the decision to re-schedule.

Consultations with the fisheries industry have been conducted by the authors for marine 2D seismic reflection surveys in the Davis Strait in 2007 – '*Environmental Impact Assessment for Marine 2D Seismic Reflection Survey, Baffin Bay / Davis Strait / Labrador Sea, Offshore Canada* ' (LaPierre et al., 2007). The primary issues raised during these consultations were concerns regarding the potential impacts of seismic operations on the spawning of Greenland halibut in general, gear conflicts, and communications with the fisheries fleet in the field.

Spawning will not be impacted as there are no concentrated areas or timing of spawning to avoid in the survey area. Regardless, the commercial species of fish spawn at the ocean bottom, at depths well-removed from the surface where the sound could potentially result in temporary dispersal of fish. Science does not currently have sufficient data to identify a set period when spawning occurs in NAFO Divisions 0A and 0B; however, research on the Flemish Cap suggests that turbot do not have a peak spawning period, with some fish in spawning conditions year-round (Fisheries and Oceans Canada, 2005).

For fishing activity that takes place concurrently with the proposed geophysical program there is potential for gear interaction between the seismic and fishing vessels / gear;

however, the presence of a fisheries liaison officer (FLO) onboard the seismic vessel will ensure good communication at sea so that areas of fishing can be avoided when fishing is taking place. In practice seismic vessel yield to and/or avoid fixed gear locations, and work around fishing activity. It is routine for seismic vessels to break off survey lines in order to avoid fishing gear.

Since 1998, fishing effort restrictions have been in place to limit the time spent by vessels fishing for Greenland halibut (turbot) in this area, as the harvesting of this species is considered a potential impact on narwhal food supply. A fifteen-year rebuilding programme started in 2004 to attain a sustainable level of exploitable biomass. This issue will be closely monitored by the operator as it develops, and the onboard FLO and operator will be made aware of any developments related to the adoption of this policy in order to be fully aware of the potential fishing activity, and to facilitate appropriate communications with expected fishers. Effective communication between fishing vessels in the field and the survey vessel is recognized as a high priority for these operations.

As mentioned early in this document, in person meetings were held with HTO groups in the communities, meetings with Federal /Provincial groups in Iqaluit prior to the commencement of the EA development. A copy of these meetings can be found in Appendix B. It is anticipated that RPS Energy will return to some communities for public meetings in late May 2011. These meetings were scheduled for May 1-6th but negative feedback due to it being election week, resulted in the decision to cancel the meetings and reschedule.

5.8 FOLLOW-UP

No specific effects monitoring programs are indicated by this assessment. The survey provides a very good opportunity to collect environmental observation data related to some of the region's VEC's, specifically seabirds and marine mammals. After the survey the observation data will be submitted to the NEB (to pass onto Environment Canada and Fisheries and Oceans Canada), and will include a report on the results of the monitoring program.

Importance of ensuring the location of the survey activity is conveyed to the communities before the program begins. Onboard MMO will communicate this to the Hunters & Trappers Organization onshore, such that there is good awareness.

Further discussions will take place with the fishing fleet's to ensure exchange of contacts before survey work commences.

Statement of Canadian Practice

Fisheries and Oceans Canada | Pêches et Océans Canada

Canada

Statement of Canadian Practice with respect to the Mitigation of Seismic Sound in the Marine Environment

Context

The Statement of Canadian Practice with respect to the Mitigation of Seismic Sound in the Marine Environment specifies the mitigation requirements that must be met during the planning and conduct of marine seismic surveys, in order to minimize impacts on life in the oceans. These requirements are set out as minimum standards, which will apply in all non-ice covered marine waters in Canada. The Statement complements existing environmental assessment processes, including those set out in settled land claims. The current regulatory system will continue to address protection of the health and safety of offshore workers and ensure that seismic activities are respectful of interactions with other ocean users.

Definitions

Cetacean: means a whale, dolphin or porpoise.

Critical habitat: means the habitat that is necessary for the survival or recovery of a listed wildlife species and that is identified as the species' critical habitat in the recovery strategy or in an action plan for the species.

Marine Mammal Observer: means an individual trained to identity different species of marine mammals and turtles that may reasonably be expected to be present in the area where the seismic survey will take place.

Marine mammals: means all cetaceans and pinnipeds.

Passive Acoustic Monitoring: means a technology that may be used to detect the subsea presence of vocalizing cetaceans.

Pinniped: means a seal, sea lion or walrus.

Ramp-up: means the gradual increase in emitted sound levels from a seismic air source array by systematically turning on the full complement of an array's air sources over a period of time.

Seismic air source: means an air source that is used to generate acoustic waves in a seismic survey.

Seismic air source array(s): means one or a series of devices designed to release compressed air into the water column in order to create an acoustical energy pulse to penetrate the seafloor.

Seismic survey: means a geophysical operation that uses a seismic air source to generate acoustic waves that propagate through the earth, are reflected from or refracted along subsurface layers of the earth, and are subsequently recorded.

"Statement": means the Statement of Canadian Practice for the Mitigation of Seismic Sound in the Marine Environment.

Whale: means a cetacean that is not a dolphin or porpoise.

Application

1. Unless otherwise provided, the mitigation measures set out in this Statement apply to all seismic surveys planned to be conducted in Canadian marine waters and which propose to use an air source array(s).

2. The mitigation measures set out in this Statement do not apply to seismic surveys conducted:
    a. on ice-covered marine waters; or
    b. in lakes or the non-estuarine portions of rivers.

Planning Seismic Surveys

Mitigation Measures

3. Each seismic survey must be planned to
    a. use the minimum amount of energy necessary to achieve operational objectives;
    b. minimize the proportion of the energy that propagates horizontally; and
    c. minimize the amount of energy at frequencies above those necessary for the purpose of the survey.

4. All seismic surveys must be planned to avoid:
    a. a significant adverse effect for an individual marine mammal or sea turtle of a species listed as endangered or threatened on Schedule 1 of the *Species at Risk Act*; and
    b. a significant adverse population-level effect for any other marine species.

5. Each seismic survey must be planned to avoid:
    a. displacing an individual marine mammal or sea turtle of a species listed as endangered or threatened on Schedule 1 of the *Species at Risk Act* from breeding, feeding or nursing;
    b. diverting an individual migrating marine mammal or sea turtle of a species listed as endangered or threatened on Schedule 1 of the *Species at Risk Act* from a known migration route or corridor;
    c. dispersing aggregations of spawning fish from a known spawning area;
    d. displacing a group of breeding, feeding or nursing marine mammals, if it is known there are no alternate areas available to those marine mammals for those activities, or that if by using those alternate areas, those marine mammals would incur significant adverse effects; and
    e. diverting aggregations of fish or groups of marine mammals from known migration routes or corridors if it is known there are no alternate migration routes or corridors, or that if by using those alternate migration routes or corridors, the group of marine mammals or aggregations of fish would incur significant adverse effects.

Safety Zone and Start-up

Mitigation Measures

6. Each seismic survey must:
    a. establish a safety zone which is a circle with a radius of at least 500 metres as measured from the centre of the air source array(s); and
    b. for all times the safety zone is visible,
        i. a qualified Marine Mammal Observer must continuously observe the safety zone for a minimum period of 30 minutes prior to the start up of the air source array(s), and
        ii. maintain a regular watch of the safety zone at all other times if the proposed seismic survey is of a power that it would meet a threshold requirement for an assessment under the *Canadian Environmental Assessment Act*, regardless of whether the Act applies.

7. If the full extent of the safety zone is visible, before starting or restarting an air source array(s) after they have been shut-down for more than 30 minutes, the following conditions and processes apply:
    a. none of the following have been observed by the Marine Mammal Observer within the safety zone for at least 30 minutes:
        i. a cetacean or sea turtle,
        ii. a marine mammal listed as endangered or threatened on Schedule 1 of the *Species at Risk Act*, or
        iii. based on the considerations set out in sub-section 4(b), any other marine mammal that has been identified in an environmental assessment process as a species for which there could be significant adverse effects; and
    b. a gradual ramp-up of the air source array(s) over a minimum of a 20 minute period beginning with the activation of a single source element of the air source array(s), preferably the smallest source element in terms of energy output and a gradual activation of additional source elements of the air source array(s) until the operating level is obtained.

Shut-down of Air Source Array(s)

Mitigation Measures

8. The air source array(s) must be shut down immediately if any of the following is observed by the Marine Mammal Observer in the safety zone:
    a. a marine mammal or sea turtle listed as endangered or threatened on Schedule 1 of the *Species at Risk Act*; or
    b. based on the considerations set out in sub-section 4(b), any other marine mammal or sea turtle that has been identified in an environmental assessment process as a species for which there could be significant adverse effects.

Line Changes and Maintenance Shut-downs

Mitigation Measures

9. When seismic surveying (data collection) ceases during line changes, for maintenance or for other operational reasons, the air source array(s) must be:
    a. shut down completely; or
    b. reduced to a single source element.

10. If the air source array(s) is reduced to a single source element as per subsection 9(b), then:
    a. visual monitoring of the safety zone as set out in section 6 and shut-down requirements as set out in section 8 must be maintained; but
    b. ramp-up procedures as set out in section 7 will not be required when seismic surveying resumes.

Operations in Low Visibility

Mitigation Measures

11. Under the conditions set out in this section, cetacean detection technology, such as Passive Acoustic Monitoring, must be used prior to ramp-up for the same time period as for visual monitoring set out in section 6. Those conditions are as follows:
    a. the full extent of the safety zone is not visible; and
    b. the seismic survey is in an area that
        i. has been identified as critical habitat for a vocalizing cetacean listed as endangered or threatened on Schedule 1 of the *Species at Risk Act*, or
        ii. in keeping with the considerations set out in sub-section 4(b), has been identified through an environmental assessment process as an area where a vocalising cetacean is expected to be encountered if that vocalizing cetacean has been identified through the environmental assessment process as a species for which there could be significant adverse effects.

12. If Passive Acoustic Monitoring or similar cetacean detection technology is used in accordance with the provision of section 11, unless the species can be

identified by vocal signature or other recognition criteria:

a. all non-identified cetacean vocalizations must be assumed to be those of whales named in sections 8(a) or (b); and
b. unless it can be determined that the cetacean(s) is outside the safety zone, the ramp-up must not commence until non-identified cetacean vocalizations have not been detected for a period of at least 30 minutes.

Additional Mitigative Measures and Modifications

Mitigation Measures

13. Persons wishing to conduct seismic surveys in Canadian marine waters may be required to put in place additional or modified environmental mitigation measures, including modifications to the area of the safety zone and/or other measures as identified in the environmental assessment of the project to address:
    a. the potential for chronic or cumulative adverse environmental effects of
        i. multiple air source arrays (e.g., two vessels on one project; multiple projects), or
        ii. seismic surveys being carried out in combination with other activities adverse to marine environmental quality in the area affected by the proposed program or programs;
    b. variations in sound propagation levels within the water column, including factors such as seabed, geomorphologic, and oceanographic characteristics that affect sound propagation;
    c. sound levels from air source array(s) that are significantly lower or higher than average; and
    d. species identified in an environmental assessment process for which there is concern, including those described in sub-section 4b).

14. Variations to some or all of the measures set out in this Statement may be allowed provided the alternate mitigation or precautionary measures will achieve an equivalent or greater level of environmental protection to address the matters outlined in sections 6 through 13 inclusive. Where alternative methods or technologies are proposed, they should be evaluated as part of the environmental assessment of the project.

15. Where a single source element is used and the ramping up from an individual air source element to multiple elements is not applicable, the sound should still be introduced gradually whenever technically feasible.

Appendix A Meeting Scheduled

1. Introduction

RPS Energy on behalf of Multi Klient Invest filed with the National Energy Board a Project Description for the potential 2D Seismic Survey offshore Baffin Bay within their jurisdiction.

NEB has issued a Section 5 Federal Coordination Notification (FCN) for the proposed TGS/PGS Northeastern 2D offshore seismic program in the Baffin Bay/Davis Strait area (MKI the operator an association of PGS). Federal coordination was initiated for this project in the spring of 2010, however the project was suspended until 2011 and the project area has since expanded.

They have request that stakeholders kindly respond to this Notification by 10 February 2011.

The following documents were attached.
- a Letter of Federal Coordination Notification
- a Response Form
- a Project Description received by the NEB for the project

A public registry for this was posted on the NEB website and an opportunity for public comment on the draft scope and draft environmental screening report will be provided when available.

RPS Energy is engaged by MKI to carry out the consultation program in support of the Environmental Assessment for the proposed Seismic Project to be conducted offshore Baffin Bay in 2011.

The consultation was planned to facilitate the consideration of stakeholders regarding public issues and concerns that are relevant to the overall project and that will need to be specifically addressed in the environmental assessment report.

These consults have enabled a much better understanding on the relationship between the peoples, land, sea, and wildlife. Safeguarding wildlife and habitats through the food chain was emphasised at the Qikiqtarjuaq meeting.

The consultations conducted as part of this study were the first in the field of marine seismic 2008, and again in 2011, as such there were many questions about how the survey was to be performed, why it being done, what were the potential impacts, and what were the safeguards. Some of the feedback which came early in the consults was how appreciative the communities were to receiving this knowledge in light of the fact that work has been performed in the past without similar consultations taking place.

Thus, from the standpoint of opening up lines of communication there was no substitute for these in-person presentations. In particular, the HTO’s were very welcoming and provided facilities and their own time

The mitigation measures proposed for this survey, which follow the Statement of Canadian Practice on the Mitigation of Seismic Noise in the Marine Environment, will

ensure that any potential interaction is kept to a minimum. As this survey is a single event and the lines are widely spaced, it is highly unlikely that any measurably impact will occur during the survey considering the mitigation methods adopted.

The proposed program is an exploration survey only, designed to map the sub-sea geology, and is a first step in the exploration cycle. The issues pertaining to drilling and development were not considered here, as they represent separate processes which would occur many years in the future, if at all.

An appreciation of the traditional knowledge was obtained by consulting two major studies: *The Nunavut Wildlife Harvest Study* (Nunavut Wildlife Management Board, August 2004), and the *Final Report of the Inuit Bowhead Knowledge Study* (Nunavut Wildlife Management Board, March 2000). And this knowledge was shared in the meetings.

2. Federal/Provincial Meetings

2.1 Nunavut Department of Development and Transportation

Date & Time of the meeting	Monday Jan. 10th, 2011 10:00 - 12:00 a.m. Tuesday Jan. 11th, 2011 2:00-3:00 Separate discussions on PAM with Dave Hedgeland-PGS.
Location	Iqualuit
Organization	Nunavut Department of Development and Transportation
Proponent Speaker	Tony LaPierre / Darlene Davis-RPS Energy PGS – Dave Hedgeland – Environmental Manager
Proponent Translator	None
Personnel	Peter Frampton Senior Petroleum Advisor Eric Prosh Director Minerals & Petroleum Resources Diane LaPierre Mgr, Environmental Assessments & Reg Janelle Kennedy BSc.Envs., MMM-Environment (Sr. Advisor, Aquatic Science, Fisheries and Sealing)
Advertisement for the meeting:	Direct e-mail contact / Telephone
Delivery of the meeting	PowerPoint Presentation
Duration of the meeting	2 hour
Issues /Concerns Expressed: - Support the program - Shared knowledge and discussion on how to consult with the communities - PAM (Passive Accoustic Monitoring) discussion on the possibility of using this and benefits of using this for the program - Source Discussion - Lancaster sound (Exact Area) discussion on this program in relation to NRCan survey in 2010	
Methods of Addressing Concerns: - Discussion and follow-up correspondence - Community Meetings	
Significance of impact	Not significant
Recommendations: -Very supportive of the Program -Observer should come from the communities -Photos (graphics) are great for community meetings -Animation of “Statement of Practice” -Translate as much as possible -Bring hard copies of the maps to leave with communities -“Don’t deny that Seismic can lead to development”	
Feedback / Future meeting	Separate presentation in the afternoon at 2:00 pm with Dave Hedgeland (PGS Environmental Mgr) as he couldn’t be in the a.m. meeting, late flight arrival. February 21st-Met with Diane LaPierre to discuss the facilitation of Pubic meetings in the communities and share information.

2.2 Department of Indian and Northern Affairs (INAC)

Date & Time of the meeting	Monday, January 11th, 2011 2:00-4:00 pm
Location	Iqualuit
Organization	Department of Indian and Northern Affairs
Proponent Speaker	Tony LaPierre / Darlene Davis –RPS Energy Dave Hedgeland-PGS Environmental Manager
Proponent Translator	None
Personnel	Robynn Gillis Petroleum Advisor Bernie McIsaac Director Operations Nunavut Regional Karen Costello Mgr.Minerals Resources Linda Ham Nunavut Development Corporation Resource Development Advisor (Telephone Conference) Derek Moggy –Habitat Team Leader, Eastern Arctic -DFO Gilles Norell-Oil & Gas INAC
Advertisement for the meeting	Direct e-mail contact/Telephone
Delivery of the meeting	PowerPoint Presentation
Duration of the meeting	2 hrs

Issues /Concerns Expressed:
-Support to build a presentation for the communities and conversation on concerns
-Concerns: LanCaster Sounds, Seismic in the 70's
-Need to build trust in the communities, need for several meetings in communities
-Robyn – Will participate in assisting to build information for the communities and travel with Darlene Davis & Tony LaPierre
-Bernie McIssac expressed that there is a huge concern in the communities on "Impacts of Wildlife", migration as it is their livelihood.
-Discussions on Air Gun Sound;
-Gilles brought up the possibility to clearly graphically displace the attenuation of sound away from the source, what it means? Modeling diagrams have been created to explain this clearly and can be found within the EA. (Figure 4 & 5).
-Discussion on Passive Accoustic Monitoring, will it be used?
-Benefits plan for the northern communities / -People want to be part of the planning

Methods of Addressing Concerns:

- Prepare the proposed benefits plan by the operator in consultation with aboriginals and northern communities in the vicinity of the proposed exploration (i.e. coastal communities)
- Look into further the possibility of using Passive Accoustic Monitoring

Significance of impact	Not significant

Recommendations

- Advised consulting with northern communities; also to use diagrams while explaining issues while avoiding graphs and technical language
- Explain how low the sound from the seismic is and the response of marine mammals
- Adhere to the requirement of the Northern Benefits Requirements for New Exploration Programs
- More than one visit to the communities
- Passive Accoustic Monitoring should be a mitigation if possible
- Marine Mammal Observers from the communities
-

Feedback / Future meeting	**Darlene Davis met with Robynn Jan 11th** – afternoon for further discussion. Robynn will travel to community meetings (mid Feb). **April 4, 2011 Spoke with George McCormick and Ursela Beddoes (**INAC) who travelled last week to the communities to talk with them about the possibility of opening lease blocks. They felt the overall of their meetings was positive. That Inuit were not opposed to Exploration buy in turn don't want Harvesting affected and have concerns about spills and commercial fishery. In our consultation work, we continue to explain "The Canadian Statement of Practice and the role of the Marine Mammal Observer and Fisheries Liaison Officer onboard the vessel

2.3 Consultation with Nunavut Development Corporation

Date & Time of the meeting	Jan 10th, 2011
Location	Office of INAC
Organization	Nunavut Development Corporation
Proponent Speaker	Tony LaPierre
Proponent Translator	None
Personnel	Linda Ham
Advertisement for the meeting	Direct e-mail contact / Linda Ham came to the meeting in the Boardroom of INAC
Delivery of the meeting	Presentation given using MS PowerPoint for 1 hour.
Duration of the meeting	2.0 hours
Issues /Concerns Expressed: Participated in the conversations as above -	
Methods of Addressing Concerns: - Complete consultations prior to the survey start - Involve community members as fisheries representatives or environment observer roles on the project	
Significance of impact	Not significant
Recommendations - Complete consultations with coastal communities	
Feedback / Future meeting	Progress feedback to be sent during and after the survey

2.4 Derrick Moggy –Habitat Team Leader, Eastern Arctic Area -DFO

Date & Time of the meeting	Wednesday January 12th, 2011 Noon – 1:00 pm
Location	Iqualuit-DFO Tumit Plaza
Organization	Department Fisheries & Oceans
Proponent Speaker	Tony LaPierre RPS Energy Dave Hedgeland PGS Environmental Mgr
Proponent Translator	None
Personnel	Derrick Moggy-Habitat Leader Eastern Arctic Area DFO
Advertisement for the meeting	Direct e-mail derrick.moggy@dfo-mpo.gc.ca Telephone (705) 522-9909 Cell: (705) 919.6255
Delivery of the meeting	Powerpoint
Duration of the meeting	1 Hr
Issues /Concerns Expressed: Tony LaPierre and Dave Hedgeland met in-person with Derrick Moggy for further discussions on the project. -	
Methods of Addressing Concerns: Consultation in the communities Mitigation Measures Observers from the communities -	
Significance of impact	Not significant
Recommendations -	
Feedback / Future meeting	

2.5 Consultation with Baffin Fisheries Coalition

Date & Time of the meeting	Tuesday January 11th 2:00pm.
Location	Iqualuit
Organization	Baffin Fisheries Coalition
Proponent Speaker	Darlene Davis
Proponent Translator	None
Personnel	Jerry Ward
Advertisement for the meeting	Direct e-mail contact / Telephone
Delivery of the meeting	Meeting cancelled.
Duration of the meeting	
Issues /Concerns Expressed: Jerry was unable to be in Iqaluit at this time as he travels back and forth to Newfoundland. Tried to re-schedule and Jerry would be in Halifax on March 30th, schedules did not allow. Darlene to try to facilitate a meeting with Jerry when back in Newfoundland if possible. -	
Methods of Addressing Concerns: -	
Significance of impact	Not significant
Recommendations -	
Feedback / Future meeting	Will be advised of Public Meeting

2.6 Consultation with Nunavut Wildlife Management Board

Date & Time of the meeting	November 30, 2011
Location	Iqaluit
Organization	Nunavut Wildlife Management Board
Proponent Speaker	Tony LaPierre / Darlene Davis
Proponent Translator	None
Personnel	Robert Kidd-Director of Wildlife Management
Advertisement for the meeting	Direct e-mail contact /Telephone
Delivery of the meeting	
Duration of the meeting	

Issues /Concerns Expressed:

In order to meet with NWMB you must send a letter in both languages and ask permission to make a presentation. There next scheduled meeting is in March 2011.

-

Methods of Addressing Concerns:

RPS Energy will be returning to Iqaluit first week in May for a public meeting. The meeting will be posted and on the radio. This will give members of NWMB and opportunity to attend if they want information on the project.

Due to election meeting in Iqaluit is to be re-scheduled. This will be a public meeting.

-

Significance of impact	Not significant

Recommendations

-

Feedback / Future meeting	Public Meeting

2.7 Consultation with Nunavut Research Institution

Date & Time of the meeting	Tuesday, January 11th 10:00 a.m.
Location	Iqualuit-Frobisher Inn
Organization	Nunavut Research Institution
Proponent Speaker	Tony LaPierre/Darlene Davis/Dave Hedgeland
Proponent Translator	None
Personnel	Mary Ellen Thomas Senior Research Officer
Advertisement for the meeting	Direct e-mail contact
Delivery of the meeting	Brief ½ hour meeting in her office.
Duration of the meeting	.30 hours

Issues /Concerns Expressed:

- Review the need for Fisheries Liaison Officers and Environmental Observers for the seismic program
- Two year Environmental tech program
- 15 first year students, 10 second year
- Don't see a lot of support from the communities
- Bowhead hunt in Iqaluit area will bring discussions
- Lancaster Sound, makes "Seismic a Dangerous word in Baffin"
- Don't expect a positive reaction in communities
- Pond Inlet the only community with an Environmental Program
-

Methods of Addressing Concerns:

- Candidates with offshore safety training and with data collection ability would be good for the MMO role
- Six candidates recently completed the Fisheries Observer program
- Their primary role, onboard fishing vessels, is monitoring catches and observations on marine mammals
- Recommended a translator though Simone (phone: 867-473-2653) for community visits

Significance of impact	Not significant

Recommendations

-Public meeting will be held (Appendix A)
-Two Marine Mammal and one Fisheries Liaison Officer will be onboard at all times
-Canadian Statement of Practice to be followed

Feedback / Future meeting	Public Meeting in Iqaluit May 1, 2011 Re-scheduled end May, early June 2011.

2.8 Consultation with Qikiqtani Inuit Association (QIA)

Date & Time of the meeting	January 11th, 2011 10:00 am -12:00 noon
Location	Iqaluit
Organization	Qikiqtani Inuit Association
Proponent Speaker	Tony LaPierre
Proponent Translator	None
Personnel	Okalik Eegeesiak President Sal Shoo Director of Lands Matthew Akavak Lands Officer Evie Eegeesiak Implementation Co-ordinator Joanasie Akumalik CLO co-ordinator Nigel Qaumariaq Env. & Regulary Affairs Advisor
Advertisement for meeting	Direct e-mail contact/Telephone
Delivery of the meeting	PowerPoint Presentation
Duration of the meeting	2 hours
Issues /Concerns Expressed: -Time of year for the project -Mitigation Measures -Community Meetings, how much time we are willing to devote? -Passive Accoustic Monitoring (PAM)? -Possibility of Nigel/president attending the community meetings -details on the vessel -Supply vessel, remaining after the survey to monitor the area for several days after -Marine Mammal Observer training, candidates from the communities -Add Artic Bay to consultation list of another communities to consult -If the communities are not happy the program will not proceed -Science says the mammals leave the area, how do you know they are gone? -	
Methods of Addressing Concerns: -Discussions -Follow /up conference call on Jan. 17/2011 at 3:00 pm Atlantic Time. (QIA advises they do not have time/resources to support the project in 2010, but they advise they would in 2011. -Attendees: Darlene Davis, Dave Hedgeland (TGS Nopec), Tony LaPierre -Nigel invited to attend community meeting in Pond Inlet. -Nigel sent his community Liaison officer to community meeting in Clyde River -	
Significance of impact	Significant
Recommendations -Passive Accoustic Monitoring -Supply vessel remain to observe after the program -Marine Mammal Observers from the communities -Several meetings with the communities, listen to their concerns and make them feel they are being asked and participating in the program -Consult information for the communities pictures and as much translated documentation as possible should be with you	
Feedback / Future meeting	Conf. Call Jan 17th at 3 pm Atlantic for further discussions. Attend Meeting Pond Inlet February 16th, 2011, Meeting Feb. 18th – Iqaluit (Nigel cancelled), Meeting Feb. 21st – Iqaluit (cancelled), Conf. call March 17th, advice on Public Meeting.

2.9 Consultation with Nunavut Tunngavik Inc.

Date & Time of the meeting	Contacted via email Nov 29th, 2011
Location	Iqaluit
Organization	Nunavat Tunngavik Inc
Proponent Speaker	Darlene Davis
Proponent Translator	None
Personnel	Jeffrey Maurice, Inuit Rights Fisheries Advisor (phone: 867-975-4734)
Advertisement for the meeting	Direct e-mail contact /telephone
Delivery of the meeting	N/A
Duration of the meeting	N//a
Issues /Concerns Expressed: - Consultation with the communities - Sent consultation note from previous project in 2008 for review	
Methods of Addressing Concerns: -	
Significance of impact	Not significant
Recommendations -	
Feedback / Future meeting	None/ Public Meeting will be advertised.

2.10 Nunavut Planning Commission

Date & Time Contact Via Email	January 19th, 2011
Location	Via Email
Organization	Nunavut Planning Commission (NPC)
Contact Initiated by	Darlene Davis, Marine Project Coordinator
Delivery	Full Project Description Summary on Meetings in Iqaluit & Planned HTO Meetings
Issues /Concerns Expressed: Good morning Darlene; Email is to confirm that the above noted/attached proposal falls outside the boundaries of the North Baffin Regional Land Use Plan. Therefore no conformity review with the approved plan is required. Any questions concerns, please do not hesitate. Brian Aglukark, NPC Arviat -	
Methods of Addressing Concerns: - Via Email sent Project Description.	
Significance of impact	Not significant
Recommendations Not within their Jurisdiction	

2.11 Parks Canada

Date & Time Contact Via Email	January 17th, 2011
Location	Via Email
Organization	Parks Canada Doug Yurick Chief Marine Program Coordinator
Contact Initiated by	Darlene Davis, Marine Project Coordinator
Delivery	Full Project Description

Issues /Concerns Expressed:
Email from Doug Yurick:

I understand that you are aware of the controversy generated last year by the proposed Canada - Germany Eastern Canadian Arctic Seismic Experiment in the Baffin Bay - Lancaster Sound region.

As you likely know, several ministers of the Government of Canada announced jointly, on December 6, 2010, the federal position regarding the boundary of the proposed NMCA. I am attaching the press release of that date, and the mapped boundary. My understanding from the petroleum regulatory affairs group in Indian and Northern Affairs Canada is that the project you are contemplating is entirely beyond the limits of territorial sea ofCanada. Nowhere does the eastern limit of the presently proposed NMCA boundary extend beyond the territorial sea.

Please contact me directly at Parks Canada should you require additional information about the NMCA.

Best wishes,

-

Methods of Addressing Concerns:
Via Fisheries and Oceans Canada to obtain a map indicting the limits of the proposed national marine conservation area (NMCA) in Lancaster Sound.

Significance of impact	Not significant

Recommendations

2.12 World Wildlife Federation (Peter Ewan)

Date & Time Contact Via Email	January 19th, 2011 Peter Ewans, D. Phil Senior Officer, Species
Location	Via Email
Organization	WWF
Contact Initiated by	Darlene Davis, Marine Project Coordinator
Delivery	Full Project Description via email

Issues /Concerns Expressed:
Email Response Peter Ewan:
many thanks Darlene. I will consult with some key colleagues on this one, especially in light of the current NEB offshore review underway, and now that the US Gulf incident report is out. Hope to get back to you soon.

best wishes

Pete

-

Methods of Addressing Concerns

NEB has placed the project description for Federal Coordination along with opportunity for public comment.
See Email:
Please find attached a Section 5 Federal Coordination Notification (FCN) for the proposed TGS/PGS Northeastern 2D offshore seismic program in the Baffin Bay/Davis Strait area. Federal coordination was initiated for this project in the spring of 2010, however the project was suspended until 2011 and the project area has since expanded.

I am requesting that you kindly respond to this Notification by 10 February 2011.

Attached are the following documents:
- a Letter of Federal Coordination Notification
- a Response Form
- a Project Description received by the NEB for the project

A public registry for this file will be posted on the NEB website shortly, and an opportunity for public comment on the draft scope and draft environmental screening report will be provided when available. Should anyone included in this notification be addressed incorrectly, or should you have any questions, please do not hesitate to contact me at the address below.

Significance of impact	Not significant

Recommendations

-

3. Communities Meetings

3.1 Consultation with Baffin HTO's (Clyde River)

Date & Time of the meeting	February 14th, Monday 7:00pm-10:00 pm
Location	Office of HTO
Organization	Baffin HTO, Clyde River Email: cedo@clyderiver.ca (Billy) Rebecca HTO Manager htoclyde@qiniq.com 867-924-6202
Proponent Speaker	Tony LaPierre Geologist Darlene Davis – Project Manager
Proponent Translator	
Personnel	HTO Manager - Rebecca Lizzy Palituq – Community Liason Officer Jayko Asheuak – Chariman Anasic Audlakiak – Vice Chairman Leah Arreak – Secretary Treasurer Tommy Kumiliusie - Director Joanasic Apak – Director Jaycopic Iqaukjuak – Director Jayko Apak (member) Deckhand Certificate INAC – Robynn Aberney Gillis
Advertisement for the meeting	Direct e-mail contact
Delivery of the meeting	Presentation given using MS PowerPoint during Meeting
Duration of the meeting	7:00 pm-9:45 pm

Issues /Concerns Expressed:

- Opportunities for local persons on the project
- How much company is looking at benefiting Clyde River?
- In the past surveyors don't give benefit to the community
- Mine further North – Is not giving them opportunities?
- Concerned that they have no birth certificates or passports, and how this will effect the ability for someone to ride onboard the vessel to be involved in project
- Wanted to know if we have approval (NEB)?
- Want to have a public meeting, $100 hour to rent community centre, give door prized to get people to attend or they won't come out, they suggest 45 gal of fuel and 45 gal of heating oil, cash prize
- HTO will set up public meeting for April 1st or 2nd and communicate with Darlene Davis on details
- Overall very concerned about Marine Mammals./harvesting/Migration and effects from seismic activity

Methods of Addressing Concerns:

- Conduct public meeting
- Keep them informed
- Notify them when the vessel starts work and is in the area
- Select MMO from their community
- Look into Transport Canada would they need passport to ride vessel in Canada
- Involve community members as fisheries representatives or environment observer roles on the project

While in Clyde River, Tony LaPierre (Geologist) taught two classes in Geology to grade 10

students and told then about the project.	
Significance of impact	Not significant
Recommendations -	
Feedback / Future meeting	Public Meeting April 1st or 2nd, follow up meeting Provide copies of Marine Mammal reports after survey. -RPS follow-up with an email upon return, no meeting was set up by HTO, RPS has proceeded to schedule meetings via meeting notice for return visits Appendix A. Due to negative feedback from HTO Manager Clyde river, the meeting is being re-scheduled due to election week.

3.2 Consultation with Baffin HTO's (Pond Inlet)

Date & Time of the meeting	February 16th (Wednesday) 2011 1:00 pm
Location	Office of HTO
Organization	Baffin HTO, Pond Inlet
Proponent Speaker	Tony LaPierre – Geologist / Project Darlene Davis – Project Manager
Proponent Translator	
Personnel	James – Acting Vice Chairman Charmin and Vice Chairmen out of town to another meeting QIA-Nigel Qaumariaq INAC-Robyn Aberney Gillis
Advertisement for the meeting	Direct e-mail contact
Delivery of the meeting	Presentation given using MS PowerPoint for 1 hour.
Duration of the meeting	1.5 hours

Issues /Concerns Expressed:

- Ships spilling into the water, happened last year?
- Will it bother the whales?
- Narwhales start migrating June – August ?
- Ice is always going through this area
- Very concerned about are whales and sensitive about are food supply
- While we are here, we are protective of our animals and are way of life
- How loud is the sound?
- Will you have a public meeting?
- Concerned about the Narwhales
- Are you coming back?
- QIA (Nigel attended meeting) advised he would be back for Public meeting
- QIA advised possible two other projects, he would return to speak about this
- Robyn – INAC would return to speak to them about their opinions on opening up lease blocks?

Methods of Addressing Concerns:

- This marine wildlife area extends from the coast to 12 nautical miles, however as the survey area does not commence until the 12 nautical mile limit, the project area does not encroach into this area.
- Involve community members as fisheries representatives or environment observer roles on the project
- Conduct Public Meeting

Significance of impact	Not significant

Recommendations

-

Feedback / Future meeting	Public Meeting, as per Appendix A. Meeting re-scheduled due to election.

3.3 Consultation with Baffin HTO's (Qikiqtarjuaq)

Date & Time of the meeting	February 17th (Thursday) 2011-02-20 7:00 pm – 9:30 pm
Location	Office of HTO
Organization	Baffin HTO, Qikiqtarjuaq
Proponent Speaker	Darlene Davis – Project Manager
Proponent Translator	
Personnel	HTO Manager – Harry Alookie Samuel Nuqingaq – Secretary-Treasurer Board Members Robyn Aberthy Gillis - INAC
Advertisement for the meeting	Direct e-mail contact
Delivery of the meeting	Presentation given using MS PowerPoint during meeting. Minutes of the meeting were kept by the General Secretary.
Duration of the meeting	2.5 hrs

Issues /Concerns Expressed:

- Harvesting activities are very important, very concerned about the whales and their way of life;
- They know that seismic will hurt the whales, they will be dead and not float to the surface for three months because they are heavy
- Concerned about sedimentary areas for the turbot fish live their
- Concerned about Corel zone and how airguns will affect this?
- Concerned about Trophy Week, fishing trip they make to take people to catch a whale in Baffin Bay in July August time, they make $2500 per trip, Will this affect them catching whales?
- Will you get approval whether we agree or not?
- Do you have permission?
- We want to be informed
- We will work with you
- Government doesn't listen to us
- Will you do a public meeting
- What did the other communities think of this project? We are certain they would not agree
-

Methods of Addressing Concerns:

- Hold a public meeting
- Deal with HTO Manager to share information and keep them informed
- Stay in contact
- Share information via email

Significance of impact	Not significant

Recommendations

-

Feedback / Future meeting	Public Meeting as per Appendix A. Meeting being re-scheduled due to election.

3.4 Consultation with Baffin HTO's (Iqaluit)

Date & Time of the meeting	February 21st, 2011 (Monday) 4:00-4:30 pm
Location	Office of HTO Jose – HTO Manager amrok@qiniq.com Phone: 867-979-3066
Organization	Iqaluit HTO Chairman
Proponent Speaker	Darlene Davis Project Manager
Proponent Translator	Not necessary
Personnel	David Alexander Baffin Fisheries Coalition Manager Chairman for HTO
Advertisement for the meeting	Contacted while in Iqaluit to set up a short meeting to introduce myself and RPS Energy role in the permit process.
Delivery of the meeting	Conversation.
Duration of the meeting	30 min
Issues /Concerns Expressed: - Introduced myself, told him about the proposed program offshore Baffin Bay. - Asked him to set up a meeting with HTO members and public meeting for a return visit end of March 2011-02-21 - He expressed if we want their approval they would need support letters from other communities, supporting the project - Expressed he is concerned with commercial fisheries as he works with - Baffin Fisheries Coalition - Left him a copy of the program - Left him a copy of the Canadian Statement of Practice both in English and Inuktitut	
Methods of Addressing Concerns: - Left him a copy of Canadian Statement of Practice both in English and Inuktitut - Will send follow up information via email - Will hold a public meeting, and meeting with all HTO and follow up meeting when they have been completed to address additional questions -	
Significance of impact	Not significant
Recommendations - Share information about the proposed project, and have representatives from the communities onboard as environmental observers	
Feedback / Future meeting	Public meeting as per Appendix A. Meeting will be re-scheduled due to election week.

3.5 Consultation with Baffin HTO's (Pangnirtung)

Date & Time of the meeting	No Meeting
Location	
Organization	Baffin HTO, Pangnirtung
Proponent Speaker	Darlene Davis
Proponent Translator	
Personnel	
Advertisement for the meeting	Direct e-mail contact Contracted Eric Joamie from Pang to set up meeting.
Delivery of the meeting	
Duration of the meeting	
-We were unable to get a scheduled meeting unfortunately in Pang on this visit. They were in the process of changing HTO managers and this meeting did not come together. -Upon arrival for the other communities, the contracted translator (Eric Joamie) did not show. This made the task much more difficult in each community. -March 3th – Eric Joamie advised he had worked with council and mentioned the matter to the new HTO Manager. (Jackie Maniapik new HTO Manager) -March 7th – HTO board to hold meeting -March 8th – Provide Jacki with information (Project Description sent via email) -March 10th – Advised best dates for meeting approximately April 3 or 4th -April 7th – Sent RPS schedule for meetings in communities to include Pang in both languages.	
Significance of impact	Not significant
Recommendations : Include Pang in the public meeting notice (Appendix A). -	
Feedback / Future meeting	Public meeting being re-scheduled due to the election week.

4. Baffin Bay Public Meetings

Upon completion of the initial meetings with Hunters and Trappers Associations in the communities, it was apparent that a need for public meetings would be adhered to.

Upon completion of the in-person meetings with the HTO groups it was understood that HTO Managers would set up public meetings by communicating and working together to do so. Unfortunately time did not allow for this to come together.

In a conference call meeting with QIA on March 17, 2011 it was recommended that RPS Energy take the following steps to set-up public meetings:

- Select Dates Translate
- Send to SAO of Hamlet
- Advertise on the Radio
- Rent meeting Hall

A copy of the meeting notice can be located in Appendix A.

The meetings have been re-scheduled, due to negative feedback based on the timing being election week. RPS is making efforts currently to make arrangements to re-schedule and get notices out to the communities for tentatively late May, early June 2011.

Appendix A.

A representative of RPS Energy of Behalf of Multi Klient Invest (MKI) will be in your community on the following dates for Public Meeting to share information on a potential 2D Seismic Survey offshore Baffin Bay for the 2011 season.

Community	Date	Location	Time
Iqaluit	May 1/11	Frobisher Inn	7:00 pm
Clyde River	May 2/11	Community Centre	7:00 pm
Pond Inlet	May 3/11	Community Centre	7:00 pm
Quik	May 4/11	Community Centre	7:00 pm
Pangnirtung	May 5/11	Community Centre	2:00 pm

Please listen to your local Radio Station for further updates or you may contact:

Marine Seismic Operations

An Overview

Produced by IAGC to provide a reference to other marine operations in general and the fishing industry in particular.

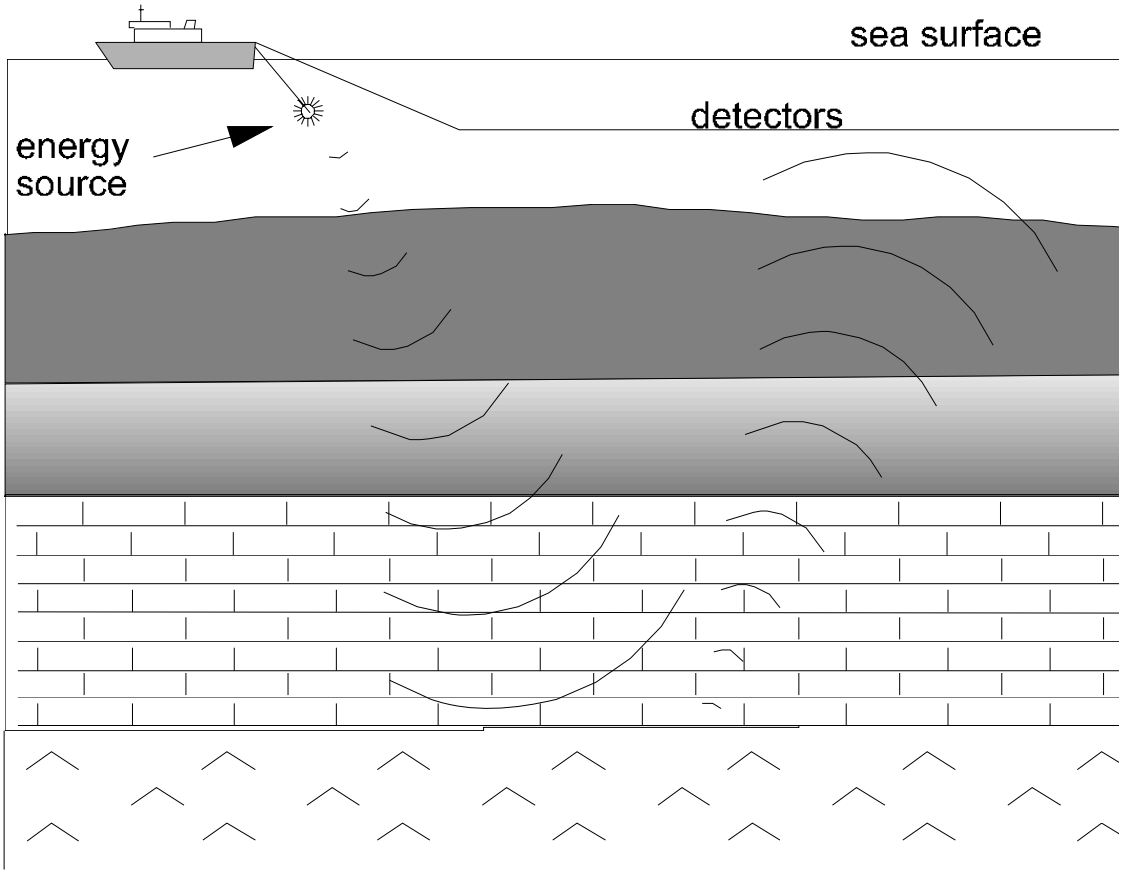
© IAGC March 2002.

Underlying Principles

The dictionary definition for the word seismic means "of or relating to an earthquake" and indeed it comes from the Greek word seismos meaning an earthquake. In its broad scholarly or teaching sense this is what seismic study is about. It involves earthquake measurement, monitoring and prediction. What is measured are the energy waves created by the earthquakes and the effect of these waves close to where the earth's crust actually moved.

Basic Seismic Reflection

In seismic surveying, geophysicists use the same basic physical properties as the earthquake seismologists. Relatively low energy waves are mechanically generated and directed into the earth. Some of the energy is reflected back to the surface from the different layers of rock below the surface. The returning waves are detected with sensitive measuring devices that accurately record the strength of the wave and the time it has taken to travel through the various layers in the earth's crust and back to the surface. These recordings are then taken and, after various adjustments, done mostly by computers, transformed into visual images that give a picture of what the subsurface of the earth is like beneath the seismic survey area. To summarise, although geophysicists cannot see directly beneath the ground, they can use seismic surveying to get a picture of the structure and nature of the rock layers indirectly.



There are many reasons for doing seismic surveys. They are used to check foundations for roads, buildings or large structures such as bridges. They can help to

© IAGC March 2002.

detect ground water. They can be used to assess where coal and minerals are. One of the most common uses is in the search for hydrocarbon resources, gas and oil, and most commercial seismic surveying is carried out in this energy sector.

Oil and gas exploration takes place all over the Earth's surface. It can be generally considered as falling into the two main categories:
- Onshore or Land Exploration
- Offshore or Marine Exploration.

There is a third zone, which is currently of lesser commercial significance. This is commonly called Shallow Water Exploration, but is also sometimes referred to as Transition Zone Exploration (TZ). This involves shallow water areas such as tidal zones, river estuaries or swamplands. Exploration activities in these areas can be very complex.

This document will focus on marine seismic exploration.

2D and 3D Seismic Methodology

The complexity of the seismic survey operation can vary enormously. There are, however, two main types of seismic surveying. These are Two Dimensional or 2D Exploration and Three Dimensional or 3D Exploration. 2D can be described as a fairly basic and inexpensive survey method, which although somewhat simplistic in its method, has been and still is used very effectively to find oil and gas. 3D surveying on the other hand is a much more complex and accurate method of seismic surveying, which involves greater investment and much more sophisticated equipment than 2D surveying. Until the beginning of the 1980's, 2D work predominated in oil and gas exploration but now 3D is the dominant exploration tool.

2D Acquisition

In the 2D method, a single seismic cable or streamer is towed behind the seismic vessel, together with a single source. The reflections from the subsurface are assumed to lie directly below the sail line that the seismic vessel traverses – hence the name 2D. The processing of the data is, by nature of the method, less sophisticated than that employed for 3D surveys. 2D lines are typically acquired several kilometres apart, on a broad grid of lines, over a large area. The method is generally used today in frontier exploration areas before drilling is undertaken, to produce a general understanding of the regional geological structure.

3D Acquisition

A 3D survey covers a specific area, generally with known geological targets generated by previous 2D exploration. Prior to the survey, careful planning will be undertaken to ensure that the survey area is precisely defined, usually carried out by the Oil Company or by specialist contractor personnel. Since much time, money and effort will be put into the acquisition, processing and interpretation of the survey, it is very important that it is designed to achieve the survey objectives. The result of the detailed planning will be a map defining the survey boundaries and the direction of the survey lines. Specific acquisition parameters such as energy source, firing and receiver station intervals, together with the seismic listening time, will also be defined. In 3D surveying, groups of sail lines (or swathes) are acquired with the

© IAGC March 2002.

same orientation, unlike 2D where there is a requirement for orthogonal or oblique lines to the prominent acquisition direction. Simplistically, 3D acquisition is the acquisition of many 2D lines spaced in parallel close together over the area.

The 3D sail line separation is normally of the order of 200 to 400 metres. By utilising more than one source and many parallel streamers towed by the seismic vessel, the acquisition of many closely spaced sub-surface 2D lines, typically between 25 and 50 metres apart, can be achieved by a single sail line. A 3D survey is therefore much more efficient in that many times more data is generated than for 2D. The size of a 3D survey is usually referred to in square kilometres or sometimes the number of line kilometres to be acquired. A small 3D survey size is of the order of 300 square kilometres or 1000 sail line kilometres or 12000 sub-surface 2D kilometres.

3D surveys are typically acquired with a racetrack pattern being employed, to allow adjacent sail lines to be recorded in the same direction (swathe), whilst reducing the time necessary to turn the vessel in the opposite direction. This increases the efficiency of acquiring the data and minimises processing discontinuities, which could adversely affect the interpretation of the data.

With the number of sail line kilometres involved, 3D surveys can take many months to complete. The way in which the data is acquired greatly affects the efficiency of the acquisition and considerable planning goes into this aspect. Whilst a racetrack approach is the favoured one, size and shape of the survey, obstructions, tides, wind, weather, fishing vessels and client specifications amongst others, will clearly affect the efficiency and design of the operations. Usually, a survey is broken into areas and swathes of lines are completed in phases or individual racetracks, but there is no rigid procedure which is followed.

Powerful computers are required to process the large volume of data acquired into a three-dimensional image of the subsurface – hence the term 3D seismic. 3D surveys have now become the preferred method for providing the geological interpreter with subsurface information and account for more than 95% of marine seismic data acquired worldwide. 3D surveys are used in all phases of hydrocarbon exploitation from identifying geological structures which are considered likely to contain hydrocarbons to, in areas of established production, establishing those portions of the reservoir which are not being drained by existing wells. Increasingly, 3D surveys are being repeated regularly on established production fields to monitor the reservoir characteristics and depletion rates, so-called Time Lapse surveys.

Seismic Survey Vessel

Now days, seismic vessels are purpose built with many special features, including accommodation for the seismic crew, the instruments, helideck and quiet engines and propellers. The Captain, is responsible for the safety of the seismic vessel and he has the final say in how the seismic vessel is operated and manouvered.

© IAGC March 2002.

A recently built seismic vessel has the following specifications:
Length: 84 m
Beam: 18.5 m
Draft: 6.2 m
Displacement: 5600 metric tons
Cruising speed: 13.5 Knots
Berths: 50
Endurance at sea: 50 days

The instrument room

This is where the main seismic instrumentation is located and operated. The position of the instrument room varies from vessel to vessel but normally is located centrally, somewhere below the bridge and forward of the back deck. It contains the main seismic instruments for recording seismic data and controlling the seismic streamer(s) and energy source firing. The main navigation system is also here with its links to satellite, radio systems, compasses and all the various positioning control devices and monitors. There is usually a working area for instrument testing and repair.

The back deck

This is an area, which although in detail can vary from vessel to vessel, has the same basic purpose – storage, retrieval and deployment of the seismic equipment that is placed in the sea. The seismic streamers are stored here on large reels and when acquisition is ongoing, they are deployed over the back and/or sides of the vessel and towed directly behind the vessel, subject to feather. The number of streamers varies depending on the vessel but can be as many as sixteen for 3D surveys. All the wiring from the streamers is fed through special connectors to the instrument room. Most vessels have a small streamer repair area on the back deck. The seismic streamers are under control of the geophysical observer section of the crew.

© IAGC March 2002.

The back deck is also the location of the energy source equipment. The energy source is usually made up of airguns, which are fed with high-pressure air. Each source is made up of an array of many different sizes of airguns, linked together with special harnesses and fed with airlines and electronic control cables. When not in use, these cables are stored on reels usually at the forward end of the back deck. During deployment, they are put to sea through a slipway at the rear of the deck. The air feed from the seismic vessel compressors to the arrays is monitored from a control panel, which is housed in a small work shack where airgun repairs can also be done.

In association with the streamers and source arrays is the towing equipment. This is a complex, carefully designed arrangement of specialised gear that enables the multiple streamers and source arrays to be positioned accurately behind the seismic vessel and allows different source and streamer separations depending on the survey design. The airgun system and the towing equipment are the main responsibilities of the mechanical section of the seismic crew.

Finally on the back deck is the navigation or positioning equipment. This usually involves buoy systems containing navigation instruments. Tail buoys are attached to the end of each of the streamers furthest from the vessel. Additional buoys can be attached to the source arrays and towing equipment for example. These are not the only buoys in the system however, and in complex multi streamer/ source/ boat arrangements, the navigators need a lot of other control and monitoring systems on sources, streamers and any other vessels so that the relative positions of all the equipment can be recorded.

© IAGC March 2002.

Compressor room

This contains the compressor engines and compressors, which supply high pressure (nominally 2000 psi) air to the source arrays. The compressors are capable of recharging the airguns rapidly and continuously, enabling the airgun arrays to be fired, typically every ten seconds or so during acquisition of data and for periods of up to 12 hours continuous firing, depending on the length of the sail line. This room is under the mechanics' control and is usually situated in proximity to the back deck.

Seismic Streamer

It is worth noting that due to the action of wind, tides and currents, the seismic streamer does not normally tow directly behind the seismic vessel, but lies in an arc offset from the nominal sail line. This is referred to as feathering and whilst such lateral displacements are not typically crucial to the success of 2D data surveys, they are critically important in 3D, where accurate knowledge of the positions of all sources and receivers is fundamental to the successful application of the technique.

The seismic cable or streamer detects the very low level of reflection energy that travels from the seismic source, through the water layer down through the earth and back up to the surface, using pressure sensitive devices called hydrophones. The hydrophones convert the reflected pressure signals into electrical energy, that is digitised and transmitted along the seismic streamer to the recording system on board the seismic vessel, where the data is recorded on magnetic tape.

The sensitivity and robustness of the streamers is remarkable. Normal noise levels in calm weather conditions are of the order of 2-3 μbar and it is quite common for streamers to remain operating in the water for months at a time.

The streamer itself is made up of five principal components:
- hydrophones, usually spaced one metre apart, but electrically coupled in groups of 12.5 or 25 metres in length.
- electronic modules, which digitise and transmit the seismic data.
- stress members, steel or kevlar, that provide the physical strength required, allowing the streamer to be towed in the roughest of weather. Each streamer may be subjected to several tonnes of towing strain.
- an electrical transmission system, for power to the streamer electronic modules and peripheral devices, and for data telemetry.
- the skin of the streamer in which all the above are housed.

The streamer is divided into sections, each 50-100 metres in length, to allow modular replacement of damaged components. Each section is terminated with a connector unit, which houses the electronic modules. Each section is filled with electrical isolating fluid, which has a specific gravity of less than one, to make the overall streamer neutrally buoyant. Although historically, this fluid was an organic compound, more recently a purely synthetic material has been used.

Recent advances in cable technology have led to a new generation of seismic streamers, moving away from the traditional fluid filled cable to a solid cable, constructed of extruded foam, where the requirement for fluid is minimised or removed entirely. This generation of streamers has many advantages in that they

© IAGC March 2002.

are more robust and resistant to damage, do not leak when damaged either on the vessel or in the sea, and are less sensitive to weather and wave noise. This has been achieved without reducing the sensitivity of the cable to the reflection energy.

Streamer lengths have increased over time with improving technology. The streamer length utilised is dependent on the depth and type of the geological target for a given survey. Recent surveys have seen streamer lengths typically in the order of 5000 to 6000 metres, with some detailed surveys using streamers up to 12000 metres in length. This increase in length, coupled with the increasing number of deployed streamers, has resulted in a marked increase in the quantity of streamers in the water, with seismic vessels deploying 40 to 50 kilometres of streamer becoming more prevalent.

Streamer tow depths are a compromise between the requirement to operate these sensitive devices away from the surface weather and wave noise, which limits the usability of the recorded data, and other technical requirements. The deeper the tow depth, the quieter the streamer and the greater the immunity to weather noise, but also unfortunately, the narrower the bandwidth of the data.

Typically the range of operating depths varies from 4 to 5 metres for shallow, high resolution surveys in relatively good weather areas to 8 to 10 metres for deeper penetration, lower frequency targets in more open waters.

In addition to the internal components of the streamer, there are three types of external device, which are attached to the streamer:
- depth control units or birds.
- magnetic compasses.
- acoustic positioning units.

Power for these systems is provided both through the streamer itself, inductively coupled, and by batteries in each external device.

In addition, a tailbuoy is connected to the far end of each streamer to provide both hazard warning of the submerged towed streamer, especially important at night, and positional information.

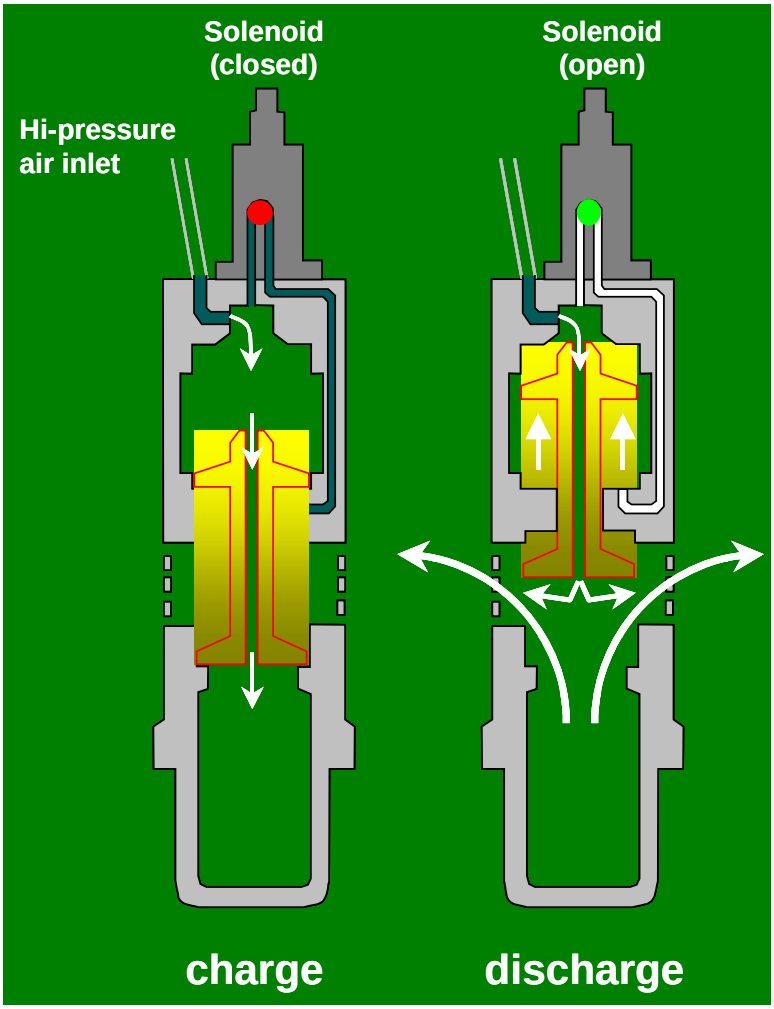
The Seismic Source

Although there are now three types of seismic source, airguns, waterguns and vibrators, that can be utilised, almost all surveys conducted world-wide use airguns. Explosives are an historic source, and are not used in present day operations.

The airgun, comprises two high pressure air chambers; an upper control chamber and a discharge chamber. High pressure air, at typically 2000 to 2500 psi, is supplied to the upper control chamber from the compressor onboard the seismic vessel via an air hose and bleeds into the lower firing chamber through an orifice in the shank of the shuttle. The airgun is actuated by sending an electrical pulse to the solenoid valve which opens, allowing high pressure air to flow to the underside of the triggering piston. The high pressure air in the lower (firing) chamber is

© IAGC March 2002.

discharged into the surrounding water through the airgun ports. The air from these ports forms a bubble, which oscillates according to the operating pressure, the depth of operation, the temperature and the volume of air vented into the water.
The shuttle is forced back down to its original position by the high-pressure air in the



control chamber, so that once the discharge chamber is fully charged with high-pressure air, the airgun can be fired again. The opening of the shuttle is very rapid, taking only a few milliseconds, which allows the high-pressure air to be discharged very rapidly.

Total energy source volumes vary from survey to survey and are designed to provide sufficient seismic energy to illuminate the geological objective of the survey, whilst minimising environmental disturbance.

An airgun array is made up of sub-arrays or strings, which are suspended from floatation devices to maintain the specified operating depth. Array dimensions are usually of the order of 25 metres wide by 15 to 20 metres long.

Typical source outputs in use today will output approximately 220 dB relative to 1µ Pascal/Hz at 1 metre. In pressure terms the zero-peak output of an array is of the order of 40 bar-metres.

Source arrays are designed to focus energy downward into the subsurface.

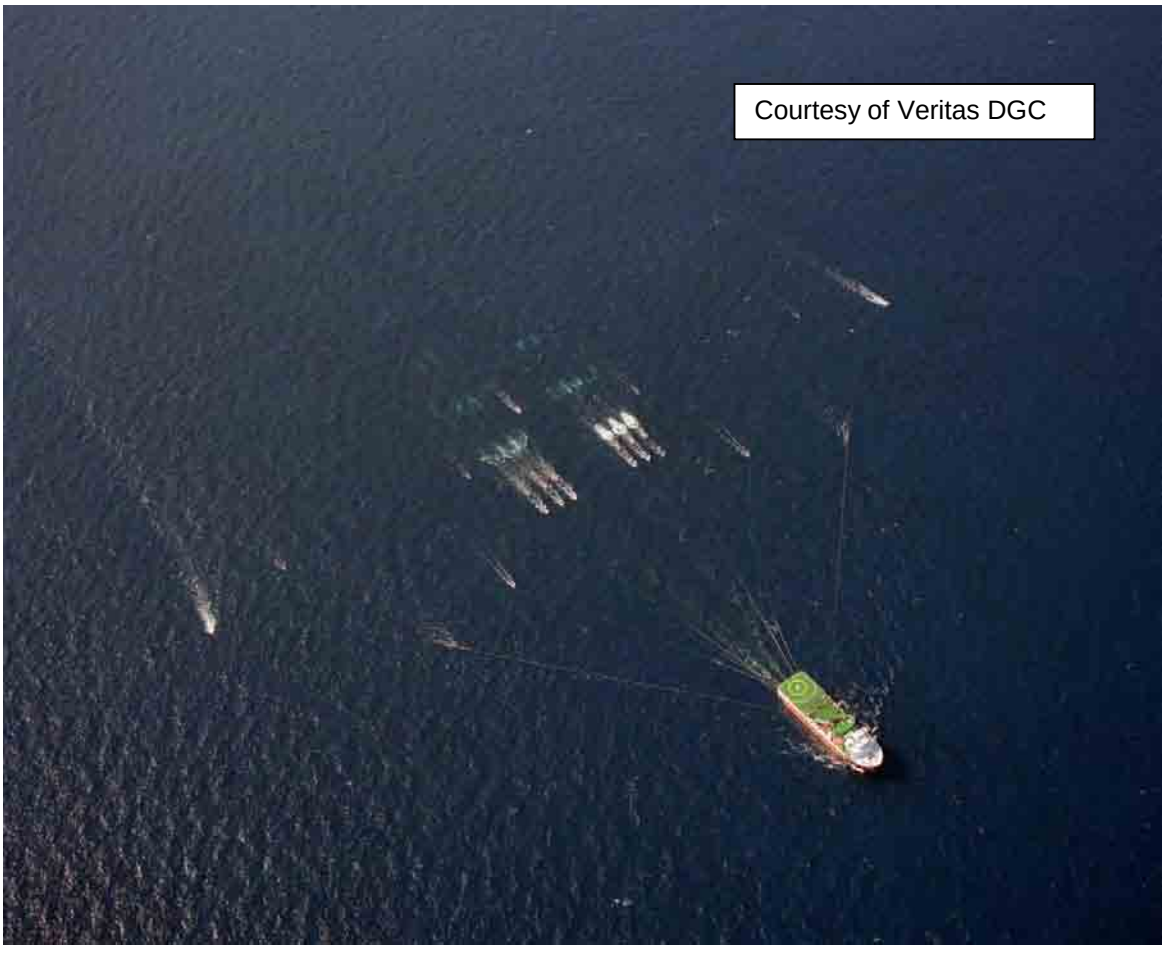
© IAGC March 2002.

Operations

The first stage of normal operations is that the seismic vessel should be fully supplied with all necessary fuel, water, food, seismic equipment and crew. It will then transit to the designated survey site. The seismic vessel will have been provided in advance with all necessary details regarding the survey layout and design and what and how much equipment will be deployed. The navigators will have information, which specifies where each seismic line must start and finish, and what the energy source firing, or shooting, interval must be. This information will have been fed into the onboard integrated navigation system.

On the bridge, the captain will ensure that while the seismic vessel is under normal manual control, he will be navigating as agreed to the first line start position. The seismic vessel will maintain a constant speed of around 5 Knots. He and the seismic crew (party) manager will be closely monitoring wind, weather and any incoming reports.

As the survey area is approached, the geophysical observers will deploy and check the streamers, attaching depth monitor and control devices (birds) as they go. The mechanics will start the compressors and prepare and check the required airgun arrays. These will be launched when necessary but after the streamers. The navigators will work with both mechanics and observers to attach the necessary buoys for positioning.



© IAGC March 2002.

In the instrument room, all equipment will be powered up, tested and checked for trouble free operation. Test records (no airguns operating) for insea noise will be made. The streamer, airgun and buoy links will all be checked and tested and the whole system confirmed as OK and ready to go.

As the seismic vessel approaches the line start or first firing point, it is said to be on the run in. This is the stage where it is very close to the agreed start position and the seismic vessel has the correct heading and the streamers are as much in line behind the seismic vessel as conditions will allow. The seismic vessel by this point is steered according to the input from the navigation system. Around the seismic vessel all involved crew members will be monitoring the seismic vessel's position from information screens in their areas. The navigator will be at his desk keeping a close eye on his console, where he can monitor in detail the approach to line start in terms of distance to go, heading and speed and can ensure that no positioning problems arise at the last moment. The mechanics will be keeping a close eye on the compressor monitors and will make a last minute visual inspection of the airgun equipment that can be seen from the vessel. The observers will take final test records and record the system noise for future reference and will check out the airgun control system.

It is during the approach to the line start, that environmental protection procedures may be applicable. Depending on the country of operations and the area specific environmental controls in place, a visual watch for marine mammals from the seismic vessel may be ongoing for at least 30 minutes before the first firing of the airguns. On some surveys, acoustic methods may additionally be utilised to identify the presence of marine mammals within the vicinity of the airgun array. It is only when the crew has been informed that no marine mammals are present, that the survey line can proceed with the firing of the airguns. A 20 minute run-in is required in some regions where the airgun array energy output is slowly increased to full power.

All systems are now ready to go and at the first predetermined position, the first shot is fired from the airgun array and data recorded. At successive intervals, as determined by the navigation system programme, the recording process is repeated and so on, to the end of the line. Throughout the recording period, all personnel involved perform detailed prescribed tasks. The navigator monitors the system output, checking for any discrepancies and completes the line paperwork and prepares plans for moving to the next line to be recorded. The mechanic watches the compressor performance, checks the back deck towing systems and is ready to deal with any hose or airgun problems. The geophysical observer monitors each shot, keeps an eye on insea noise, changes recording media and fills in the line log as the line progresses.

When the line is complete, all systems stop recording. The ship is now in line change mode. The navigator has planned how the vessel should manoeuvre to get into the run in for the next line. The line change time varies according to the layout of the survey and the configuration of the equipment but is usually between one and three hours. During the changeover period, all the crew involved work quickly to resolve any problems and make modifications or repairs in readiness for the next line. The run in is then started, all equipment is readied, and the cycle repeats.

© IAGC March 2002.

Infrequently, technical failures occur and line starts are delayed or lines are terminated early.

Other types of Seismic Source

Waterguns

Waterguns operate in a similar manner to airguns, but in place of air being vented into the water when the gun is triggered, a volume of water is used. The advantage of this is that as there is no air in the water, there is consequently no air bubble to oscillate, so the need to use differing volumes of guns is removed.

The disadvantage is that the low frequency bandwidth of the signal generated by forcing water under high pressure into the surrounding water, is much less than that provided by an equivalent airgun and thus the signal is unable to penetrate as deeply into the subsurface. Water guns were briefly popular in the 1980s but are not used commercially today.

Marine Vibrators

A marine vibrator operates by using either hydraulic or electrical power to drive an actuating plate, that is immersed in the sea, in a controlled manner.

The advantage of this is that a very precise signal can be injected into the subsurface. The signal usually employed is a sweep of frequencies, say 10-80 Hz for example, over a 10-second interval. The instantaneous sound pressure level is much lower than that from an airgun. The recorded data is then correlated against the input sweep to recover the reflection record.

The control of these devices is very complex. The output from a single vibrator is comparable to that from an airgun sub-array but suffers the disadvantage, like waterguns, that its low frequency response has historically been poor, so that deep penetration into the subsurface has not been possible. The vibrator has also suffered poorly in comparison with airguns with regards to mechanical failure, having a much higher failure rate.

Other insea equipment

Depth control birds are used to control the depth of the streamer to an accuracy of typically plus or minus 1 metre. The wings on the bird are electronically controlled to pivot in response to the hydrostatic pressure (depth) measured by a pressure transducer inside each bird. As the streamer is weighted to be neutrally buoyant, the birds are used to counteract depth variations in the streamers introduced by seismic vessel pitching movements in heavy weather or when different currents are experienced, with corresponding fluctuations in density and/or temperature of the sea water.

© IAGC March 2002.

Birds are normally spaced approximately 300 metres apart on each streamer.

Positioning

One of the most critical elements in the 3D seismic method is the positioning of the in-sea equipment. The tailbuoy is used to house Differential Global Positioning System (DGPS) receivers that are used in the positioning solution for the hydrophone groups in the streamers. Compasses, and acoustic ranging units are fitted along each streamer which contribute to the location accuracy of 3 to 8 metres absolute, with which seismic surveys are normally conducted. Differential GPS is the standard system used for positioning the seismic vessel itself and Relative

DGPS is used to position both source floats and tailbuoys.

Vessel Configurations

The 2D method involves the use of a single source and a single streamer from which one subsurface data is generated. In 1984, the first twin streamer operation was undertaken, which effectively doubled the efficiency of the seismic vessel by generating two subsurface lines per vessel traverse. By moving to twin source/twin streamer configurations in 1985, the output was increased to four lines per pass. The next logical step of towing three streamers and two sources behind a single vessel, six lines per pass, was not achieved until 1990, but thereafter the rate of progress has been very rapid.

© IAGC March 2002.

Multi-Vessel Operations

In addition to the single vessel geometries described above, the industry has been using a number of multi-vessel operations.

By using two three streamer seismic vessels side-by-side, with two sources deployed from one vessel, twelve subsurface lines per traverse can be achieved.

There are many variations in the numbers of vessels, streamers and configurations, and the techniques to acquire data.

The system used for a particular survey will best match the objectives of the survey and the conditions found at the survey site.

Other Marine Seismic Techniques

Seabed Recording Systems

There are three principal types of seabed recording systems used in marine seismic; Ocean Bottom Seismometers (OBS), Dragged Array (DA) and Ocean Bottom Cables (OBC). Of these, OBS and DA are used in multi-component (sensor) acquisition and OBC is used in both dual component and multi-component data acquisition. The term multi-component refers to the use of three component geophones in addition to a hydrophone for each seismic receiver location. The term dual component refers to the use of just a single geophone in addition to a hydrophone. A geophone measures particle displacement velocity in contrast to pressure which a hydrophone detects. The use of geophones, which must be in contact with the sea floor, sense particle motion along three orthogonal axes, allowing the geophysicist to infer more information concerning the subsurface geological layers from which the reflections occur. This has particular application in producing reservoirs, where multi-component techniques have the potential to enhance hydrocarbon recovery.

Of the three techniques, OBC is by far the most prevalent technique in use in world-wide marine acquisition.

Ocean Bottom Seismometers

Such systems have been historically used by university research groups to provide large-scale information for crustal studies and lithospheric investigations. They are battery powered individual units, which contain both the three-component geophones and hydrophone detectors, in addition to the associated recording system. The electronics are placed in a pressure housing, which also includes a flotation collar and navigation pinger. The unit, with an anchor system attached, is deployed onto the sea floor, typically in fairly deep water. The unit is then used to record data internally from a seismic energy source operating near the sea surface as in conventional marine seismic. Once this has been accomplished, the unit is released from its anchor to float up to the sea surface to be recovered. The data recorded on the internal tape drive is then removed from the buoy for subsequent processing and analysis, the batteries replaced or recharged and the whole operation repeated.

© IAGC March 2002.

Buoys are typically deployed several kilometres apart for crustal investigations, but more recently have been used in areas like the Atlantic Margin for oil related projects in a closely spaced configuration. The interest here has been to see if the OBS method can assist in enabling geophysicists to “look through” the basalt rocks which cover much of the subsurface area and which are opaque to conventional towed streamer seismic techniques.

The fact that the buoys are physically separate and their positions are not, especially in deep water, sufficiently accurately known for 3D means that this technology is unlikely to see large volume commercial usage.

Dragged Array

In this system, a number of multi-component sensors are connected together by a short length of streamer that is electrically connected to a recording vessel. The equipment, which can comprise no more than 16-24 individual sensor stations, is lowered onto the seabed and a separate seismic source vessel used to conduct a 2D shot line over the seabed deployed sensors. The data is transmitted to the recording vessel, which is usually dynamically positioned off to one side of the survey line. Once this line has been acquired, the recording vessel repositions itself online and moves forward along this line, carrying the seabed deployed equipment with it, the so-called dragging operation. The system is moved forward to provide continuous coverage of the subsurface and the shot line re-acquired by the source vessel. The system used has operational capability down to 2000 metres of water depth.

Dual Component/Multi-Component Ocean Bottom Cable

The dual component or multi-component OBC technique utilises both geophones and hydrophones in a combined cable that is deployed from a cable/recording vessel down to the seabed. Existing equipment design has limited the depth to which these sensors can be used to less than 200 metres, although newer generations of cables are being used in deeper waters. Unlike the dragged array, the equipment is laid out or dropped on the seabed and data recorded using a separate source vessel.

The principal difference between OBC and dragged array operations is that as much as 72 kilometres of ocean bottom cables can be laid or deployed on the seabed, compared to less than one kilometre for the dragged array. This allows the OBC method to be used for 3D surveys.

The separations of source and recording vessel allow for different acquisition approaches to be used in ocean bottom cable 3D surveys. Two different methods are typically used: swath, where the source and seabed receiver lines are oriented along the same direction, and patch where they are oriented at right angles.

© IAGC March 2002.

Vertical Cable

A rarely used technique, closely related to VSP. Only one survey has been conducted in the North Sea so far. This involves the use of hydrophone cables set out vertically in the water column across the survey area.

Each cable typically comprises single hydrophones spaced at intervals, together with a concrete anchor block, subsurface flotation buoys and a surface buoy, which houses the recording and radio telemetry systems.

The vertical cables are deployed at pre-determined locations by a dynamically positioned cable-laying vessel. The separation of the cables is determined by both the water depth and the geological objective. A separate source vessel fires its airguns into the 2D source lines producing a regular grid of shot point locations. The cable vessel replaces batteries and recovers the recorded data. The source technology is identical to that used for conventional towed streamer.

Survey duration will depend on the specific target objective for the survey but the method is more focussed towards reservoir imaging rather than general exploration.

Vertical Seismic Profiling (VSP)

In this technique, a number of geophones are lowered into a well and used to record data from a seismic source deployed from the well platform itself, called zero offset VSP, or from a source vessel which travels away from the well, known as offset VSP.

The main advantage of this method is that the seismic energy only has to travel one way through the earth. The reflected signal only has to travel a short way from the reflector to reach the downhole geophones. This results in higher bandwidth data being recorded, since there is less absorption of the higher frequency energy due to the shorter ray path lengths.

Source volumes are generally smaller than for conventional data but larger than for site surveys. The duration of these surveys is typically short, one or two days at most.

There have been a number of 3D VSPs recorded but these are relatively expensive to acquire. Much like the dragged array system, they require many passes of the source vessel to achieve complete 3D coverage and are hence relatively expensive, especially when the cost of the well time is included.

Site Surveys

Before a well is drilled, there is both a legal and operational need to have detailed information about the seabed in the area immediately surrounding the well location and the geological layers immediately below the subsurface.

The information about the nature of the seabed is needed to ensure that the rig legs and/or anchors will not encounter any problems when they are lowered to the seafloor and will provide the necessary stability for the structure. If the well is

© IAGC March 2002.

successful, this information will also be needed for any platform or subsea completion systems that would be installed.

The near subsurface data is needed to ensure that there are no unforeseen hazards, such as shallow gas pockets or buried river channels, that could have catastrophic effects when penetrated during the drilling process. The sudden release of gas below a drill rig could result in a catastrophic loss of life.

The resolution from conventional seismic is not sufficient for these purposes and a high resolution or site survey is undertaken. This technique is identical in principle to conventional 2D marine, except that the energy source is much smaller, and the streamer is much shorter at between 600 to 1200 metres. The source and streamer are towed at a depth of only two or three metres, corresponding to the much shallower depth of investigation. This limits operations to very good weather conditions only, to avoid wave noise.

Survey durations are short, depending on weather, but are usually of the order of four or five days. Other equipment may be deployed from the survey vessel during the course of the site survey. This may include side scan sonar fish for seabed profiling and the dropping of coring equipment to determine the seabed conditions.

Transition Zone Acquisition

This is by far the most complex and challenging area of seismic acquisition.

Shallow shelving waters are the most common problem, for they often require small, shallow draft, specialised vessels to move cables, sources, people and equipment around. With bad surf conditions it is very difficult to deploy, retrieve or operate equipment in a flat-bottomed boat.

Source types may have to be varied across an area. Where water is deep enough, it might be possible to deploy the source from the back of a barge for example, but where it is shallow, the use of explosives might be required, which are jetted or pushed into the mud or sand of the sea bottom.

Providing reliable recording sensors is also problematic. Marine hydrophones are suitable, provided they are located in deep enough water to enable them to operate properly, They are unreliable when the tide goes out for example. An additional problem involves placing the cable at a reasonable depth in the deeper water. In these environments, the streamer is not being pulled through the water with depth controlling devices. Personnel are often required to weight the cable to the sea bottom with chains and anchor blocks. With active surf or current conditions, it is likely that the cables will move and then subsequently have to be manhandled back into position.

One form of cable that can be used very successfully in transition areas is called a bay cable. It is effectively a very well sealed land cable with geophones on gimbals so that they remain upright. Some variants of these cables can contain hydrophones as well. This cable is lighter and easier to handle than a marine type of cable, but it is still not either straightforward or effortless in its use.

© IAGC March 2002.

Another method of recording data in these zones is to integrate the sensors with electronics, creating rugged sensor stations that radio transmit the received earth signal back to an instrument position, either continuously or on command from the observer. In some areas this is often the only equipment that can be effectively used, but these units still need to be positioned and anchored appropriately and this is seldom easy.

Positioning of the equipment can be complicated. Close inshore areas are usually less problematic, but the highly variable mid zone complete with fast currents, drifting cables, wandering shots, big tides and lots of mud can make it a navigator's nightmare.

Transition zone surveys conducted in UK waters are limited in number and are unlikely to become more numerous in the future.

Operational Performance

The rate of progress for a seismic survey is constrained by many factors but the most dominant is usually the weather. Other issues that affect the duration of a specific survey are:

- Survey Location
- Time of Year
- Survey Size, particularly Sail Line Length
- Technical Acquisition Parameters
- Vessel Configuration
- Line Orientation and Prevailing Current Direction
- Fishing and Shipping Activity in the Survey Area – trawling especially
- Other Seismic Operations nearby
- Marine Mammal Activity
- Drilling and Subsea Equipment Maintenance, including diving
- Technical Equipment Downtime

The net effect of all of these factors is to limit the time actually spent acquiring seismic data to just 35-40% of the available time.

The reason the weather is so important is that the signal levels that are recorded by the seismic streamer are very small. Because there is a requirement to record data with as wide a bandwidth as possible, to improve the resolution with which geologic features in the subsurface can be identified and mapped, the streamers are towed at quite shallow depths to avoid technical problems. Thus any wave action, which is directly proportional to weather conditions, causes noise that degrades the quality of the recorded data.

The location of the survey dictates the weather environment for the survey, as does the time of year the survey is being conducted. Offshore West Africa, for example, the weather is much better than in the North Sea, and thus two identically sized surveys in these two regions would have significantly different durations.

Activity Levels – Historical - Europe

The first 2D seismic was acquired in the Dutch sector of the North Sea in 1959. Activity started in the UK sector some three years later, Norway two years after that. A steady increase in exploration saw a peak in the mid seventies, followed by a lull until the late eighties. 2D activities have been trailing off since then apart from the UK non North Sea area, namely the Atlantic Margin area, which has seen a major upturn in activity since 1993.

The decline in 2D acquisition has been matched by a rapid increase in the use of the 3D technique. This is a result of the reduction in unit costs for 3D, following the rapid increase in the capabilities of seismic vessels to tow more streamers. From just two streamers towed in 1989, 8 to 10 streamers in 1998, up to the current maximum of 16 in 2001. 3D seismic acquisition therefore, has changed from being just a tool to appraise discoveries and fine tune production, to being used for exploration purposes in frontier areas.

The sharp peaks and troughs in seismic acquisition operations can be traced to a number of factors. Exploration seismic is usually acquired in the period immediate before and after Licencing Rounds issued by the governments, originally annually in the UK but now every two years or so. Oil company budgets are subject to the vagaries of the oil price; downturns in the oil price have led historically to reductions in exploration.

Other Marine Operations

If the survey is in an area of high shipping activity or other marine operations, seismic operations can be difficult. A seismic vessel is limited in its manoeuvrability due to the streamers deployed from the stern, which may be several kilometres long. The seismic vessel itself is in little danger, but with lots of vessels in close proximity, the streamers may well be fouled or cut. Trawl fishing can be a particular hazard. With very high towing strain (may be several tonnes) on the insea equipment cables, there is a danger of both a safety and environmental accident. Aside from the large financial loss from the value of the streamers themselves this can mean a serious loss of earnings through disrupted operations. In difficult areas, chase or escort boats are employed. These are smaller vessels, usually ex-fishing boats, which contact potentially threatening shipping traffic and direct them away from possible contact with the streamers.

Legislative Environment - UK

Under the terms of the Petroleum (Production) Act of 1934 and the 1964 Continental Shelf Act, the Exploration Companies (oil companies) of all surveys conducted in the UKCS to search for petroleum in the strata in the islands and in the sea and subsoil require a license from the UK Department of Trade and Industry (DTI). These exploration licenses have a three year term, are renewable, and have no specific geographical reference.

Production licences for specific blocks or areas are usually applied for in response to invitations issued by the DTI or national equivalent, in respect of blocks or areas specified in the invitation or ‘Round of Licencing’. The licence grants the holder exclusive rights to explore for, and produce petroleum, in the block covered by the

© IAGC March 2002.

licence. The duration of the licence has varied with each Round. Blocks or areas may on occasion be offered for Licencing between Rounds (out-of-Round).

The conditions for each licensed area have evolved over time.

JNCC Requirements

All seismic surveys in designated areas in the UK are subject to the JNCC (Joint Nature Conservation Committee) Guidelines for Minimising Acoustic Disturbance to Marine Mammals. These guidelines have been in place, and formed part of licence conditions, since 1995. These guidelines cover:

1) Before starting a survey line, seismic company personnel should carefully make a visual check to see if there are any cetaceans within 500 metres

   If cetaceans are present, the start of the survey should be delayed until the cetaceans have moved away, allowing adequate time after the last sighting (30 minutes) for the animals to move well out of range. Hydrophones may also be useful in determining when cetaceans have moved out of range.

2) Airgun energy should be built up slowly from low energy to operating level over 30 minutes, to give adequate time for cetaceans to leave the vicinity.

3) Throughout the survey, the lowest practicable energy levels should be used.

4) Reporting of sightings and details of watches (using standard forms)

All seismic acquisition contractors have agreed to conduct survey operations in the UK in accordance with these guidelines and have employed marine mammal observers on their vessels. The JNCC have reported that the data that has been gathered from seismic vessels in the Atlantic margin in recent years has added significantly to their knowledge of cetacean population distributions in the area.

Future Trends

3D survey sizes have historically been increasing due to a variety of economic and technical factors. This trend is likely to be maintained for exploration 3D, but the areas covered in the mature UKCS in recent years are very large and there is a finite limit to the acreage to be surveyed. This does not, however, take into account the potential for reacquiring older 3D surveys in the light of new acquisition and processing technology when it becomes available.

Reservoir specific 3D surveys, which are designed to maximise hydrocarbon recovery from a given reservoir, are necessarily much smaller than exploration 3Ds, since almost all reservoirs in the North Sea are much less than 100 square kilometres in extent. With increased subsurface imaging potentially available from multi-component data, it is probable that there will be a number of geographically small, but geophysically intense, production 3D surveys in the coming years. The exact configurations and techniques employed will be very specific to each particular reservoir, but will involve combinations of most, if not all, the methods described in this booklet.

© IAGC March 2002.

The complexity of the equipment deployed in the water has dramatically increased in the last decade and whilst there are geophysical limits to how many streamers can be used to image a specific geological target, it is certain that this trend will continue.

The use of seabed receivers, especially multi-component systems, will increase for both 3D surveys and the newly emerging 4D or time lapse 3D technique. In this method, successive 3D surveys acquired months or years apart depending on the characteristics of reservoir production, are compared to determine where fluid movement has occurred (or not) in the reservoir itself.

Research into how improvements to both the quality and productivity of the seismic method will continue as will investigations into how best to quantify and minimise any environmental impact that seismic surveys may have.

Marine seismic surveys have experienced strong growth in the last ten years and it is likely that this growth will continue well into the next millennium. However activity levels will always reflect the economic conditions in which the oil companies are working.

Worldwide there are presently a total of some 80 seismic vessels available. In the past a maximum of about 120 seismic vessels were operating.

Appendix E
Sanco Spirit Maritime and Seismic Specification

Maritime Specification Summary

Name	**Sanco Spirit**
IMO number	9429936
Owner	Sanco Shipping AS
Maritime operator	Jon Aklestad (Sanco Shipping AS)
Flag	GIBRALTAR
Port of registry	Gjerdsvika, Norway
Call sign	ZDJN 3
Builder	Vaaggland Båtbggeri AS, Norway
Built	2009
Classification society and notations to class	DNV + 1A1, ICE-C, HELDK-SH, RP, EO, DYNPOS-AUTR.

Vessel Dimensions

Length	86 M
Breadth	16,00 M
Draft	5,80 Loaded . 4,50 M in Ballast

Vessel Tonnage

Gross (IMO-69)	4396
Net	1319

Vessel Capacities

Fuel	1100m3
Maximum endurance (shooting/transit)	Transit = 27m3/day..Shooting endurance..?10 m3.day,when not towing cables
Vessel Cruising Speed Knots	13 kts
Vessel Speed Knots	13
Maximum Transit Speed Knots	15 kts
Power Plant	4 x 1593 kW, ABC Diesel, 8 DZC, 900 RPM
Propulsion type	2 x Stadt Stascho 2500 KW
Pumps	[Pumps]
Fresh water maker capacity	117m3
Accomodation	47 (13 x Single cabins and 17 double cabins)
Helideck	Diameter 20 m, 11 ton

Communications Systems

Inmarsat B	+870764946968 (69)
Direct Phones	[Direct Phones]
Norsat	+31107130612 (13) (14)

Navigational Aids

Radar	3 cm Furuno FR 2117 and 10 cm Furuno FR 2137 S, Arpa
Auto pilot	Kongsberg with track steering
Heading sensor	Kongsberg Seapath
Echosounder	Furuno FE-700
Water speed log	Furuno DA-80

Vessel Fire Fighting Equipment

Fire detection system	
Pumps	Allweiler
Portable Fire Extinguishers	[Portable Fire Extinguishers]
Hydrants and hoses	[Hydrants And Hoses]

Inert gas and other fixed systems	CO2.Flexifog/ Water mist
Foam deluge system	Foamsystem for helideck ,

Vessel Safety and Survival

Fireman's outfits	4
Breathing apparatus	[Breathing Apparatus Spares] spares
Life boats	n/a
Life rafts	6 x 25 persons
MOB raft	n/a
Life jackets	99
Survival suits	52
Life buoys	10

HSE

[Vessel HSE]

Seismic Specifications

Streamer Systems

Manufacture and type	PGS GeoStreamer® Solid
Skin material	Polyurethane
Outside diameter	62mm cm
Length of each group	12.5m m
Streamer set-up	Typical 1 x 10050m
Manufacture and type of hydrophones	Hydrophones: Teledyne T-2BX or equivalent, Velocity Sensors: PGS confidential (MarkIII)
Type of array (e.g. linear, binomial)	Linear
Number of hydrophones per group/distance apart	Hydrophones: 12 per 12.5m, Velocity Sensors: PGS confidential
Coupling between phones and pre-amp	Capacitive
Sensitivity of near group at 1/P to recorder	20V/Bar
Sensitivity of far group at 1/P to recorder	20V/Bar
Bandwidth over which above sensitivities apply	Specified at 100Hz
Availability of shoreside spares if required	Pool system
Manufacturer and type of depth controller	ION DigiCourse 5011
Manufacturer and type of compass	ION DigiCourse 5011

Recording System

Manufacturer, type	Acquisition System: PGS GeoStreamer 24bit, Recording System: PGS gAS
Number of seismic and auxiliary channels	Typical 1 x 804 + 48
Format(s) available	SEG-D revision 1.0 and 2.1
Tape drives	IBM 3592
Sample rates	1ms, 2ms, 4ms
High cut filter	428Hz, 214Hz, 107Hz @ 341dB/oct
Low cut filter	Hydrophones: 3.04Hz @ 7.5dB/oct, 4.4Hz @ 12dB/oct, Velocity Sensors: PGS confidential
Auxiliary channels allocation	Recorded as separate streamer or appended to streamer 1
Telemetry systems array forming capabilities	Optional

Energy Source

Manufacturer and type	Sercel – G Gun 2
Effective volume of standard array(s)	3111 ci
Maximum number of sub-arrays	6
Standard array depth(s)	7 M
Position of depth transducers	Front and tail of sub-array
Working pressure	2000 psi psi
Type of firing sensors	Pressure activated
Position of firing sensors	Mounted directly on the gun.
Type of firing synchroniser unit	RTS BigShot
Timing resolution	0.1ms ms
Timing accuracy	+/- 1.0ms
Position of near field phones	1 mounted on each gun hang frame.
Air compressors capacity	Neuman & Esser, 2200 cfm each
Number of air compressors	2

Navigation and Positioning Systems

Differential GPS

Standard system	Starfix XP and HP
Subcontractor	[Subcontractor Differential GPS]
Processing software	[Processing Software Differential GPS]

Relative GPS

Standard system	Fugro Seatrack RGPS
Processing software	[Processing Software Relative GPS]

Vessel Heading Sensors

GPS heading reference	[GPS Heading Reference]
Survey gyrocompasses, No/Make/Model	SGBrown Meridien

Acoustic Ranging System

Manufacturer/Model	n/a
Frequency	n/a
Type of units	n/a

Sound Velocity Meters	[Sound Velocity Meters]

Echosounder

Manufacturer, type and model number	Kongsberg EA-600
Frequencies	18 Khz and 32kHz to be confirmed
Maximum sounding depth	[Maximum Sounding Depth M] m

Integrated Navigation Computer System

Type	ORCA
Supplier	Concept - ORCA
Hardware description	[Hardware Description Integrated Navigation Computer System]
Tape drives	[Tape Drives Integrated Navigation Computer System]

Binning System

Type	n/a
Supplier	Concept System, Limited
Hardware description	Reflex

National Capital Region **Habitat Status Report 2004/002**

Review of Scientific Information on Impacts of Seismic Sound on Fish, Invertebrates, Marine Turtles and Marine Mammals

Background

A Workshop to develop a "Decision Framework for Seismic Survey Referrals" held in March 2003 produced an inventory of ecological factors that DFO should consider when dealing with referrals for seismic surveys in Canadian waters. The workshop also discussed the sources of uncertainty about effects of seismic sounds on those ecological factors, and ways that the uncertainty could be presented in science documents evaluating possible impacts. The workshop did not attempt to review critically the scientific literature on impacts of seismic sounds or effectiveness of mitigation options. Consequently the meeting did not address tolerances for ecological impacts, if any, or operational standards for respecting such tolerances.

Following that Workshop, teams of scientists prepared major literature reviews of the primary and secondary literature that reports on experimental studies and field monitoring of effects of sound, particularly seismic sound, on marine organisms. Reviews were also contracted of the standards and mitigation methods applied by other national and international bodies which regulate seismic surveys in marine ecosystems, and of the strengths and problems with various sound propagation models in marine environments. These papers were reviewed at a National Advisory Process meeting on Seismic Impact Evaluation Framework in May 2004, although time did not allow a detailed critical review of the paper on standards and mitigation methods.

Figure 1: Map of Canada

Summary

- From the evidence available, it can be concluded that seismic sounds in the marine environment are neither completely without consequences nor are they certain to result in serious and irreversible harm to the environment. In the huge range of effects between those extremes, however there are many *potential* detrimental consequences. In general risks of these consequences are poorly quantified, often unknown, and likely to be variable with both conditions of the environment and of the organisms exposed to the sounds. The long and widespread history of seismic surveys globally in marine environments with no documented fish or invertebrate kills, and only circumstantial evidence of associations with infrequent strandings of marine mammals and giant squid, suggest that seismic surveys with fairly routine mitigation measures in place are unlikely to pose high risk of mortality of marine organisms. However, this suggestion must be qualified, because sublethal or longer-term effects could have occurred and not have been detected by the monitoring programs typically in place.

- Immediate behavioral reactions to exposure to seismic sound have been widely documented in marine organisms, especially marine mammals; particularly behaviors which would result in avoiding the immediate area where the sounds are being produced, or reducing vocalisations. The possible longer-term consequences of these short-term behavioral changes are debated among experts. The debate is largely speculative and there is little empirical basis to determine the likelihood of the full chain of events which would lead to serious longer-term consequences of the short-term behavioral reactions. However, the risk to be managed would be the combined probability of all the events in the chain occurring.

- Whatever the absolute level of risk posed by seismic sounds, there are mitigation measures available which the evidence available suggests can reduce the risk by varying, but sometimes substantial, amounts. The effectiveness of specific mitigation measures was not reviewed in detail at the meeting, but was generally agreed likely to depend on the effect of concern and how the measures are implemented. The impact on the seismic operations of application of some mitigation methods, such as not conducting surveys in critical times and places, will also vary with many factors, but sometimes also could be large. Clearly much more research and monitoring are needed to better clarify and quantify the unknown risks and uncertain effects, if they occur, and the effectiveness of mitigation measures to a wider range of potential effects. Towards that end, some key research needs are listed below.

Introduction

Literature reviews of the primary and secondary literature that reports on experimental studies and field monitoring of effects of sound, particularly seismic sound, on marine organisms were evaluated in May 2004, by a group of scientists from DFO, other federal and international agencies, the hydrocarbon exploration industry and environmental groups. The review indicated that information was incomplete to varying degrees in essentially all areas related to impacts of seismic sound on marine ecosystems. Nonetheless, the background papers and scientific deliberations resulted in a body of information that allowed the following conclusions to be reached.

These conclusions provide a science basis for developing a regulatory framework for use of sound in aquatic environments, at least in the frequencies used for seismic surveys. Some of the conclusions based on the laboratory studies reviewed may generalise to higher frequencies as well, but the review focused on scientific studies directly applicable to seismic sound. The conclusions also contribute to the scientific basis for an integrated approach to managing human impacts on marine ecosystems, and for dealing with referrals of applications for seismic surveys at the regional to national level within DFO.

Habitat Concern

The issue of concern was the effects of sound, particularly seismic sound, on marine organisms. Advice was sought to provide a scientific basis for developing a regulatory framework for use of sound in aquatic environments, at least in the frequencies used for seismic surveys.

Management Considerations

Overall Considerations:

1) The following statements and conclusions are based on information available and presented at the time of the Seismic Impacts Evaluation Framework workshop. Additional research is needed in many areas, and a number of these are identified in the meeting proceedings. These statements and conclusions

should be re-evaluated as new information becomes available.

2) When considering the possible impacts of seismic sounds on the marine ecosystem, it makes sense to embed these considerations within the larger framework of the impact of all anthropogenic noise on the ecosystem. The major anthropogenic sources of noise that might be appropriate to consider in a holistic view would include seismic sounds, shipping, explosives, construction, and low-frequency SONAR. Moreover, the significance of impacts of sound in the environment, if any, should be evaluated in the context of other uses of ecosystem.

3) The dearth of scientific information, especially concerning field experiments on fish, invertebrates, and the larger marine mammals, makes it extremely difficult to evaluate the impact of a particular type of seismic sound, or more generally noise, on a particular species. Restricting our consideration to only seismic sound impacts would have reduced the already-sparse information base to one that would not have supported any conclusions with an acceptable level of confidence, so we have looked more widely for relevant information.

4) If was not just for convenience that we looked for information more widely than just considering publications on effects of seismic sound on marine species. Given the scarcity of hard information on so many facets of this multi-dimensional problem, it is likely that a meaningful appreciation of risk can only be obtained by taking an integrated view of all the sources of information available.

5) Many conclusions refer to the likelihood of various biological effects, if animals were exposed to seismic sound. Likelihood is used in a relative sense, and not as the product of quantitative risk assessments, which are not possible with the information available. Saying that an event has a "high likelihood" does not mean we necessarily expect to see it in nine out of every ten animals exposed to the sound, or even in nine out of ten replicates of the same experiment. Rather, it means that compared to the expectation of the event in the absence of seismic sound, the likelihood of the event has increased substantially, and it would be observed if sought with due diligence. However, it still may not be the typical event. Where quantification of the probability of an event is possible, we use the term "probability" rather than "likelihood".

6) The conclusions that follow often refer to "seismic sound" and "field operating conditions". These terms are used colloquially and are not defined prescriptively. In this document "seismic sound" refers generally to that produced by the types of airguns and arrays normally used at present in Canadian waters. "Field operating conditions" refers to 2-D and 3-D seismic surveys using measures such as ramp-up of sound level at onset, and ceasing sound emissions when cetaceans are known to be in the proximity of the operations.

7) Both the likelihood and severity of biological effects that may result from seismic surveys are likely to vary with local conditions of the environment (ice coverage, bottom topography, sea state, etc.) and conditions of the organisms (breeding state, nutritive condition, etc.). These conditions should not be ignored when evaluating risks and the potential for mitigation, however regulatory frameworks do not need complex rules to be effective.

Limitations for quantitative conclusions:

8) It was agreed that the biologically meaningful aspect of seismic sound is the "received sound" by the organism(s) potentially being affected. However, "received sound" is multi-dimensional. Seismic sound (or noise in general) can

be characterised by its frequency spectrum (acoustic energy or pressure as a function of acoustic frequencies), peak pressure (a time domain concept, referring to the maximum instantaneous amplitude of the pressure signal), rms pressure (mean pressure averages over a time interval), Sound Exposure Level (a measure of the "dosage" of sound energy received over a time interval), and in other ways.

9) The mechanisms by which exposure to seismic sound could result in biological impacts are sufficiently varied that no one metric may be sufficient to describe the risk of impact from a particular type of seismic sound. Some mechanisms may be well characterised by one or two of these metrics; others may not be well characterised by any of them. For example, peak pressure may be the most relevant parameter for risk of trauma, whereas rms pressure may be the most relevant parameter for non-trauma effects such as Temporary Threshold Shifts [TTS]. The frequency band, intensity, and duration of exposure all contribute to auditory effects, because although the impact must occur within the frequency band of exposure, we anticipate that auditory impact is greater within the hearing range of a species, and will decline towards the margins of its hearing threshold.

10) Many studies of the impacts of seismic sound on marine animals reduce the information about the sound used or received to a few numbers. This practice often discards important information, and makes inter-comparison of results across studies very difficult.

11) Although careful experimentation ought to be able to determine which feature(s) of the sound stimulus caused the observed reactions (when they occurred), the existing literature on experiments with marine fish and invertebrates rarely describes completely enough the characteristics of the sounds used to allow biological observations to be interpreted with confidence.

12) The literature on experiments and field observations of marine mammals exposed to sound stimuli is more extensive than the literature on effects on other types of marine organisms, and therefore likely to provide a more complete (but still partial) basis for setting thresholds. However the results, taken together, were complex and inconsistent and were an insufficient basis for agreement on quantitative thresholds for impacts on marine mammals, even from those studies where there were adequate descriptions of the sound characteristics. The major review by the NMFS Acoustic Criteria Panel is devoting much more time to this information, and may contain a quantitative synthesis of stimulus-response relationships from the information available at present. That review, when released, may comprise a useful source of information for defining regulatory tolerances. Where sensitivities of marine turtles, fish, or invertebrates are documented to be greater than sensitivities of marine mammals those factors should be taken into account in the Canada standards, guidelines and/or regulations. It was conjectured that sedentary species that cannot leave an area may experience higher levels of exposure to seismic sound than mobile animals, and this factor may be taken into account in management as well.

13) Ecological "significance" can be a value-laden term, although in these conclusions "significant" is used only in the context of DFO's areas of responsibility. Specifically, DFO has a responsibility for conservation of aquatic species (except birds) and ecosystems, and where detrimental population-scale impacts are considered likely, DFO must ensure that the impacts are mitigated or remediated. Likewise, for aquatic species protected under Schedule 1 of SARA, if deaths, harm or harassment of individuals is considered likely to occur, DFO must

either act to ensure the impacts are ameliorated, or issue permits under the provisions of Section 73 of SARA.

Other limitations:

14) A number of studies reported sub-lethal effects on marine organisms, such as elevated stress-related chemicals, and damage to ears or other morphological structures. The dearth of long-term studies of marine organisms exposed to seismic sounds means that the long-term consequences of these effects, when they occur, are unknown.

15) The severity of impact at the population level may be higher for an effect like auditory masking, if it occurs, because masking has the potential to affect a very large geographical area for low frequency sounds. Masking also may have few immediately observable signs that impacts are occurring, so mitigation may be less likely to be triggered than with individual mortalities due to trauma, (which have limited geographical extent and are more easily observable).

Conclusions Regarding Fish

Physical Effects

1) There are no documented cases of fish mortality upon exposure to seismic sound under field operating conditions. With regard to the detectability of fish kills, if they occurred, it was noted that in Canada seismic surveys have frequently, but not always, included follow-on vessels instructed to watch for fish kills, and none have been observed. It was also noted that fish kills are not necessarily cryptic events, and kills caused by anoxic events, toxic spills etc are often readily detected. However, it was also argued that the efficiency of detecting fish kills by the follow-on vessels was not tested independently, so the possibility of undetected fish kills cannot be eliminated.

2) Under experimental conditions one study found that some subjects from three of four species tested suffered lethal effects from low-frequency (<500 Hz) tonal sounds, under exposure levels of 24 h at >170 dB. Participants noted that the experimental regime differed greatly from field operating conditions of seismic surveys, so extrapolation of the results to seismic surveys was not warranted. However some participants argued that the result indicates that risk of direct fish mortality from sounds with some characteristics of seismic sound cannot be discounted completely.

3) One anecdotal report of fish mortality upon exposure to an airgun less than 2 m away was discussed and found to be inconclusive when considered relative to field operating conditions. Overall, exposure to seismic sound is considered *unlikely* to result in direct fish mortality.

4) Under experimental conditions, sub-lethal and/or physiological effects, including effects on hearing, have sometimes been observed in fish exposed to an airgun. The experimental design made it impossible to determine to the satisfaction of all experts what intensity of sound was responsible for the observed damage to ear structures, nor the biological significance of the damage that was observed. Simulated field experiments attempting to study such effects have been inconclusive. Currently, information is inadequate to evaluate the likelihood of sub-lethal or physiological effects under field operating conditions. The ecological significance of sub-lethal or physiological effects, were they occur, could range from trivial to important depending on their nature.

Behavioral Effects

5) There is high likelihood of obtaining the following effects in some fish exposed to seismic sound:

   - startle response,

- change in swimming patterns (potentially including change in swimming speed, and directional orientation), and
- change in vertical distribution.

6) These effects are expected to be short-term, with duration of effect less than or equal to the duration of exposure, are expected to vary between species and individuals, and be dependant on properties of received sound. The ecological significance of such effects is expected to be low, except where they influence reproductive activity.

7) Several scientific studies have investigated other behavioral effects on fish during seismic surveys. Some have found the effects listed below and some have not:

- Change in horizontal distribution of fish not closely associated with habitat structures such as a reefs or pinnacles,
- Change in catchability of fish possibly related to changes in behavior. Differences in experimental regimes and lack of adequate controls in some of the experiments means that the published results are an insufficient basis to predict the nature of any change that may occur, or even if a change will occur.

8) The duration of these effects may or may not extend beyond the duration of exposure, are expected to vary between species and individuals, and be dependant on the properties of received sound. The ecological significance of such effects is expected to be low, except when they may lead to a dispersion of spawning aggregations or deflection from migration paths. The magnitude of effect in these cases will depend on the biology of the species and the extent of the dispersion or deflection.

Functional Uses of Sound

9) The potential for seismic sound to disrupt communication, detection of predators/prey, navigation and other functional uses of sound by fish has not been studied. There is speculation that the discontinuous nature of seismic signals may allow these functions to occur between sound "pulses". There is also speculation that behavioral responses may include cessation of sound production by fish. If it were to occur, hearing damage would also be expected to impact these functions. Ecological significance of such effects is unknown.

Conclusions Regarding Invertebrates

Physical Effects

1) There are no documented cases of invertebrate mortality upon exposure to seismic sound under field operating conditions. An anecdotal report of beachings of giant squid on two occasions, which corresponded to periods of seismic activity, was discussed and found to be inconclusive.

2) Under experimental conditions, lethal and/or sub-lethal effects, including effects on external structure, have sometimes been observed in invertebrates exposed close to (less than 5 m) an airgun.

3) Therefore, exposure to seismic sound is considered *unlikely* to result in direct invertebrate mortality.

Physiological Effects

4) There is a series of publications showing effects of extended exposure to non-seismic sounds on the physiology of crustacean under experimental conditions. Effects include reduced growth and reproduction rates and behavioral changes, which indicate the

sensitivity of some invertebrates to noise. In a gastropod (mollusc) the physiological effects (sign of stress) were reported under field seismic operating conditions. In other species such effects were rarely present, except for some sign of excitation of ensonified crabs compared to control crabs.

5) Currently, information is lacking to evaluate the likelihood of sub-lethal or physiological effects on crustaceans during pre-molt, molting and post-molt periods.

6) The ecological significance of sub-lethal or physiological effects, were they occur, could range from trivial to important depending on their nature.

Behavioral Effects

7) There is high likelihood of obtaining the following effects in some invertebrates exposed to seismic sound:

   - startle response,
   - change in swimming/movement patterns (potentially including change in swimming/movement speed, and directional orientation).

8) Both increases and decreases in catch rates of commercially exploited species have been documented, but changes do not occur consistently.

9) These effects are expected to be short-term, with duration of effect often less than the duration of exposure, are expected to vary between species and individuals, and be dependent on properties of received sound.

10) Some invertebrates are sedentary or have limited locomotive capacity. Therefore their capacity to avoid seismic sound is extremely limited compared to many fish and marine mammals. This may increase their exposure to seismic sounds, but there is no basis on which to assume that increased exposure makes such species inherently more or less sensitive to those sounds.

11) The ecological significance of the effects is expected to be low, except if effects of exposure to seismic sounds were to influence reproductive or growth (molting) activities, or lead to a dispersion of spawning aggregations or deflection from migration paths. The magnitude of effect in these cases will depend on the biology of the species and the extent of the dispersion or deflection.

Functional Uses of Sound

12) The potential for seismic sound to disrupt communication, orientation, detection of predators/prey, locomotion and other functional uses of sound by invertebrates has not been studied. Loud sounds will reduce the efficiency of communication and other functional uses of sounds, but the severity and conditions under which this occurs with invertebrates are unknown. It is not known if invertebrates can communicate acoustically during the inter-pulse intervals that occur between seismic transmissions. Ecological significance of such effects, if they occur, is unknown.

Conclusions about Zooplankton, Eggs and Larvae of Fish and Invertebrates

1) Few studies of the effects of seismic sound on eggs and larvae or on zooplankton were found. A number of these provided inadequate description of experiment design, properties of the sound applied as treatments, or had methodological shortcomings.

2) Data are generally insufficient to evaluate the potential damage to eggs and larvae of fish and shellfish (or other planktonic organisms) that might be caused by seismic sound under field operating conditions.

3) From the experiments reported to date, results do show that exposure to sound may arrest development of eggs, and cause developmental anomalies in a small proportion of exposed eggs and/or larvae; however these results occurred at numbers of exposures much higher than are likely to occur during field operation conditions, and at sound intensities that only occur within a few meters of the sound source.

4) Effects of seismic sounds on behavioral functions and sensory perception of fish and invertebrate eggs and larvae are unknown;

5) In general, the magnitude of mortality of eggs or larvae that models predict could result from exposure to seismic sound would be far below that which would be expected to affect populations. However, special life history characteristics such as extreme patchiness in distribution and timing of key life history events in relation to the duration and coverage of seismic surveys may require case by case assessment.

6) No studies were found which specifically investigated the role of seismic sounds in recruitment variation of marine fish or invertebrates. There have been a large number of research studies on causes of variation in recruitment of marine fish or invertebrates, and none has considered that there are recruitment anomalies (positive or negative) which might be linked in space or time to seismic survey operations. This negative evidence applies at the scale of stocks, but does not provide information about the potential for effects on local-scale recruitment dynamics.

Conclusions Regarding Marine Turtles

1) Auditory studies suggest that sea turtles, specifically loggerhead and green turtles, are able to hear and respond to low frequency sound, but their hearing threshold appears to be high.

2) In three studies, the following behavioral responses of sea turtles in enclosures exposed to airgun sounds were sometimes observed:

   - increased swimming speed,
   - increased activity,
   - change in swimming direction, and
   - avoidance.

3) Sea turtles may become accustomed to seismic sound over time, but results of three studies were inconclusive on this matter.

4) Loss of hearing sensitivity and physiological stress response has also been considered as a possible consequence of exposure of sea turtles to seismic sound, but the one study reviewed was inconclusive.

5) The response, if any, of free-ranging sea turtles to seismic sound conducted under field operating conditions is unknown.

6) Based on studies that have been conducted to date, it is considered *unlikely* that sea turtles are more sensitive to seismic operations than cetaceans or some fish. Therefore, mitigation measures designed to reduce risk or severity of exposure of cetaceans to seismic sounds may be informative about measures to reduce risk or severity of exposure of sea turtles to seismic sounds. However sea turtles are harder to detect both visually and acoustically than are many species of cetaceans, so mitigation strategies based on sightings or acoustic detection of turtles, are expected to be less effective for turtles than for cetaceans.

Conclusions Regarding Marine Mammals

Mortality and Physical Effects

1. There are no documented cases of marine mammal mortality upon exposure to oil and gas exploration seismic surveys. There is one case of a stranding event involving two whales coincident in space and time with a research vessel conducting seismic operations. There is one stranding event involving the same vessel and whales, coincident in time but not space, with no obvious mechanism that could bridge the distance between the vessel and the stranding site. In both cases the research vessel was also operating mid-frequency airgun systems that produce sound significantly more similar in character to the tactical mid-frequency sonar implicated in whale mass stranding events, than is seismic sound. The role of the different sound sources in the stranding events could not be resolved by the study. Therefore, although whale strandings have been linked to exposure to anthropogenic sound, exposure to seismic sound is considered *unlikely* to cause direct marine mammal mortality.

2. Under experimental conditions, sub-lethal, temporary elevations in hearing thresholds (TTS) have sometimes been observed in captive marine mammals exposed to pulsed sounds. Currently, the likelihood of these effects have not been evaluated under field operating conditions; for some species of marine mammals the levels and types of sounds which may produce TTS can be predicted, so such evaluations may be possible. The significance of such TTS effects, were they occur, are likely to be unimportant, unless:

    a. the threshold was elevated repeatedly or for an extended period of time, which could result in a Permanent Threshold Shift [PTS]; or

    b. other threats were present at the same time as the temporary elevations in hearing thresholds, and the threats were ones normally avoided by acoustic means, such as predators or entanglements in fishing gear.

3. There are no documented cases of a marine mammal experiencing damage to non-auditory body tissues upon exposure to seismic surveys under field operating conditions. Therefore, exposure to seismic sound under field operating conditions is considered *unlikely* to result in such types of tissue damage to marine mammals, but the presence of other sound sources operating simultaneously with seismic operations should be taken into account when proposals are evaluated.

Direct Behavioral Effects

<u>Displacement and Migratory Diversion:</u>

4) There is documented displacement and migratory diversion in some marine mammal species exposed to seismic sound. The duration of these effects may or may not extend beyond the duration of exposure. The effects are expected to vary between contexts, species, gender and age class, and individuals, and be dependant on the properties of received sound. The ecological significance of such effects is expected to be low, but may be higher if they:

- displace feeding marine mammals from areas where there are no alternates,
- displace marine mammals from resting areas where there are no alternates,
- displace marine mammals from breeding or nursery areas, or
- divert migrating animals from routes for which their alternate routes either do not exist or would incur substantially greater costs to traverse.

5) The magnitude of effect in these cases will depend on the biology of the species and the extent and duration of the dispersion or deflection. Also, there is a risk that a seismic project occurring in another area could cause incursion of displaced competitors into the critical habitat or area of high biological productivity occupied by other species.

6) In summary, exposure to seismic sound can result in displacement and/or migratory diversion in some marine mammals, but this effect is species, individual, and contextually-related. The ecological significance of such effects is *unknown*, but there are conditions under which the worst-case scenarios could be high.

Changes in Dive and Respiratory Patterns

7) There are documented changes in dive and respiratory patterns in some marine mammal species (e.g., bowhead whales, harbour and grey seals) exposed to seismic sound. There are records of the duration of these effects extending beyond the duration of exposure. The effects are expected to vary between contexts, species and individuals, and be dependant on the properties of received sound. The ecological significance of such effects is expected to be low, except if such effects:

   - interfere with feeding, or
   - incur substantial energetic costs;

   The magnitude of effect in these cases will depend on the biology of the species and the extent and duration of the dispersion or deflection.

8) In summary, exposure to seismic sound can result in changes in dive and respiratory patterns in some marine mammals, but this effect is expected to vary with species, individual, and context. The ecological significance of such effects is *unknown*, but there are conditions under which the worst-case scenarios could be high.

Changes in Social Behavior

9) Social behavior can include a wide variety of activities such as mating, cooperative feeding, play, aggressive interactions, and communication (see below). Studies of behavioral changes in other subsections of this summary describe effects on some of the activities that could be considered "social". However, there have been no directed studies of the effects of seismic sounds on mating, cooperative feeding, play, or aggressive interactions.

10) In summary, it is *unknown* if exposure to seismic sound can result in changes in marine mammal social behavior, but if it were to occur there are conditions under which the worst-case consequences of such changes could be highly significant.

Changes in Vocalisation Patterns

11) There have been direct studies of the potential for anthropogenic sound to cause changes in the vocalisation patterns of marine mammals. For most cetacean species studied, there were measurable changes in vocalisation patterns, but these studies were not conducted during seismic operations. In the UK, Norway, and the Sable Gully, sperm whales did not stop calling when exposed to seismic sounds. A study off Heard Island, found that sperm whales did not call during distant (690-1070 km away) seismic transmissions in some parts of the study, but did call during seismic transmissions during another part of the study. Blue whales in the NE Pacific stopped calling for approximately one hour when within 10 kilometers of a small (1600 in^3) seismic array; they resumed calling as they swam away from the array.

12) There is evidence that exposure specifically to seismic sounds has sometimes caused changes in vocalisation patterns in marine mammals. However, it has not been possible to measure the functional consequences of

these changes (such as loss of contact between individuals or reduced ability to coordinate social behaviors), if any, nor the percent of time which they would occur.

13) In summary, it is *known* that exposure to seismic sound can result in changes in marine mammal vocal behavior, and when it occurs there are conditions under which the worst-case consequences could be highly significant.

Functional Consequences of Physical and Behavioral Effects

Reduced Communication Efficiency

14) Many species of marine mammals both produce and respond to sounds. Studies have shown these vocalisations to sometimes communicate information that is functionally important for feeding, breeding, parental care, predator avoidance, or maintenance of social groupings. Studies have also found vocalisations can occur when there are no observable functional consequences, although in such cases it is unclear if the vocalisations had no consequences, or if the effects were longer term or farther afield than the studies. Hence it is difficult for research to produce conclusive results about the frequency of occurrence and consequences of disruption of communication by anthropogenic activities, including seismic sounds.

15) There have been no published studies of the potential for seismic sound to reduce the efficiency of communication in marine mammals. Loud sounds will reduce the efficiency of communication but the severity and conditions under which this occurs with marine mammals are poorly known. When seismic sounds are produced there are inter-pulse intervals which present the opportunity for cetaceans to place vocal communication signals, but cetaceans have not been shown to use this mechanism in the field. Moreover, there is unpublished information that when multi-path echoes occur, such as in areas of complex bathymetry, the pulses of the seismic sound may smear over distance and time, such that the quieter inter-pulse intervals may be reduced or eliminated. This creates the potential for calls of cetaceans such as blue whales to be masked by seismic sounds although the distances over which the masking would be effective, if it were to occur, are unknown. It is unknown if whales could reduce the effects of masking through processes such as changes in their calling patterns, and the consequences of these changes (if they occur) are unknown. This facultative response has been documented in some other marine mammal species exposed to loud manmade sounds. Therefore, it is *unknown* if exposure to seismic sound can result in such reduced communication efficiency in marine mammals.

Reduced Echolocation Efficiency

16) There have been no direct studies of the potential for seismic sound to reduce the efficiency of echolocation in marine mammals. Therefore, it is *unknown* if exposure to seismic sound can result in reduced echolocation efficiency in marine mammals.

Hampered Passive Acoustic Detection of Prey

17) There have been no direct studies of the potential for seismic sound to hamper the passive acoustic detection of prey by marine mammals. In a published study on the effects of whale watching vessels on killer whale behavior, it was postulated that sounds from these vessels could reduce the ability of killer whales to detect their prey. It is not known if such an effect could result during exposure to seismic sounds, or even which species of marine mammals use passive acoustic detection of prey as an important feeding strategy. However the potential for an effect is greatest for mysticetes whose best hearing sensitivity is thought to be at lower frequencies than other marine mammals. Therefore, it is *unknown* whether exposure to seismic sound could hamper the passive acoustic detection of prey by marine mammals.

Hampered Passive Acoustic Detection of Predators

18) There have been no direct studies of the potential for seismic sound to hamper the passive acoustic detection of predators by marine mammals. The potential for an effect is greatest for mysticetes, whose best hearing sensitivity is thought to be at lower frequencies than other marine mammals. However it is not known if such an effect occurs during exposure to seismic sounds, and if so, to what extent. Therefore, it is *unknown* whether exposure to seismic sound could increase the vulnerability of marine mammals to predators.

Hampered Avoidance of Anthropogenic Threats (such as ship strikes, net entanglement)

19) There have been no direct studies of the potential for seismic sound to reduce the ability of marine mammals to avoid anthropogenic threats. There are published reports of other types of sounds interfering with the ability of individual whales to avoid anthropogenic threats such as ship strikes and net entanglements, but it is not known how widespread this response is. It is also not known if such an effect could result from exposure to seismic sounds. Therefore, it is a *concern* that exposure to seismic sound could reduce the ability of marine mammals to avoid anthropogenic threats, but the risk has not been demonstrated.

Hampered Parental Care or Bonding

20) There have been no direct studies of the potential for seismic sound to hamper parental care or bonding in marine mammals. Therefore, it is *unknown* if exposure to seismic sound can hamper parental care or bonding in marine mammals.

Chronic Effects (e.g., stress-related physiological changes, reduced fecundity)

21) There have been no studies of the potential for seismic sound to induce chronic effects, such as immunosuppression or reduced fecundity, in marine mammals. Therefore, it is *unknown* if exposure to seismic sound can result in such chronic effects on marine mammals.

Indirect Effects (e.g., reduced prey availability)

22) There have been no studies of the potential for seismic sound to reduce prey availability, through displacement or reduced catchability, for marine mammals. Therefore, it is *unknown* if exposure to seismic sound can result in such indirect effects on marine mammals.

Research Needs

In the review a large number of areas of future research were identified. Some emerged as particularly helpful in increasing the information available to those quantifying and those managing the risks of seismic surveys in marine ecosystems.

1) More work is required to determine the sound characteristics and environmental conditions under which seismic effects on behavior, physiology, and physical well-being of all types of marine species might occur.

2) The available information on the effectiveness of mitigation measures needs to be more fully evaluated, as a basis for both interim advice on appropriate operational requirements in the short term and additional research needs to increase our knowledge in the longer term.

3) In addition to targeted research, there is great value to linking a program of structured collection of information to the conduct of seismic surveys, to facilitate learning-by-doing. However, such information collection programs must be well coordinated, and accompanied by the resources to analyse, interpret, and apply the new information, as it is collected and submitted to scientific authorities.

4) A few representative studies on distance-effect relationships for all taxa, but particularly eggs and larvae, would greatly aid understanding of potential risks posed by seismic sound. The potential for effects stemming from sound exposure level (cumulative over a survey) as well as peak received sound pressure level should be considered, including under conditions of 3-D surveys.

5) Specific research is needed on the level of received sound experienced by sessile invertebrates, and the effects of seismic sounds on such organisms. The physics of the sound levels to which benthic organisms are exposed is complicated due to shear effects interacting with pressure effects, and the proximity to the bottom substrates. Hence results of generic sound propagation models are likely to be misleading with regard to exposure levels of sessile benthic species. However, the errors could be in any direction, and in sites of complex bathymetry there could be very patchy distributions of areas with higher intensities of exposure than predicted by sound propagation models and other areas with lower intensities.

6) There is a specific absence of information on the effects of seismic sounds on molting of invertebrates with hard exoskeletons.

7) There is a need to further clarify the best sound propagation models for the areas likely to host seismic exploration, and how habitat characters should influence model selection. Generic models also need to be evaluated relative to the sensitivity and precision of their predictions relative to requirements for evaluating potential impacts, although site-specific implementations of generic models will continue to be desirable.

8) Better data input is needed during modelling of the expected pattern of spread of seismic sounds during surveys. Near-and far-field sound measurements should be encouraged as part of seismic operations planned for an area that has not been surveyed previously, or if previous models have been shown to be inaccurate.

9) Further research on potential impacts of seismic sound on marine mammals is urgently needed. The issues in most need of attention through scientific research or further analysis of existing data include:

    a) An important scientific unknown limiting our ability to predict the effects of seismic surveys on marine mammal populations is knowledge of their spatio-temporal distribution, and physiological state and needs. Without knowledge about what species are present in which areas at what time of the year and for what purpose, there will always be risks of disturbance and injury to sensitive species. An effort should also be made to characterise the degree of

long-term natural variation in abundance and residency.

b) There is a need for significantly more information regarding the reactions of marine mammals (and their prey) to underwater sound from seismic arrays. Baseline studies prior to seismic operations, plus comparative reports during periods with and without seismic would contribute important new data.

c) There is a need for better and more accurate information on naturally-occurring and man-made noise in the ocean.

d) The effectiveness of all potential mitigation measures needs to be explored and documented more fully. In particular there is a need to document the extent to which passive and/or active acoustic monitoring of marine mammals from the source vessel is an effective mitigation strategy.

e) There is a particular need for directed studies of social behavior of marine mammals during seismic exposures, given the importance of these activities to marine mammals' biology.

f) The effects of anthropogenic sounds on the vocalisation patterns of marine mammals are well documented, but the effects of specifically seismic sounds are poor known, and warrant further study.

Many of these factors are also poorly known for many taxa of marine turtles, fish, and invertebrates. Research to fill in such knowledge gaps, particularly with regard to spatio-temporal distribution of important prey taxa and their reactions to seismic sound, would be valuable, although the topics listed above were given higher priority. A number of other topics requiring additional research were proposed by various individuals, and are recorded in the meeting proceedings.

The Leach's Storm-Petrel:
General information and handling instructions

Urban Williams (Petro-Canada)
&
John Chardine (Canadian Wildlife Service)

The Grand Banks is an area that is frequented by large numbers of seabirds, representing a variety of species. Large populations are found in this area in both summer and winter, and come from the Arctic, northern Europe, and the south Atlantic, as well as from colonies along the Newfoundland Coast. One of the species found in the area of the Terra Nova Field is the Leach's Storm-Petrel (*Oceanodroma leucorhoa*).

The Bird:

Leach's Storm-Petrels are small seabirds, not much bigger than a Robin. They have relatively long wings and are excellent fliers. Leach's Storm-Petrels are dark brown in colour and show a conspicuous white patch at the base of the tail. In the hand, you can easily notice a small tube at the top of their bill, and you will also notice that the birds have a peculiar, not unpleasant smell (although some Newfoundlanders call these birds "Stink Birds"). Storm-Petrels are easy prey for gulls and other predators, and so to protect themselves from predation, Leach's Storm-Petrels are only active at night when on land at the breeding colonies.

Nesting Habitat:

Leach's Storm-Petrels are distributed widely in the northern hemisphere, however, their major centres of distribution are Alaska and Newfoundland. The bird breeds on offshore islands, often in colonies numbering tens or hundreds of thousands of pairs, even millions at one colony in Newfoundland. The nest is a chamber, sometimes lined with a some grass, located at the end of a narrow tunnel dug in the topsoil.. Depending on the colony, burrows may be under conifer or raspberry thickets or open grassland.

Reproduction:

In Newfoundland, Leach's Storm-Petrels lay their single egg in May and June. The egg is incubated by both parents alternately, sometimes for stretches exceeding 48 hours. The egg is incubated for 41-42 days, which is a long time for such a small egg. The peak hatching period is in the last half of July. The young petrel remains in the tunnel for about 63-70 days. Once breeding is over in late-August or early September, the birds disperse from the colonies and migrate to their wintering grounds in the Atlantic. September is the most important period for migration of Storm-Petrels to the offshore areas such as near the Terra Nova field.

Populations:

Canada alone supports more than 5 million pairs of Leach's Storm-Petrels. Most of them are found in Newfoundland. The Leach's Storm-Petrel colony located on Baccalieu Island is the largest known colony of this species.

Nesting sites for Leach's Storm-Petrels are found along the southeast coast of Newfoundland. These are - i) Witless Bay Islands (780,00 nesting pairs), ii) Iron Island (10,000 nesting pairs), iii) Corbin Island (100,000 nesting pairs), iv) Middle Lawn Island (26,000 nesting pairs), v) Baccalieu Island (3,336,000 nesting pairs), vi) Green Island (72,000 nesting pairs), and vii) St. Pierre Grand Columbier (100,000 nesting pairs).

Feeding Habits:

Leach's Storm-Petrels feed at the sea surface, seizing prey in flight. Prey usually consists of myctophid fish and amphipods. The chick is fed planktonic crustaceans, drops of stomach oil from the adult bird, and small fish taken far out at sea. Storm-Petrels feed far out from the colony and it would be reasonable to assume that birds nesting in eastern Newfoundland can be found feeding around the Terra Nova site.

The Problem:

As identified in the C-NOPB Decision 97-02, seabirds such as Leach's Storm-Petrels are attracted to lights on offshore platforms and vessels. Experience has shown that Storm-Petrels may be confused by lights from ships and oil rigs, particularly on foggy nights, and will crash into lighted areas such as decks and portholes. Fortunately, this type of accident does not often result in mortality, however, once on deck the bird will sometimes seek a dark corner in which to hide, and can become fouled with oil or other contaminants on deck.

Period of Concern:

Leach's Storm-Petrels are in the Terra Nova area from about May until October and birds could be attracted to lights at any time throughout this period. The period of greatest risk of attraction

to lights on vessels appears to be at the end of the breeding season when adults and newly fledged chicks are dispersing from the colonies and migrating to their offshore wintering grounds. September is the most important period for migration of storm-petrels to the offshore areas. Past experience suggests that any foggy night in September could be problematic and may result in hundreds or even thousands of birds colliding with the vessel.

The Mitigation:

On nights when storm-petrels are colliding with the vessel, the following steps should be taken to ensure that as many birds as possible are safely returned to their natural habitat.

- All decks of the vessel should be patrolled as often as is needed to ensure that birds are picked up and boxed (see below) as soon as possible after they have collided with the vessel. After collision, birds will often "freeze" below lights on deck or seek dark areas underneath machinery and the like.
- Birds should be collected by hand and gently placed in small cardboard boxes. Care should be taken not to overcrowd the birds and a maximum of 10-15 birds should be placed in each box, depending upon its size. The birds are very easy to pick up as they are poor walkers and will not fly up off the deck so long as the area is well-lit. They will make a squealing sound as they are picked up- this is of no concern and is a natural reaction to be handled (the birds probably think they have been captured to be eaten!).
- When the birds are placed in the box the cover should be put in place and the birds left to recover in a dark, cool, quiet place for about 5-10 minutes. The birds initially will be quite active in the box but will soon settle down.
- Following the recovery period, the box containing the birds should be brought to the bow of the boat or to some other area of the vessel that has minimal (if any) lighting. The cover should be opened and each bird individually removed by hand. The release is usually accomplished by letting the bird drop over the side of the vessel. There is no need to throw the bird up in the air at release time. If the birds are released at a well-lit part of the vessel they usually fly back towards the vessel and collide again.
- If any of the birds are wet when they are captured (i.e. they drop into water on the deck) then they should be placed in a cardboard box and let dry. Once the bird is dry it can be released as per the previous instruction. Also, temporarily injured birds should be left for longer to recover in the cardboard box before release.
- Any birds contaminated with oil should be kept in a separate box and not mixed with clean birds. Contact Canadian Wildlife Service at (709) 772-5585 for instructions on how to deal with contaminated birds.
- In the event that some birds are captured near dawn and are not fully recovered before daylight, they should be kept until the next night for release. Storm-Petrels should not be released in daylight as at this time they are very vulnerable to predation by gulls. Birds should be kept in the cardboard box in a cool, quiet place for the day, and do not need to be fed.
- Someone should be given the responsibility of maintaining a tally of birds that have been captured and released, and those that were found dead on deck. These notes should be kept with other information about the conditions on the night of the incident (moonlight, fog, weather),

date, time, etc). THIS IS A VERY IMPORTANT PART OF THE EXERCISE AS IT IS THE ONLY WAY WE CAN LEARN MORE ABOUT THESE EVENTS.

Handling Instructions:

- Leach's Storm-Petrels are small, gentle birds and should be handled with care at all times.
- It is recommended that the person handling the birds should wear thin rubber gloves or clean, cotton work gloves. The purpose of the gloves is to protect both the Storm-Petrel and the worker.
- As mentioned Storm-Petrel's have a strong odor that will stick to the handler's hands. Washing with soap and water will remove most of the smell.
- Handling Leach's Storm-Petrels does not pose a health hazard to the worker, however some birds may have parasites on their feathers, such as feather lice. These parasites do not present any risk to humans, however, as a precaution we recommend wearing cotton work gloves or thin rubber gloves while handling birds and washing of hands afterwards.

Wilson's Storm Petrels:

A relative of the Leach's Storm-Petrel is the Wilson's Storm-Petrel. They breed in the south Atlantic and Antarctica and migrate north in our spring to spend the summer in Newfoundland waters. This species is very numerous on the Grand Banks in the summer, and shares the same nocturnal habits as the Leach's Storm-Petrel. Thus it is possible that Wilson's Storm-Petrels may also be attracted to the lights of a vessel at night. The two species are very similar and should be handled in the same way as described above for our Leach's Storm-Petrel.

Permits:
A permit to handle storm-petrels issued by the Canadian Wildlife Service will be held on board the vessel to cover personnel involved in bird collision incidents.

SEL	Sound Exposure Level: a measure of energy content, in dB re 1 $\mu Pa^2 \cdot s$
SOI	Shell Offshore, Inc.
SPL	Sound Pressure Level; the SPL for a seismic pulse is equivalent to its rms level
SZ	Shut Down of all airguns because of a marine mammal sighting near or within the safety radius
TTS	Temporary Threshold Shift
UNEP	United Nations Environmental Programme
"Useable"	Visual effort or sightings made under the following observation conditions: daylight periods within the Chukchi and Beaufort Seas, ***excluding*** periods 3 min to 1 h (pinnipeds) or 2 h (for cetaceans) after airguns were turned off (post-seismic), periods when ship speed was <3.7 km/h (2 kt), and periods with seriously impaired sightability. The following conditions were defined as involving seriously impaired sightability: all nighttime periods, and daytime periods with one or more of the following: visibility <3.5 km, Bf >5 (Bf >2 for porpoises), or >60º of severe glare between 90º left and 90º right of the bow. Sightings of marine mammals hauled out on the ice in both the Beaufort and Chukchi seas were considered "useable" for analyses. Sightings of cetaceans from the *Kilabuk* were considered "unuseable" for analyses.

EXECUTIVE SUMMARY

Background and Introduction (Chapter 1)

Shell Offshore, Inc. (SOI), collected marine seismic data in the Chukchi and Beaufort Seas during the summer of 2006 in support of potential future oil and gas leasing and development. Deep seismic acquisition for SOI was conducted in the Chukchi Sea by WesternGeco using the M/V *Gilavar*, a source vessel that towed an airgun array as well as hydrophone streamers to record reflected seismic data. Seismic acquisition was originally planned to be conducted in both the Chukchi and Beaufort Seas using the *Gilavar*; however, ice conditions during the 2006 field season precluded most data collection in the Beaufort Sea. Activities in the Beaufort Sea were confined to site clearance, shallow hazard surveys and geotechnical activities, which were conducted from the M/V *Henry Christoffersen*, an NTCL vessel.

Marine seismic surveys emit strong sounds into the water that could affect marine mammal behavior and distribution, or perhaps cause temporary or permanent reduction in hearing sensitivity. These effects could constitute "taking" under the provisions of the U.S. Marine Mammal Protection Act (MMPA) and the U.S. Endangered Species Act (ESA). The National Marine Fisheries Service (NMFS) and the U.S. Fish and Wildlife Service (USFWS) share jurisdiction over the marine mammal species that were likely to be encountered during the project. Cetaceans and most pinnipeds are managed by NMFS; Pacific walruses and polar bears are managed by USFWS.

SOI's seismic surveys and other exploration activities in the Chukchi and Beaufort seas were conducted under the jurisdiction of Incidental Harassment Authorizations (IHAs) issued by NMFS and USFWS. The IHAs included provisions to minimize the possibility that marine mammals close to the seismic source might be exposed to levels of sound high enough to cause hearing damage or other injuries, and to reduce behavioral disturbances that might be considered as "take by harassment" under the MMPA. Under current NMFS guidelines, "safety radii" for marine mammals around airgun arrays are customarily defined as the distances within which the received pulse levels are ≥180 dB re 1 μPa (rms) for cetaceans and ≥190 dB re 1 μPa (rms) for pinnipeds. Those safety radii are based on an assumption that seismic pulses at lower received levels will not injure these mammals or impair their hearing abilities, but that higher received levels *might* have some such effects. The IHA issued by NMFS required monitoring of the distances within which received sound levels would be ≥180 and ≥190 dB, and implementation of appropriate mitigation when marine mammals were seen within or about to enter those zones. The IHA also required monitoring of the distance within which received sound levels might be ≥160 dB re 1 μPa (rms).

NMFS and USFWS granted the IHAs to SOI on the assumptions that

- the numbers of whales and seals potentially harassed (as defined by NMFS criteria) during seismic operations would be "small",
- the effects of such harassment on marine mammal populations would be negligible,
- no marine mammals would be seriously injured or killed,
- there would be no unmitigated adverse effects on the availability of marine mammals for subsistence hunting in Alaska, and
- the agreed upon monitoring and mitigation measures would be implemented.

The main purpose of the mitigation program was to avoid or minimize potential effects of SOI's seismic survey on marine mammals. This required that shipboard personnel detect marine mammals

within or about to enter the designated safety radii, and in such cases initiate an immediate power down (or shut down if necessary) of the airguns.

Mitigation was also required at the 160 dB isopleth. This area was monitored by the chase boat that accompanied the seismic vessel. Power down of the seismic airgun array was required if an aggregation of 12 or more non-migratory bowhead or gray whales was detected ahead of, or perpendicular to, the seismic vessel track. Monitoring of the 120 dB isopleth around the seismic vessel was also required after 25 September in the Chukchi Sea and after 1 September in the Beaufort Sea. Power down was required if 4 migratory cow/calf pairs were detected within the surveyed 120 dB isopleth.

The primary objectives of the monitoring program were as follows:

1. provide real-time sighting data needed to implement the mitigation requirements;
2. estimate the numbers of marine mammals potentially exposed to strong seismic pulses; and
3. determine the reactions (if any) of marine mammals potentially exposed to seismic sound impulses.

This 90-day report describes the methods and results for the monitoring work specifically required to meet the above primary objectives.

Seismic Surveys Described (Chapter 2)

The *Gilavar* was used as the seismic source vessel during SOI's activities in the Chukchi Sea in 2006. The *Gilavar* was accompanied by the *Jim Kilabuk*, an icebreaker-class support vessel (chase vessel). The proposed deep seismic survey was originally scheduled to occur in two phases. Phase one commenced in July in the Chukchi Sea and was planned to continue there until late summer when the *Gilavar* and *Kilabuk* were to transit to the Beaufort Sea to conduct phase two seismic surveys on Shell lease-holdings in the mid- and eastern parts of the Alaskan Beaufort Sea. Heavy ice conditions delayed the date when operations could have transferred to the Beaufort Sea, and seismic operations continued in the Chukchi Sea. During September, SOI decided not to attempt to conduct deep seismic exploration in the Beaufort Sea during 2006 due to high concentrations of ice and other operational considerations. The *Gilavar*'s airguns and streamers were retrieved on 19 September and the *Gilavar* departed southward from the project area and left the Chukchi Sea on 23 September. The geographic region where the deep seismic survey occurred was located in the Chukchi Sea MMS OCS Program Area designated as Chukchi Sea Sale 193 (1989) and in the proposed 2002–2007 Chukchi Sea Program Area.

SOI used WesternGeco's 3147 in^3 3-string array of Bolt airguns for its 3–D seismic survey operations in the Chukchi Sea. For each airgun shot, WesternGeco's source array was composed of 3 identically-tuned Bolt airgun sub-arrays, each with 8 airguns and a total volume of 1049 in^3, operated at an air pressure of 2000 psi. This energy source was towed approximately 245 m behind the *Gilavar*. The system also included 6 hydrophone streamers 4200 m in length and spaced 100 m apart, which recorded reflected sound energy. Air compressors aboard the *Gilavar* were the source of high pressure air used to operate the airgun arrays. Seismic pulses were emitted at intervals of 25 m (~10 sec) while the *Gilavar* traveled at a speed of 4.5 to 5 knots (8.3–9.3 km/h).

SOI used the *Henry Christoffersen* to conduct site clearance and shallow hazards surveys of potential exploratory drilling locations within SOI's lease areas in the Beaufort Sea. The surveys were conducted between 8 Aug. and 2 Oct. 2006, on an intermittent basis as allowed by ice and weather conditions at specific nearshore areas ranging from east of Kaktovik west to Thetis Island near the Colville River Delta.

Offshore site clearance surveys use various geophysical methods and tools to acquire graphic records of seafloor and sub-seafloor geologic conditions. Small geophysical survey sources with limited energy output were employed to measure bathymetry, topography, geohazards, and other seabed characteristics. The strongest sound source was a cluster of four 70 in^3 airguns, which was used on 8 Aug. during the sound source measurements. Two 70 in^3 airguns were used during a deeper site clearance survey on 25 Sept. Those were the only dates in 2006 when SOI operated airguns in the Beaufort Sea. Other equipment used during the shallow hazards surveys included a bubble pulser operating at frequencies near 400 Hz for medium penetration and a chirp sonar operating at 2–7 and 8–23 Hz for shallow penetration. Other acoustic sources used to map the seafloor included multibeam bathymetric sonar operating at 240 kHz and side-scan sonar operating at 190–210 kHz.

SOI originally intended to conduct aerial surveys in the Beaufort Sea in support of deep seismic acquisition by the *Gilavar*. Since SOI did not conduct any deep seismic acquisition from the *Gilavar* in the Beaufort Sea in 2006, aerial surveys in the Beaufort Sea were only in support of the shallow hazards and site clearance activities conducted from the *Henry Christoffersen*.

A series of 8 north-south transect lines was established to monitor the project area in Camden Bay where SOI planned to conduct shallow hazard and site clearance surveys. Nine aerial surveys of the project area were conducted using a Twin Otter aircraft flown at 1000 ft above ground level at airspeed of approximately 120 knots. The first 7 surveys, conducted from 26 Aug. to 14 Sept., were pre-seismic surveys intended to collect baseline data on the distribution and abundance of marine mammals in the project area. On 23 and 24 Sept., surveys were flown to monitor the 120 dB zone around the *Henry Christoffersen* prior to seismic activities on 25 Sept.

Acoustic Modeling (Chapter 3).

Prior to conducting seismic and shallow hazards survey activities, SOI contracted with JASCO Research Ltd. to provide an acoustic model to estimate the extent of ensonification from the seismic acquisition and shallow hazards survey equipment in the Chukchi and Beaufort seas. The purpose of the modeling was to provide estimates of the received sound levels as a function of distance and aspect around the various acoustic sources when operating in the planned study regions. The model applied by JASCO takes account of the specific configuration of the airgun array. It also allows for the effects of the anticipated environmental conditions, including water properties, bathymetry, and bottom conditions, on the propagation of the sound through the water and bottom.

The main sound sources that were considered in this modeling study included three configurations of airgun arrays planned for use during seismic acquisition on the *Gilavar*. These consisted of one, two and three strings of airguns with 8 airguns per string and total volumes of 1049 in^3, 2098 in^3 and 3147 in^3 respectively. Also considered in the modeling were three potential shallow hazards survey sound sources. These were individual airguns of 10 in^3 and 20 in^3 volume, and a small airgun array consisting of four 70 in^3 airguns.

The acoustic modeling predicted distances at which the received sound level, on an rms basis, would be 190, 180, …, 120 dB re 1 μPa rms. In the original calculations the radii were "flat weighted" and did not take into account differences in hearing sensitivity among marine mammal groups. In addition, sensitivity weighting (*M*-weighting) was applied to underwater sound levels to weight the sound at various frequencies in accordance with the hearing characteristics of different marine mammal groups, i.e., baleen whales, toothed whales, and pinnipeds. The safety radii applied during initial airgun operations were the unweighted distances predicted by the modeling. Those predicted distances were used until the actual sound field around the operating airguns was measured empirically in the field (Chapter 4).

Acoustic Measurements (Chapter 4)

Seismic and shallow hazards surveys conducted by SOI relied on the generation of underwater acoustic pulses. Greeneridge Sciences, Inc., measured the underwater sound levels produced by the acoustic equipment that was used, including airguns and shallow-hazards sources, and by the vessels involved, including both seismic and support vessels. These measurements were acquired at the start of the respective periods of operation in the Chukchi and Beaufort Seas.

Values measured by Greeneridge were compared to the values that JASCO Research Ltd. had estimated (Chapter 3) by modeling, and were used to recommend updated mitigation radii for use by marine mammal observers on the seismic and shallow hazards ships during data acquisition.

Airgun pulses were received and analyzed at distances of 0.3–34 km in the Chukchi Sea and 0.06–20.5 km in the Beaufort Sea. Logarithmic sound propagation models were fitted to pulse sound pressure levels (SPL), sound exposure levels (SEL), and peak levels. A three-string array (24 airguns totaling 3147 in^3) used in the Chukchi Sea produced the highest values but showed little aspect dependence. A one-string array (8 airguns totaling 1049 in^3) used in the Chukchi Sea showed stronger aspect dependence, with the broadside aspect producing the highest values. Received levels produced by the small airgun array used in the Beaufort Sea (4 airguns totaling 280 in^3) were generally ~15–30 dB lower (depending on distance from the source) than those in the Chukchi Sea, mainly because the Beaufort Sea array was considerably smaller.

A comparison of empirical vs. modeled SPL values showed that the empirical distances exceeded predicted distances in most (but not all) situations. For the *three-string array,* the E:P (Empirical:Predicted) ratios ranged from 1.2× to 2.0× for the 160 dB, 180 dB, and 190 dB distances, depending on aspect. E:P ratios for the 120 dB distance were higher: 2.6× to 3.2× (considering only bow and stern aspect). For the *single-string array*, E:P ratios were somewhat higher for the 190 dB and 120 dB distances than for the 160–180 dB distances, but in some cases the empirical distances were in fact less than the predicted distances (E:P < 1.0). The E:P ratios for the airgun array used in the Beaufort Sea were in general lower (better) than those obtained in the Chukchi Sea.

Broadband (10–20,000 Hz) levels of vessel sound were analyzed as a function of distance from the sound source. Received levels at 500 m distance were 125–132 dB re 1 μPa for the seismic ship *Gilavar*, and 127–135 dB for the chase vessel *Jim Kilabuk*, depending on aspect (bow, stern, broadside). Both of these ships were recorded in the Chukchi Sea. In the Beaufort Sea, the received broadband level for the tug *Henry Christoffersen* at 500 m distance was ~122 dB re 1 μPa.

Monitoring and Mitigation Methods (Chapter 5)

The main purposes of the vessel-based monitoring program were to ensure that the provisions of the IHAs issued to SOI by NMFS and USFWS were satisfied, effects on marine mammals were minimized, and residual effects on animals were documented.

Under current NMFS guidelines, "safety radii" for marine mammals around airgun arrays are customarily defined as the distances within which received pulse levels are ≥180 dB re 1 μPa (rms) for cetaceans and ≥190 dB re 1 μPa (rms) for pinnipeds. Marine mammals exposed to ≥160 dB (rms) are assumed by NMFS to be potentially subject to behavioral disturbance. For the current seismic project there has also been concern that received pulse levels as low as 120 dB (rms) may have the potential to disturb some whales. In 2006, there was a requirement to implement special mitigation measures if specified numbers of bowhead cow/calf pairs might be exposed to ≥120 dB rms or if large groups (≥12

individuals) of bowhead or gray whales might be exposed to ≥160 dB rms. Sound levels were measured in the field to determine safety and disturbance radii to be used for mitigation during seismic acquisition and shallow hazards surveys.

The primary mitigation measures that were implemented during the seismic activities in the Chukchi and Beaufort seas included ramp up, power down, and shut down of the airguns. Mitigation was implemented by marine mammal observers (MMOs) onboard the *Gilavar* and *Kilabuk* who visually monitored the safety radii, and informed the airgun operators when a marine mammal was observed within or about to enter the appropriate safety radius.

In summary, during the seismic and shallow-hazards surveys in the Chukchi and Beaufort Seas, at least one MMO onboard the source vessel (*Gilavar* or *Henry Christoffersen*) maintained a visual watch for marine mammals during all daylight hours while seismic or shallow-hazards surveys were underway. During the surveys, two visual observers were on duty for 45% of the time watches were conducted on the *Gilavar* and for 2% of the time watches were conducted on the *Henry Christoffersen*. Observers focused their search effort forward of the vessel but also searched aft of the vessel while it was underway. Watches were conducted with the naked eye, Fujinon 7 × 50 reticle binoculars, and Zeiss 20 × 60 binoculars. MMOs instructed seismic operators to power down or shut down the airguns if marine mammals were sighted within or about to enter the appropriate safety radii.

An aerial survey program was conducted in support of the shallow-hazards program in the Beaufort Sea during fall of 2006 to advise the *Henry Christoffersen* as to the presence of marine mammals in the general area of operation. During the aerial surveys, observers also collected data on the distribution and abundance of marine mammals. Nine aerial surveys were conducted between 26 Aug. and 24 Sept. SOI's only use of airguns in the Beaufort Sea in 2006 occurred on 8 Aug. and 25 Sept., and was related to site clearance and shallow hazard surveys. Aerial surveys were conducted on 23 and 24 Sept. to monitor the 120 dB zone prior to airgun operations on 25 Sept.

In general, vessel-based data were categorized as "seismic", "post-seismic", or "non-seismic". "Seismic" included all data collected from the source vessel (*Gilavar* or *Henry C.*) while the airguns were operating. Non-seismic included all data obtained before the airguns were activated (pre-seismic) or >1 or >2 h (for pinnipeds and cetaceans, respectively) after the airguns were deactivated. Data collected during post-seismic periods from 3 min to 1 h (for pinnipeds) or 2 h (for cetaceans) after cessation of seismic activity were considered either "recently exposed" (3–30 min) or "potentially exposed" (30 min to 1 or 2 h) to seismic sound levels, and were excluded from analyses. Thus, the post-seismic data (3 min to 1 or 2 h after cessation of seismic) were not included in either the "seismic" or "non-seismic" categories.

Marine mammal sightings during the "seismic" and "non-seismic" periods were used to calculate sighting rates. Sighting rates were then used to calculate the corresponding densities of marine mammals near the survey and chase ships during seismic and non-seismic periods. These densities were used to estimate the numbers of marine mammals that may have been exposed to various levels of ensonification, and to determine the estimated take by harassment.

Monitoring and Mitigation Results (Chapter 6)

Marine mammal observers aboard the *Gilavar* conducted 13,527 km and 1537 h of visual observation and MMOs aboard the *Kilabuk* conducted 14,058 km and 1251 h of visual observation, together documenting 353 sightings of 442 pinnipeds and 115 sightings of 219 cetaceans (Table ES.1). There were numerous sightings of supply and chase vessels within 5km of each of the observation vessels.

TABLE ES.1. Summary of *Gilivar*, *Kilabuk*, and *Henry Christoffersen* operations, observer monitoring effort, and marine mammal sightings during SOI marine geophysical surveys in the Chukchi and Beaufort Seas 2006.

[a] See *Acronyms and Abbreviations for description of "useable" sightings.*

A total of 8213 km and 526 hours of visual observation was conducted aboard the *Henry Christoffersen*, during which 412 sightings of 451 marine mammals were logged. The ringed seal was the most abundant species recorded. No sightings were noted during the limited periods when airguns were in use in the Beaufort Sea. Few vessels were sighted during the cruise, and only two of these approached within 5 km of the *Henry Christoffersen*.

Based on the estimated densities of marine mammals in the Chukchi Sea during this project, about 416 different individual seals, 49 walruses, and 91 cetaceans would be expected to occur within the areas ensonified to ≥190 dB re 1 μPa (rms) for pinnipeds and 180 dB re 1 μPa (rms) for cetaceans at some time during the field season. Calculated estimates for individual pinnipeds and cetaceans potentially exposed to sound levels ≥160dB re 1 μPa (rms) were 1317 and 198 respectively.

No animals observed from the *Henry Christoffersen* were potentially exposed to sound levels ≥180 dB re 1 μPa (rms). Based on calculations involving estimated densities of marine mammals, there would have been approximately 180 seals exposed to sound levels ≥160 dB re 1 μPa (rms).

On the two days of aerial surveying in support of seismic activities on the *Henry Christoffersen*, 219.4 km of transect were flown, of which 188.4 km were flown in good surveying conditions. There was one sighting of a bowhead during these surveys.

1. BACKGROUND AND INTRODUCTION[1]

Shell Offshore, Inc. (SOI), collected marine seismic data in the Chukchi and Beaufort seas during the summer of 2006 in support of potential future oil and gas leasing and development. Deep seismic acquisition for SOI was conducted in the Chukchi Sea by WesternGeco using the M/V *Gilavar*, a seismic vessel that towed an airgun array as well as hydrophone streamers to record reflected seismic data. Seismic acquisition was originally planned to be conducted in both the Chukchi and Beaufort Seas using the *Gilavar*; however, ice conditions during the 2006 field season precluded most data collection in the Beaufort Sea. Activities in the Beaufort Sea were confined to site clearance, shallow hazard surveys and geotechnical activities, that were conducted from the M/V *Henry Christoffersen*, an NTCL vessel.

Marine seismic surveys emit sound energy into the water (Greene and Richardson 1988; Tolstoy et al. 2004a,b), and have the potential to affect marine mammals given the reported auditory and behavioral sensitivity of many such species to underwater sounds (Richardson et al. 1995; Gordon et al. 2004). The effects could consist of behavioral or distributional changes, and perhaps (for animals close to the sound source) temporary or permanent reduction in hearing sensitivity. Either behavioral/distributional effects or (if they occur) auditory effects could constitute "taking" under the provisions of the U.S. Marine Mammal Protection Act (MMPA) and the U.S. Endangered Species Act (ESA), at least if the effects are considered to be "biologically significant".

Numerous species of cetaceans and pinnipeds inhabit parts of the Chukchi and Beaufort seas. Two species listed as "Endangered" under the ESA do or may occur in portions of the survey area, including bowhead whale (*Balaena mysticetus*) and perhaps the fin whale (*Balaenoptera physalus*). The National Marine Fisheries Service (NMFS) and the U.S. Fish and Wildlife Service (USFWS) share jurisdiction over the marine mammal species that were likely to be encountered during the project. USFWS manages two species occurring in the Chukchi and Beaufort Seas, the walrus (*Odobenus rosmarus*) and the polar bear (*Ursus maritimus*); NMFS manages all the other marine mammals occurring in those areas.

Other species of concern (birds) that might occur in the survey area are the spectacled (*Somateria fischeri*) and Steller's (*Polysticta stelleri*) eiders that are listed as "Threatened" under the ESA. Of the two species, spectacled eiders are more abundant, have been documented farther offshore (40 km) in the Beaufort Sea, and use some lagoon systems in the Beaufort and Chukchi seas during their molt migration.

On 16 November 2005, SOI requested that NMFS issue Incidental Harassment Authorizations (IHAs) to authorize non-lethal "takes" of marine mammals incidental to SOI's planned seismic operations in the mid- and eastern parts of the Alaskan Beaufort Sea (SOI 2005a) and in the Chukchi Sea (SOI 2005b). The IHAs were requested pursuant to Section 101(a)(5)(D) of the MMPA. A single IHA to cover activities in both the Beaufort and Chukchi seas was issued to SOI by NMFS on 5 July 2006 (Appendix A). The IHA authorized "potential take by harassment" of various cetaceans and seals during the marine geophysical cruises described in this report. On 10 Jan. 2006, SOI also requested from USFWS an IHA to authorize potential "taking" of walruses and polar bears in the Chukchi Sea. USFWS issued that IHA to SOI on 29 June 2006 (Appendix B).

This document serves to meet reporting requirements specified in the IHA. The primary purposes of this report are to describe the seismic survey in the Chukchi and Beaufort seas, to describe the associated marine mammal monitoring and mitigation programs and their results, and to estimate the

[1] Chapter 1 by R. Rodrigues, B. Haley, and D. Ireland (LGL).

numbers of marine mammals potentially exposed to levels of sound generated by the project at or above presumed effects levels.

Incidental Harassment Authorization

IHAs issued to seismic operators include provisions to minimize the possibility that marine mammals close to the seismic source might be exposed to levels of sound high enough to cause hearing damage or other injuries. During this project, sounds were generated by the *Gilavar*'s airguns, as used during the seismic study, and by several types of lower-energy sound sources on the *Henry Christoffersen* including bottom mapping and seafloor imaging sonar, a chirp sonar, a bubble pulser, and a cluster of four small airguns. No serious injuries or deaths of marine mammals were anticipated from the seismic and shallow hazards surveys, given the nature of the operations and the mitigation measures that were implemented, and no injuries or deaths were attributed to these activities. Nonetheless, the seismic survey operations described in Chapter 2 had the potential to "take" marine mammals by harassment. Behavioral disturbance to marine mammals is considered to be "take by harassment" under the provisions of the MMPA. Appendix C provides further background on the issuance of IHAs relative to seismic operations and "take".

Under current NMFS guidelines (e.g., NMFS 2005a, 2006a), "safety radii" for marine mammals around airgun arrays are customarily defined as the distances within which the received pulse levels are ≥180 dB re 1 μPa (rms)[2] for cetaceans and ≥190 dB re 1 μPa (rms) for pinnipeds. Those safety radii are based on an assumption that seismic pulses at lower received levels will not injure these mammals or impair their hearing abilities, but that higher received levels *might* have some such effects. The mitigation measures required by IHAs are, in large part, designed to avoid or minimize the numbers of cetaceans and pinnipeds exposed to sound levels exceeding 180 and 190 dB (rms), respectively. The development and implementation of the safety radii for the current project are discussed in detail in Appendix C.

Disturbance to marine mammals could occur at distances beyond the safety (shut down) radii if the mammals were exposed to moderately strong pulsed sounds generated by the airguns or perhaps by sonar (Richardson et al. 1995). NMFS assumes that marine mammals exposed to airgun sounds with received levels ≥160 dB re 1 μPa (rms) are likely to be disturbed. That assumption is based mainly on data concerning behavioral responses of baleen whales, as summarized by Richardson et al. (1995) and Gordon et al. (2004). Dolphins and pinnipeds are generally less responsive than baleen whales (e.g., Stone 2003; Gordon et al. 2004), and 170 dB (rms) may be a more appropriate criterion of potential behavioral disturbance for those groups (LGL Ltd. 2005a,b). In general, disturbance effects are expected to depend on the species of marine mammal, the activity of the animal at the time of disturbance, distance

[2] "rms" means "root mean square", and represents a form of average across the duration of the sound pulse as received by the animal. Received levels of airgun pulses measured on an "rms" basis (sometimes described as Sound Pressure Level, SPL) are generally 10–12 dB lower than those measured on the "zero-to-peak" basis, and 16–18 dB lower than those measured on a "peak-to-peak" basis (Greene 1997; McCauley et al. 1998, 2000a,b). The latter two measures are the ones commonly used by geophysicists. Unless otherwise noted, all airgun pulse levels quoted in this report are rms levels. Received levels of pulsed sounds can also be described on an energy or "Sound Exposure Level" basis, for which the units are dB re $(1\ \mu Pa)^2 \cdot s$. The SEL value for a given airgun pulse, in those units, is typically 10–15 dB less than the rms level for the same pulse (Greene 1997; McCauley et al. 1998, 2000a,b), with considerable variability (Madsen et al. 2006; see also Chapter 4 of this report). SEL (energy) measures may be more relevant to marine mammals than are rms values, but the current regulatory requirements are based on rms values.

from the sound source, the received level of the sound and the associated water depth. Some individuals may exhibit behavioral responses at received levels somewhat below the nominal 160 or 170 dB (rms) criteria, but others may tolerate levels somewhat above 160 or 170 dB without reacting in any substantial manner. For example, migrating bowhead whales in the Alaskan Beaufort Sea show avoidance at received levels substantially lower than 160 dB re 1 μPa_{rms} (Miller et al. 1999; Richardson et al. 1999). In contrast, bowhead whales on the summer feeding grounds tolerate received levels of 160 dB or sometimes more (Richardson et al. 1986; G. Miller et al. 2005). Beluga whales also show avoidance at levels below 160 dB (G. Miller et al. 2005).

A notice regarding the proposed issuance of an IHA for the survey in the Chukchi and Beaufort seas was published by NMFS in the *Federal Register* on 3 May 2006 and public comments were invited (NMFS 2006a). On 24 Aug. 2006, NMFS published a second notice in the *Federal Register* to announce the issuance of the IHA (NMFS 2006b). The second notice responded to 32 comments received by NMFS during the 30-day public comment period. A copy of the IHA is included in this report as Appendix A.

The IHA issued by NMFS to SOI authorized harassment "takes" of one ESA-listed species (bowhead whale) as well as several non-listed species: gray (*Eschrichtius robustus*), killer (*Orcincus orca*), and beluga (*Delphinapterus leucas*) whales, harbor porpoises (*Phocoena phocoena*), and ringed (*Phoca hispida*), spotted (*Phoca largha*), and bearded (*Erignathus barbatus*) seals.

NMFS granted the IHA to SOI on the assumptions that

- the numbers of whales and seals potentially harassed (as defined by NMFS criteria) during seismic operations would be "small",
- the effects of such harassment on marine mammal populations would be negligible,
- no marine mammals would be seriously injured or killed,
- there would be no unmitigated adverse effects on the availability of marine mammals for subsistence hunting in Alaska, and
- the agreed upon monitoring and mitigation measures would be implemented.

USFWS determined in 2006 that proponents of arctic seismic projects should operate under IHAs issued by USFWS. The process of obtaining an IHA from USFWS was very similar to that of obtaining one from the NMFS. On 10 January 2006, SOI requested an IHA from USFWS for the incidental taking of walruses and polar bears in conjunction with seismic activities in the Chukchi Sea (SOI 2006). A notice regarding the proposed issuance by USFWS of an IHA for the survey in the Chukchi Sea was published in the *Federal Register* on 8 May 2006 and public comments were invited (USFWS 2006). This IHA was issued to SOI by USFWS on 29 June 2006. USFWS did not publish a second notice in the *Federal Register* to announce the issuance of the IHA. A copy of the USFWS IHA is included in this report as Appendix B. The IHA required SOI to observe a 190 dB safety radius for walruses and polar bears.

Mitigation and Monitoring Objectives

The objectives of the mitigation and monitoring program were described in detail in SOI's IHA applications (SOI 2005a,b, 2006) and in the IHA issued by NMFS to SOI (Appendix A). Explanatory material about the monitoring and mitigation requirements was published by NMFS and USFWS in the *Federal Register* (NMFS 2006a,b; USFWS 2006).

The main purpose of the mitigation program was to avoid or minimize potential effects of SOI's seismic survey on marine mammals. This required that shipboard personnel detect marine mammals within or about to enter the designated safety radii (190 dB for pinnipeds and 180 dB for cetaceans), and in such cases initiate an immediate power down (or shut down if necessary) of the airguns. A power down involves reducing the source level of the operating airguns, in this case by reducing the air volume. A shut down involves temporarily terminating the operation of all airguns. An additional mitigation objective was to detect marine mammals within or near the safety radii prior to starting the airguns, or during ramp up toward full power. In these cases, the start of airguns was to be delayed or ramp up discontinued until the safety radius was free of marine mammals insofar as this can be determined visually for a period of 30 minutes (see Appendix A and Chapter 5).

In 2006 mitigation was also required, as specified by the IHA, at the 160 dB isopleth. This area was monitored by the chase boat that accompanied the seismic vessel. Power down of the seismic airgun array was required if an aggregation of 12 or more non-migratory bowhead or gray whales was detected ahead of, or perpendicular to, the seismic vessel track and within the 160 dB isopleth. Monitoring of the 120 dB isopleth around the seismic vessel(s) was also required after 25 September in the Chukchi Sea and after 1 September in the Beaufort Sea. Power down would be required if 4 migratory cow/calf pairs were detected within the surveyed 120 dB isopleth.

The primary objectives of the monitoring program were as follows:

1. provide real-time sighting data needed to implement the mitigation requirements;
2. estimate the numbers of marine mammals potentially exposed to strong seismic pulses; and
3. determine the reactions (if any) of marine mammals potentially exposed to seismic sound impulses.

Specific mitigation and monitoring objectives identified in the IHAs are described in Appendices A and B. Mitigation and monitoring measures that were implemented during the activities in the Chukchi and Beaufort seas are described in detail in Chapter 5.

This 90-day report describes the methods and results for the monitoring work specifically required to meet the above primary objectives. Various other marine mammal and acoustic monitoring and research programs not specifically tied to the above objectives were also implemented by SOI (or by SOI plus other industry operators) in the Chukchi and/or Beaufort Seas during 2006. Results of those additional efforts are, for the most part, not mentioned in this 90-day report. Those additional results will be reported at a later date.

Report Organization

The primary purpose of this report is to describe the 2006 seismic survey activities in the Chukchi and Beaufort seas including the associated monitoring and mitigation programs, and to present results as required by the IHAs (Appendices A and B). This report includes six chapters:

1. background and introduction (this chapter);
2. description of SOI's seismic and site clearance studies;
3. sound source and propagation modeling prior to the field season;
4. sound source measurements during the field season;
5. description of the marine mammal monitoring and mitigation requirements and methods,

including safety radii; and

6. results of the marine mammal monitoring program, including estimated numbers of marine mammals potentially "taken by harassment".

Those chapters are followed by Acknowledgements and Literature Cited sections.

In addition, there are nine Appendices that provide copies of relevant documents and details of procedures that are more-or-less consistent during seismic surveys where marine mammal monitoring and mitigation measures are in place. These procedural details are only summarized in the main body of this report. The Appendices include

A. a copy of the IHA issued by NMFS to SOI for this study;

B. a copy of the IHA issued by USFWS to SOI for this study;

C. background on development and implementation of safety radii;

D. characteristics of the *Gilavar* and *Henry Christoffersen*;

E. details on visual and acoustic monitoring, mitigation, and data analysis methods;

F. conservation status and densities of marine mammals in the project region;

G. monitoring effort and list of marine mammals seen or heard during this cruise;

H. marine mammal sightings with power downs and shut downs during the seismic activities;

I. marine mammal density estimates for the project area.

2. SEISMIC SURVEYS DESCRIBED[3]

Chukchi Sea

The *Gilavar* was used as the source vessel during SOI's activities in the Chukchi Sea in 2006. The *Gilavar* was accompanied by the *Jim Kilabuk*, an icebreaker-class support vessel (chase vessel). Two other support vessels were also used in the Chukchi Sea at various times during the field season. The *Gulf Provider* was used as a supply vessel for transfer of personnel during crew changes, for fuel transfers to the *Kilabuk*, and to resupply the *Gilavar* with equipment and supplies. In addition, the *Peregrine*, a flat-bottom landing craft with minimal draft, was used for transfer of personnel and equipment from shore areas to the *Gulf Provider*. Appendix D contains a description of the vessels used during the seismic activities. These four vessels operated in accordance with the provisions of a Conflict Avoidance Agreement (CAA) between the seismic industry, the Alaska Eskimo Whaling Commission (AEWC), and the Whaling Captains Associations with respect to subsistence activities including but not limited to the hunts for bowhead and beluga whales. The objective of the CAA was to provide avoidance and other mitigation guidelines to be followed by industry participants working in or transiting the vicinity of active whaling crews. Under the terms of the CAA, communication centers were established at Barrow and Deadhorse, and Call Centers at Pt. Hope, Pt. Lay, Wainwright, and Kaktovik. The CAA outlined a communication program and specified times and areas to be surveyed in order to avoid any possible conflict with the subsistence hunts.

Operating Areas, Dates, and Navigation

The proposed deep seismic survey was originally scheduled to occur in two phases. Phase one commenced in July when sea ice conditions allowed access to the Chukchi Sea. Operations were originally planned to continue there until some date in late summer when the *Gilavar* and *Kilabuk* were to transit to the Beaufort Sea to conduct seismic surveys on Shell lease-holdings in the mid- and eastern parts of the Alaskan Beaufort Sea. Heavy ice conditions delayed the date when operations could have transferred to the Beaufort Sea, and seismic operations continued in the Chukchi Sea. During September, SOI decided not to attempt to conduct deep seismic exploration in the Beaufort Sea during 2006 due to high concentrations of ice and other operational considerations. The *Gilavar*'s airguns and streamers were retrieved on 19 September and the *Gilavar* departed southward from the project area and left the Chukchi Sea on 23 September.

The geographic region where the deep seismic survey occurred was located in the Chukchi Sea MMS OCS Program Area designated as Chukchi Sea Sale 193 (1989) and in the proposed 2002–2007 Chukchi Sea Program Area (see Fig. 2.1). Since the Chukchi Sea deep seismic program was conducted as a pre-lease activity, the exact locations where operations occurred remains confidential for business reasons. That is, the seismic data acquired in 2006 will be used by SOI to identify leases on which it may bid in a forthcoming competitive lease sale. However, in general, seismic acquisition occurred in the Chukchi Sea well offshore from the Alaska coast in OCS waters averaging greater than 40 meters (m) or 131 ft deep and outside the polynya zone.

The *Gilavar* left Dutch Harbor on 7 July to travel to the project area, and entered the Chukchi Sea on 10 July. Operations were then delayed due to ice conditions in the planned operating areas and to avoid potential disruption of the Pt. Lay beluga hunt. SOI's seismic contractor began deploying the seismic acquisition equipment on 21 July. After deployment of the airguns, the underwater sounds

[3] Chapter 2 by R. Rodrigues, B. Haley, and D. Ireland (LGL).

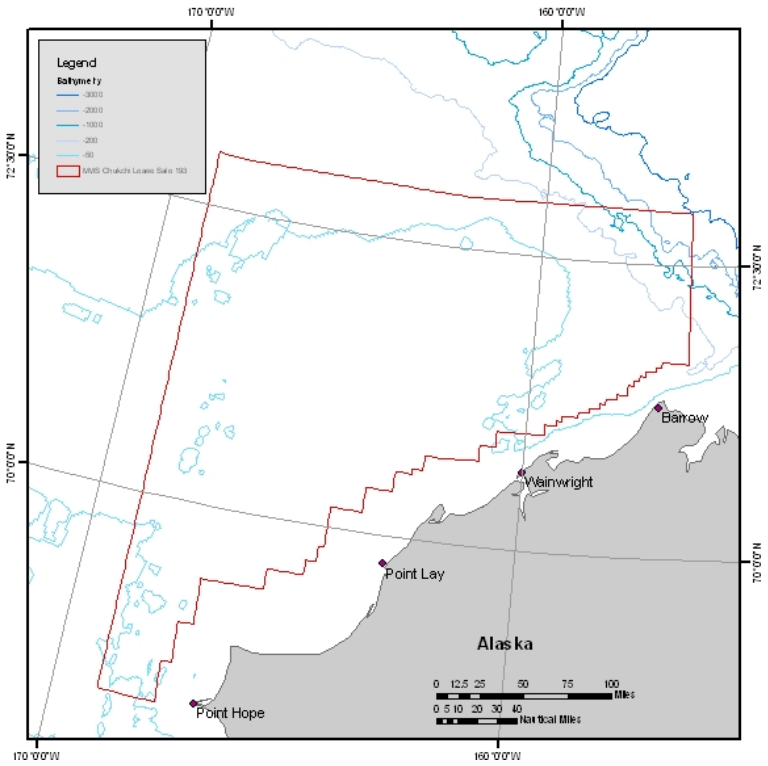

FIGURE 2.1. Location of the proposed MMS Chukchi Sea Lease Sale 193 within which SOI's 2006 high-energy seismic activities were conducted.

produced by the airgun array were recorded and analyzed to verify or refine the various radii to be used for mitigation purposes during the exploration activities (see Chapter 4 below). Those radii had been predicted prior to the field season via acoustic modeling procedures (see Chapter 3), but site-specific empirical measurements were required to confirm or refine the predictions. The airgun sounds were recorded as a function of airgun configuration, distance, and aspect on 21 and 22 July, and safety and disturbance radii based on these measurements were determined within 72 hrs. Seismic acquisition began on 27 July 2006 and continued through most of the field season until 19 September. SOI then determined that ice conditions and other operational considerations precluded continuation of the exploration program or a transition of the program into the Beaufort Sea, and seismic activities were terminated. SOI completed ~5297.4 km (3291.7 statute mi) of deep-seismic survey line in the Chukchi Sea in 2006.

Throughout the survey the *Gilavar's* position, speed, and water depth were logged digitally every ~60 s. In addition, the position of the *Gilavar*, water depth, and information on the airgun array were logged for every airgun shot while the *Gilavar* was on a seismic line and collecting geophysical data. The geophysics crew kept an electronic log of events, as did the marine mammal observers (MMOs) while on duty. The MMOs also recorded the number and volume of airguns that were firing when the *Gilavar* was offline (e.g., prior to shooting at full volume) or was online but not recording data (e.g., during airgun or computer problems).

Airgun Description

SOI used WesternGeco's 3147 in^3 3-string array of Bolt airguns for its 3–D seismic survey operations in the Chukchi Sea. WesternGeco's source array was composed of 3 identically-tuned Bolt airgun sub-arrays, each with 8 airguns and a total volume of 1049 in^3, operated at an air pressure of 2000

psi. Each string was 15 m in length, and each string was 8 m from the adjacent string(s). The individual airguns ranged in volume from 30 to 235 in^3, and each string included two 235 in^3 and two 125 in^3 airguns in 2-gun clusters. This energy source was towed approximately 245 m behind the *Gilavar*. The system also included 6 hydrophone streamers 4200 m in length and spaced 100 m apart, which recorded reflected sound energy. In general, the *Gilavar* towed this system along a predetermined survey track although adjustments were made during the course of the field season in accordance with ice conditions.

Air compressors aboard the *Gilavar* were the source of high pressure air used to operate the airgun arrays. Seismic pulses were emitted at intervals of 25 m (~10 sec) while the *Gilavar* traveled at a speed of 4 to 5 knots (7.4–9.3 km/h). The airgun arrays were towed at a depth of 6 m and were 8 m apart. Characteristics of the airgun arrays are detailed in Appendix D.

Beaufort Sea—Vessel-based Component

In addition to deep seismic surveys in the Chukchi Sea, SOI also conducted site clearance and shallow hazards surveys of potential exploratory drilling locations within SOI's lease areas in the Beaufort Sea as required by MMS regulations. Before drilling can begin, a site clearance survey and analysis is necessary to identify and/or evaluate potentially hazardous or otherwise sensitive conditions and sites at or below the seafloor that could affect the safety or appropriateness of operations. Examples of such conditions include subsurface faults, fault scarps, shallow gas, steep-walled canyons and slopes, buried channels, current scour, migrating sedimentary bedforms, ice gouging, permafrost, gas hydrates, unstable soil conditions, pipelines, anchors, ordnance, shipwrecks, or other geophysical or man-made features.

Offshore site clearance surveys use various geophysical methods and tools to acquire graphic records of seafloor and sub-seafloor geologic conditions. The data acquired and the types of investigations outlined below are performed routinely for most exploratory drilling and production facilities in marine areas, and for submarine pipelines, port facilities, and other offshore projects. High-resolution geophysical data such as two-dimensional, high-resolution multi-channel seismic, medium penetration seismic, subbottom profiler, side scan sonar, multibeam bathymetry, magnetometer, and possibly piston core sediment sampling are typical types of data acquired. These data are interpreted to define geologic, geotechnical and archeological conditions at the site and to assess the potential engineering significance of these conditions. The following section provides a brief description of the operations and instrumentation used during SOI's 2006 Beaufort Sea site clearance program insofar as they may impact marine mammals.

Operating Areas, Dates, and Navigation

The site clearance surveys were confined to very small specific areas within defined OCS blocks (Fig. 2.2). The surveys were conducted from the M/V *Henry Christofferson*. This vessel is 47 m (153 ft) long and the gross tonnage is 783 metric tons. It is powered by four Caterpillar V16 D399 diesel engines and can travel at a speed of 14 knots (see Appendix D). Small geophysical survey sources with limited energy output were employed to measure bathymetry, topography, geohazards, and other seabed characteristics. The strongest sound source was a cluster of four 70 in^3 airguns, which was used during the sound source measurements. Two 70 in^3 airguns were used during a deeper site clearance survey on 25 Sept. Chapter 4 describes results of measurements of sounds from this and other acoustical sources used during site clearance operations.

Measurements of sounds from the 4-airgun array and from other acoustic sources on the *Henry C.* were conducted on 8 Aug. in the Beaufort Sea east of Kaktovik (see Chapter 4 for details). The sound sources (including the cluster of 4 airguns) were operated for 2.5 hours on this date. Between

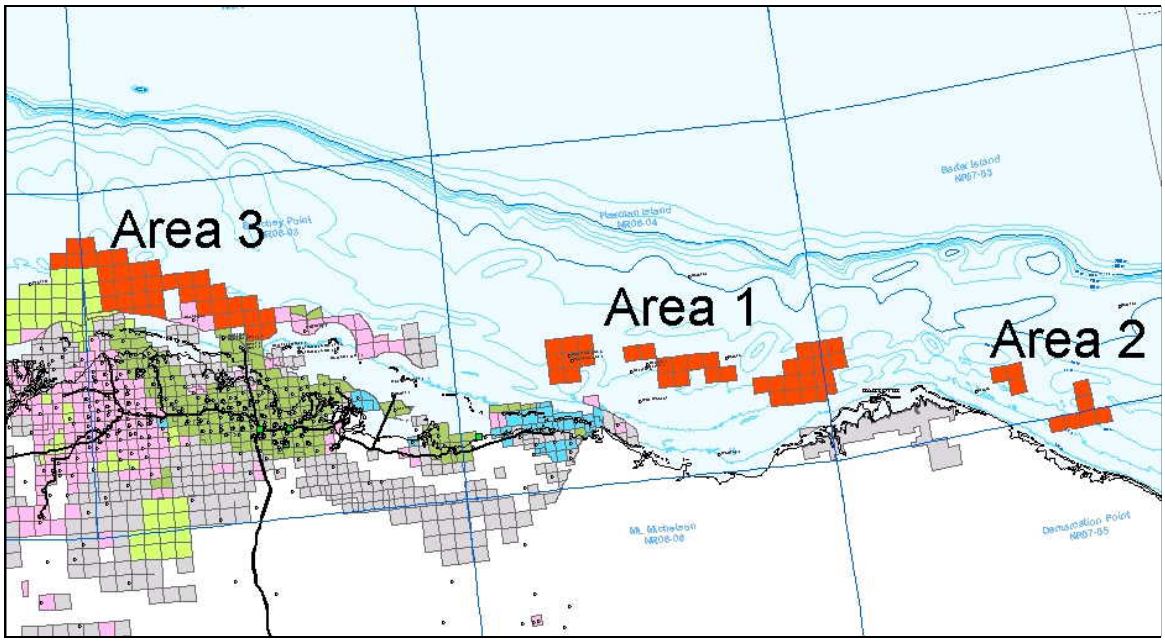

FIGURE 2.2. Location of SOI lease holdings in the Alaskan Beaufort Sea.

8 Aug. and 2 Oct. 2006, on an intermittent basis as allowed by ice and weather conditions, various types of site clearance surveys were conducted from the *Henry C.* These operations were in specific nearshore areas ranging from east of Kaktovik west to Thetis Island near the Colville River Delta (Fig. 2.2). Site clearance survey activities occurred on ~23 days during this period. However, during that period the airgun cluster (2 airguns) was operated only once for ~12 hrs on 25 Sept. At all other times during surveys, the acoustical sources in use were lower-energy medium- and high-frequency sources as described below. On days when surveys did not occur, the *Henry Christoffersen* was usually transiting to a new site or anchored while waiting for bad weather or ice conditions to subside.

Throughout the survey the *Henry Christoffersen*'s position, speed, and water depth were logged digitally every ~60 s. In addition, the position of the *Henry C.*, water depth, and information on the output of the airgun array or other geophysical tools were logged during all site clearance activities. The geophysics crew kept an electronic log of events, as did the marine mammal observers (MMOs) while they were on duty.

Geophysical Tools for Site Clearance

An airgun cluster consisting of four 70-in^3 airguns was planned for use during site clearance operations to locate potential hazards, such as gas deposits, at relatively shallow locations. The results of the source measurements indicated to the operators that the use of the 4-airgun array was excessive for their needs. Therefore, a pair of 70-in^3 airguns was the sound source used during the ~12-h of airgun operations on 25 Sept.

Several other lower-energy acoustic sources were operated for shallow-penetration subbottom surveys and to map the bottom. A bubble pulser operating at frequencies near 400 Hz was used for medium penetration and a chirp sonar operating at 2–7 and 8–23 Hz was used for shallow penetration. Other acoustic sources used to map the seafloor included a multibeam bathymetric sonar operating at 240

kHz and a side-scan sonar operating at 190–210 kHz. Characteristics of this equipment are described in more detail in Appendix D.

Beaufort Sea—Aerial Component

SOI originally intended to conduct aerial surveys in the Beaufort Sea in the summer (July to late Aug.) to collect pre-seismic baseline data and to conduct fall surveys (late Aug. to Oct.) as part of the monitoring and mitigation effort associated with seismic survey activities. Logistical problems early in the summer season precluded SOI's ability to conduct summer aerial surveys, and since SOI did not conduct any deep seismic acquisition from the *Gilavar* in the Beaufort Sea in 2006, the aerial surveys in the Beaufort Sea were only in support of the shallow hazards and site clearance activities conducted from the *Henry Christoffersen*.

A series of 8 north–south transect lines was established to monitor the project area in Camden Bay where SOI planned to conduct shallow hazard and site clearance surveys using their 240 in^3 airgun array (Fig. 2.3). Nine aerial surveys of the project area were conducted using a Twin Otter aircraft flown at 1000 ft above ground level at an airspeed of approximately 120 knots. The first 7 surveys, conducted between 26 Aug. and 14 Sept., were pre-seismic surveys intended to collect baseline data on the distribution and abundance of marine mammals in the project area. Surveys were flown on 23 and 24 Sept. to monitor the 120 dB zone prior to seismic activities on 25 Sept.

3. ACOUSTIC MODELING[4]

INTRODUCTION

Shell Offshore, Inc. (SOI), conducted seismic exploration activities in the Chukchi Sea and shallow hazards surveys in the Alaskan Beaufort Sea during summer 2006. Prior to conducting these activities SOI contracted with JASCO Research Ltd. to provide an acoustic model to estimate the extent of ensonification from the seismic acquisition and shallow hazards survey equipment in the Chukchi and Beaufort seas. The purpose of the modeling was

- to characterize the acoustic environment in the areas of the Chukchi and Beaufort seas where the seismic and shallow hazards programs were to be conducted,
- to predict the anticipated source characteristics of the emitted sounds, and
- to provide estimates of the received sound levels as a function of distance and aspect around the various acoustic sources when operating in the planned study regions.

Sound propagation modeling was performed for six locations, three in the Chukchi Sea and three in the Beaufort Sea, to provide predictions representative of the areas over which seismic exploration and shallow hazards surveys were to occur. The particular type of model used is state-of-the-art. It takes account of the specific configurations of the planned airgun arrays, and also allows for the anticipated effects of local environmental conditions on propagation of sound. Those propagation effects can have strong influences on received sound levels and other acoustic parameters, especially in shallow-water environments such as those where SOI's 2006 programs were to occur. The specific modeling approach used in this study has been subject to expert review by an IUCN scientific panel (Reeves 2005). Model input parameters, notably bathymetry, seabed properties, and sound velocity profiles for the water column, were chosen to be appropriate for the respective geographic regions and seasons modeled. The site locations for modeling were near the prospect or in areas similar with respect to the parameters mentioned above.

Use of acoustic modeling techniques to estimate the noise footprint associated with the seismic and shallow hazards survey activities provided a basis for planning the mitigation procedures that were implemented to minimize impacts of SOI's project on marine mammals. However, the project plans also provided for field measurements of the actual sound levels and characteristics early in the period of operation in both the Chukchi and Beaufort Seas. Results of those field measurements are described in Chapter 4 of this report. The modeling and field measurement programs were complementary to one another.

The main sound sources that were considered in this modeling study included three airgun arrays consisting of one, two and three strings of airguns with 8 airguns per string (i.e., totals of 8, 16 and 24 airguns with a total volumes of 1049 in^3, 2098 in^3 and 3147 in^3 respectively). Also considered in the modeling were three potential shallow hazards survey sources. These were individual airguns of 10 in^3 and 20 in^3 volume, and a small airgun array consisting of four 60 in^3 airguns for a total volume of 240 in^3. The 24-airgun 3147 in^3 configuration that was modeled closely matched the actual airgun configuration used by SOI for the Chukchi Sea seismic survey. The actual airgun configuration for the limited airgun operations during the 2006 shallow-hazards survey in the Beaufort Sea was a 4-airgun 280 in^3 array, slightly larger than the configuration that was modeled. Given that peak pressure from an airgun source increases in proportion

[4] Summarized by LGL from a detailed technical report (Austin et al. 2006b; 21 August 2006 version 3) by JASCO Research Ltd. for Shell Offshore Inc.

to the cube root of the source volume, an increase from 240 to 280 in^3 would have minimal effect on the received sound levels at any distance; at any location, the change would be less than 1 dB.

JASCO's modeling is a two-stage process. *(1)* A proprietary airgun array source-level model was used to characterize the sounds emitted by individual elements within each airgun array, and by the array as a whole. This source model took account of the specifications and spacing of the individual airguns planned for use during the 2006 seismic and shallow-hazards programs. *(2)* The modeled source levels were incorporated into an N×2-D sound propagation model, JASCO's Marine Operations Noise Model (MONM), to estimate the sound field as a function of distance and direction from each source. From this, JASCO estimated the ranges corresponding to the various safety and disturbance criteria that are typically applied during seismic programs conducted under Incidental Take Authorizations issued by the National Marine Fisheries Service (e.g., the 190, 180 and 160 dB re 1 μPa rms distances). Other distances of interest, including the 170 dB and 120 dB distances, were also estimated. This Chapter summarizes the methods and results of the sound source modeling. This summary of the modeling effort and results is based on JASCO's detailed technical report on the modeling, by Austin et al. (2006b).

JASCO SOURCE MODEL

JASCO currently employs a full-waveform airgun array signature model, called AASM, to compute the source level and directionality of airgun arrays (MacGillivray et al. 2004). The source signature model numerically simulates the oscillation and radiation of a collection of airgun bubbles. The theory of the airgun array model is beyond the scope of this report but is based on the pioneering work of Ziolkowski (1970) who first modeled the pressure waveforms of seismic airguns, with additional physics to account for pressure interactions between airguns, port throttling, bubble damping and GI-gun behavior, as described by such authors as Dragoset (1984), Laws et al. (1990), and Landro (1992). The source model includes four empirical parameters that are tuned so that the model output matches observed airgun behavior. The model parameters were fitted to a large library of real airgun data using a "simulated annealing" global optimization algorithm. The airgun data used in the optimization were obtained from a previous study (Racca and Scrimger 1986) that measured the signatures of Bolt airguns, ranging in volume from 5 in^3 to 185 in^3.

The output of the airgun array source model is a set of "notional" signatures for the individual array elements (i.e., the airguns). The notional signatures are the pressure waveforms of the individual guns, which are summed together with the appropriate phase delays to obtain the far-field source signature of the array (Parkes and Hatton 1986). The far-field array signature, in turn, is filtered into 1/3-octave pass bands to compute the source level of the array as a function of frequency band and propagation azimuth.

Seismic Sources Modeled

The three seismic airgun arrays modeled in this study were configured as per the specifications for the three arrays planned for use during the seismic program. One array had total volume 3147 in^3 and consisted of three sub-strings, with eight guns each. Each string of 8 airguns was 15 m in length, and the strings were spaced 8 m apart for total array dimensions of 16 m (cross-track) by 15 m (along-track). Individual airguns in each string ranged in volume from 30 in^3 to 235 in^3, and each string included two 235 in^3 airguns in a cluster. The second airgun array had a total volume of 2098 in^3 and consisted of two identical sub-strings as described above, with eight guns each (array dimensions 8 m cross-track by 15 m along track). The third airgun array had a total volume of 1049 in^3 and consisted of one 15-m-long sub-string (as described above) with eight guns total.

All three arrays were modelled using AASM to compute notional source signatures and 1/3-octave band source levels as a function of azimuth angle. The source depth was set at the anticipated operating depth of 6 m. Broadside and endfire overpressure signatures and corresponding power spectrum levels were calculated.

Shallow Hazards Sources Modeled

Shallow hazards surveying was to be accomplished using a source such as an individual airgun or a small airgun array, an echosounder, a bubble pulser, chirp sonar (sub-bottom profiler), a multibeam sonar, or a sidescan sonar. The source signatures of a single airgun of two different sizes (10 in^3 and 20 in^3) and of a small airgun array (4 airguns totaling 240 in^3) were modeled for this report. The 4-airgun source was the strongest source anticipated for use during the shallow hazards program. Sounds from a bubble pulser and chirp sonar were not modeled in advance of the field season, but were measured in the field at the start of the shallow-hazards program (Chapter 4). The multibeam and sidescan sonars operate at very high frequencies (240 kHz and 190–210 kHz, respectively) that are too high to be of concern for the marine mammal species that inhabit the Beaufort Sea and were not considered for this report.

SOUND PROPAGATION MODELING METHODOLOGY

Acoustic models can be used to predict sound transmission loss in defined environments. Subtracting the modeled transmission loss values (in decibels) from estimated source levels provides estimates of received levels at defined receiver positions. The transmission loss model used in this study is JASCO Research's MONM acoustic model. Airgun array source levels, predicted with AASM, were input to MONM and received levels were predicted.

MONM computes the expected received sound levels in terms of energy flux density (EFD), also referred to as Sound Exposure Level (SEL), for 3-dimensional range-varying acoustic environments. It does so by utilizing a wide-angled parabolic equation (PE) solution to the acoustic wave equation. The parabolic equation code in MONM is based on the Naval Research Laboratory's Range-dependent Acoustic Model (RAM), which has been extensively benchmarked for accuracy and is widely employed in the underwater acoustics community (Collins 1993). MONM computes acoustic fields in 3-D by modeling transmission loss along radial traverses at evenly-spaced angles covering a 360º swath from the source (known as N×2-D modeling). MONM employs several kinds of environmental data, including bathymetry, sound speed profiles, and geoacoustic profiles, and samples the acoustic environment every 50 meters in range along model traverses. MONM handles frequency dependence by computing acoustic transmission loss in 1/3-octave bands from 10 Hz to 2 kHz. MONM computes received sound pressure level by combining transmission loss with frequency-dependent source levels. MONM's sound level predictions have been validated against experimental data from shallow-water environments, and in those prior applications have proven to be highly accurate (Hannay 2004).

Environmental data for each modeling location, such as bathymetry, water column profiles, and geology were obtained from various sources for the appropriate times of year. For locations in the Chukchi Sea, environmental data appropriate to the month of July were used. For Beaufort Sea locations, data for the month of August were used.

SOUND LEVEL RADII

Seismic Airgun Array

MONM computes the received energy level of an airgun pulse in SEL units, expressed in dB re 1 $\mu Pa^2 \cdot s$ (e.g., Fig. 3.1), and does not directly compute peak or rms sound pressure level (SPL, in dB re 1 µPa rms). However, current U.S. regulatory requirements are based on the SPL (rms) metric, i.e., the root-mean-square sound pressure level calculated over the interval within 90% of the pulse energy reaches the receiver (sometimes abbreviated as "90% rms"). The rms value for a received airgun pulse is a function not only of distance, but also of the extent to which the pulse duration has been extended by propagation effects. To compute sound pressure levels directly, allowing for dispersion phenomena, would require calculation times that would be prohibitive for large geographic areas like those considered in the current study.

In order to convert the MONM results (in SEL units) to rms values compatible with the U.S. regulatory requirements, the "Fourier synthesis" technique as described in Jensen et al. (1994) has been used to develop a conversion procedure. For each source configuration and modeling site, the result is a set of predicted radii at which the received sound level, on an rms basis, would be 190, 180, …, 120 dB re 1 µPa rms. Table 3.1 shows the predictions for the three modeling sites in the Chukchi Sea and the three airgun configurations that were considered (1-, 2- and 3-string; 8, 16 and 24 airguns; 1049, 2098 and 3147 in^3). These values

150	6.2	7.56	7.95	5.79	7.72	8.16	7.53	10.05	10.51
160	3.59	4.25	4.53	3.18	4.40	4.62	3.80	5.25	5.67
170	1.73	2.05	2.19	1.67	2.10	2.20	1.88	2.17	2.44
180	0.61	0.76	0.81	0.64	0.80	0.85	0.58	0.77	0.82
190	0.09	0.22	0.23	0.11	0.11	0.13	0.05	0.23	0.23

are derived based on predicted received levels at a large number of grid points (e.g., Fig. 3.1), and there is some variability in the specific distance at which the received sound level would be expected to diminish to any given level. The tabulated distances for a given level (e.g., 180 dB rms) are those encompassing 95% of the locations at which the received level is expected to be ≥180 dB re 1 μPa rms.

The sound from the main 3-string airgun array is predicted to be ~5 dB stronger in the broadside direction than in the endfire direction (e.g., Fig. 3.1). This aspect dependence is predicted to be larger for a single string array than for a 2- or 3-string array (e.g., Fig. 3.2).

The radii calculated in Table 3.1 are "flat weighted" and do not take into account differences in hearing sensitivity among marine mammal groups. Sensitivity weighting (*M*-weighting) was applied to underwater sound levels to weight the sound at various frequencies in accordance with the hearing characteristics of different marine mammal groups. Weighting sound levels in this way decreases the contribution to the overall received level by sound energy in frequency bands outside the frequency range where the mammal in question hears well. Weighting curves appropriate for various categories of marine mammals exposed to strong sounds were first presented by the Advisory Committee on Acoustic Impacts on Marine Mammals in April 2004 (Gentry et al. 2004). They have subsequently been presented in more detail by J. Miller et al. (2005) and in Southall et al. (submitted).

Baleen whales hear well at low frequencies, which are the dominant frequencies in airgun pulses, and frequency weighting would not significantly affect the estimated 190, 180, …, 120 dB rms radii for baleen whales. However, pinnipeds and especially the "mid-frequency cetaceans" (like beluga whales) do not hear as well at low frequencies, and frequency weighting appropriate to those groups was expected to result in reduced effective radii for them. Tables 3.2 and 3.3 show how frequency weighting reduces the predicted rms radii for those two groups, as compared with flat weighting (Table 3.1).

Shallow Hazards Survey Sources

10 in^3 and 20 in^3 Airgun Sources

During the planning phase for this project, it was considered possible that an individual airgun might be used to survey for shallow hazards. It was anticipated that the largest-volume single airgun that might be used in this way would be 20 in^3. Alternatively, a single 10 in^3 airgun might be used. Either of

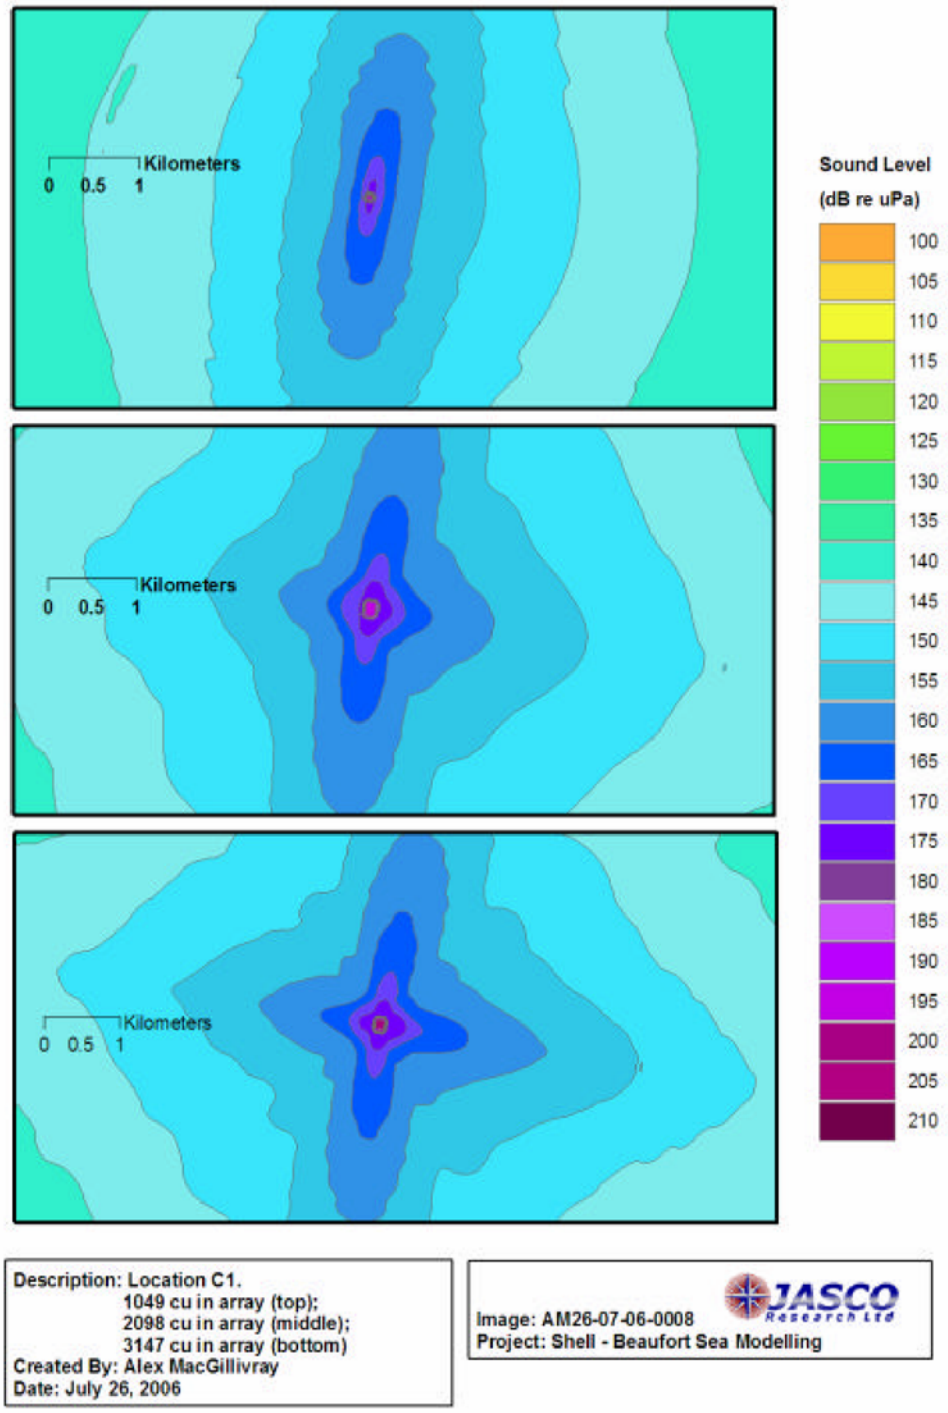

FIGURE 3.2. Maps of predicted received levels at 10 m depth, in SEL (energy) units, within several kilometers of a 1-string (top), 2-string (middle) and 3-string (bottom) airgun array being towed approximately East–West at source location C1.

these sources would be deployed at 1 m depth. The radii predicted for 90% rms levels, calculated using the Fourier synthesis technique, are presented in Table 3.4 (for the 20 in^3 source) and Table 3.5 (for the 10 in^3 source). Predicted radii both without and with frequency weighting, as described above, are shown. The predicted radii are small in part due to the small source, and in part due to the very shallow source depth (1 m). The latter would cause cancellation of a significant portion of the low frequency airgun energy through interactions between sound arriving via a direct-path and that arriving via a surface reflection path (surface ghost). Propagation modeling for these small sound sources was performed for two locations (B1 and B2) in the Beaufort Sea (Fig. 3.1).

240 in^3 Airgun Array

A small airgun array with total volume of 240 in^3 that could be used for shallow hazards surveying was also considered in the modeling. The array configuration consisted of two 2-gun clusters spaced 50 cm apart; each gun has a volume of 60 in^3. The radii predicted for the various 90% rms levels, without and with frequency-weighting, are presented in Table 3.6.

TABLE 3.4. Predicted rms radii, in kilometers, for a single 20 in^3 airgun operating at 2 modeled locations in the Beaufort Sea.

CONCLUSIONS

The acoustic environments at locations of the Beaufort and Chukchi Seas have been characterized by JASCO Research Ltd. (Austin et al. 2006b) and summarized in this chapter. The noise sources considered were three seismic airgun arrays with total volumes of 1049, 2098 and 3147 in^3 and several potential shallow hazards sources including individual airguns and a small airgun array. The acoustic output of each source was modeled and used as input to a state-of-the-art sound propagation model. This, in turn, was used to predict the acoustic energy levels that would be received as a function of distance and direction from these sources operating at representative locations in the Chukchi and Beaufort Seas. From these predictions of the received sound field in energy units, JASCO determined the distances at which received sound levels were expected to diminish below various levels that are of relevance for regulatory purposes, as measured on an rms basis (190, 180, … , 120 dB re 1 μPa rms). These predictions were expected to be considerably more accurate than could be achieved with simpler models that do not take account of site specific environmental conditions, such as sound velocity profile, water depth, and bottom and sub-bottom conditions. All of those factors are taken into account in JASCO's modeling, to the extent that these variables are known when modeling is done.

Species specific sensitivity weighting was applied to all of the model results to provide alternative safety radii that account for the relative sensitivity of different marine mammal groups to low-frequency sounds such as those that dominate seismic airgun sound. *M*-weighting curves were applied for "mid-frequency" cetaceans such as beluga whales, and for pinnipeds listening in water. These weighting functions reduced the predicted effective rms radii for airgun noise by a small amount for pinnipeds and by a larger amount for mid-frequency cetaceans. Although these reduced radii were not applied as safety radii or when calculating the number of mammals exposed to various sound levels during the project, the results indicate that the standard "unweighted" procedures used for pinnipeds and toothed whales during the project were protective in this respect.

Predicted distances for various sources and received levels are tabulated in this chapter. The maximum distances at which rms received levels of 190, 180, 160 and 120 dB re μPa were predicted to occur during operation of the 3147 in^3 airgun array in the Chukchi Sea were 0.23 km, 0.85 km, 5.7 km, and 42 km, respectively. The sound from the main airgun arrays was predicted to be ~5 dB stronger in the broadside direction than in the endfire direction. Comparisons of many of the predictions summarized in this chapter with empirical measurements from the Chukchi and Beaufort Seas can be found in Chapter 4.

4. ACOUSTIC MEASUREMENTS[5]

INTRODUCTION

During July through most of September 2006, Shell Offshore Inc. (SOI) conducted 3D seismic surveys in the Chukchi Sea. During August through early October SOI conducted shallow-hazards surveys in the Beaufort Sea. Both types of surveys relied on the generation of underwater acoustic pulses. Arrays of airguns towed behind a vessel were used for both the seismic and the shallow-hazards survey, and additional acoustic sources were used for the shallow-hazards survey. Greeneridge Sciences, Inc., measured the underwater sound levels produced by the vessels involved, including both seismic and support vessels, and by the acoustic equipment that was used, including airguns and the other shallow-hazards sources.

Shutdown or power-down radii are the ranges from a sound source within which the presence of a protected species requires suspension or alteration of operations because of the possibility of adverse effects, as defined in the applicable permits and authorizations. These mitigation criteria are commonly established to avoid or minimize the possibility of hearing damage. They may also be designed to reduce behavioral disturbance. For airguns, the government-mandated shutdown or power-down radii used in this project were the maximum distances within which received levels of the pulsed sounds could exceed 190 dB re 1 μPa SPL[6] (for pinnipeds) or 180 dB re 1 μPa SPL (for cetaceans). In certain situations, mitigation would also be required when cetaceans were found within the 160 or 120 dB re 1 μPa SPL radii.

Before the onset of field work, JASCO Research Ltd. had estimated, by numerical modeling, the distances from the airgun arrays at which the broadband (rms) received levels would be 190 dB, 180 dB, 170 dB, 160 dB, and 120 dB re 1 μPa (see Chapter 3). Early in the respective periods of operation of the seismic and shallow-hazards vessels, Greeneridge Sciences measured the actual underwater sounds from these sources to establish appropriate mitigation radii for the seismic and shallow-hazards survey equipment. Measured values were used to recommend mitigation radii for use by marine mammal observers on the seismic ships during data acquisition and subsequent data analyses, and these empirically-determined values were compared to the values that had been predicted by modeling.

This chapter reports on data collected during two separate field trips involving three different vessels. The seismic ship *MV Gilavar* and the chase vessel *MV Jim Kilabuk* were used in the Chukchi Sea for seismic data acquisition, and the tug and shallow-hazards survey vessel *MV Henry Christoffersen* (or *Henry C.*) was used in the Beaufort Sea for acquisition of shallow-hazards data.

Objectives

Field objectives were similar in the Chukchi and Beaufort seas and included three components:

- Field measurements of the sounds produced by airguns (*Gilavar* and *Henry Christoffersen*) or sources used in shallow-hazards surveys (only *Henry C.*). These measurements were to be made at the beginning of the seismic surveys in each region, and the collected data were to be analyzed immediately to the extent necessary to establish the mitigation radii. Ranges at which broadband levels were received at 190, 180, 170, 160, and 120 dB (SPL) re 1 μPa were to be determined and reported within 72 hours to Shell.

---

[5] By Susanna B. Blackwell, Robert G. Norman, Charles R. Greene Jr. (Greeneridge Sciences Inc.), and W. John Richardson (LGL).

[6] SPL: sound pressure level, i.e., root mean square (rms) pressure level averaged over duration of sound pulse.

- After the field season, the empirical data were to be further analyzed to obtain a more comprehensive assessment of pulse characteristics—including duration, peak level, and SEL (sound exposure level) as well as SPL (=rms)—as a function of range and aspect. Spectral properties of the pulses, in particular one-third octave band characteristics, were also to be documented.
- Field measurements of radiated propulsion sounds as a function of distance from all vessels involved: the seismic vessel *Gilavar* and the support/supply/chase vessel *Jim Kilabuk* in the Chukchi Sea, and the shallow-hazards survey vessel *Henry C.* in the Beaufort Sea.

Measurements were obtained in July (Chukchi Sea) and August (Beaufort Sea) 2006 and the results are presented in this report. Field reports including recommended mitigation radii were submitted to Shell on 26 July and 10 August 2006, respectively, for measurements in the Chukchi and Beaufort seas. The final versions of these field reports are appended to this chapter as Annexes 4.1 and 4.2.

METHODS

Equipment

Recordings were made using two Autonomous Seafloor Acoustic Recorders model B (ASAR-B). A picture and schematic representation of an ASAR-B are shown in Figure 4.1. The ASAR-B consists of a pressure housing containing the recording electronics and a rechargeable gel cell battery. The recorder includes a two-channel signal digitizer with 16-bit quantization. It was initially programmed to sample at 44.1 kHz on each channel, providing a useable frequency range of 5 to 20,000 Hz. One of the ASAR-Bs in the Beaufort Sea measurements was re-programmed to sample at 192 kHz, because of the presence of higher frequency sound sources (see below). Data were written to an 8 GB solid state memory (Flash card), providing ~13 hours of continuous recording at the 44.1 kHz sampling rate. For deployment on the sea floor the ASAR-B housing was mounted in the center of a pyramidal steel frame weighing ~41 kg (~90 lbs, Fig. 4.1). Hereafter ASAR-Bs will be referred to simply as ASARs.

Two different types of hydrophones were used concurrently, one on each recording channel:

- A calibrated ITC model 8212 broadband hydrophone with a low-noise preamplifier: This was the more sensitive of the two hydrophone types, best suited for recording sound levels below ~135 dB re 1 μPa (this type of hydrophone saturated at peak levels of about 145 dB re 1 μPa 0-peak).
- A calibrated ITC model 1032 spherical broadband hydrophone without preamplifier: This hydrophone was included to permit undistorted recordings of high-level sound pulses. This type of hydrophone saturated at peak levels close to 207 dB re 1 μPa 0-peak.

The hydrophone cables were threaded through the top of the pyramidal frame and the hydrophones were buoyed up from the sea floor by a glass sphere (Fig. 4.1A). When deployed, the two hydrophones were ~3.5 m (1032) and ~2 m (8212) off the sea floor. The hydrophone cables were faired to minimize strumming (see Fig. 4.1B).

All hydrophones had been calibrated before the onset of the field season at the ITC calibration facility in Goleta, California, which employs standards traceable to the National Standards for underwater sound measurements. The ITC 8212 hydrophones were recalibrated on 9 November 2006. Thorough calibration of the hydrophones and recording equipment allowed all results to be referred to the standard acoustic

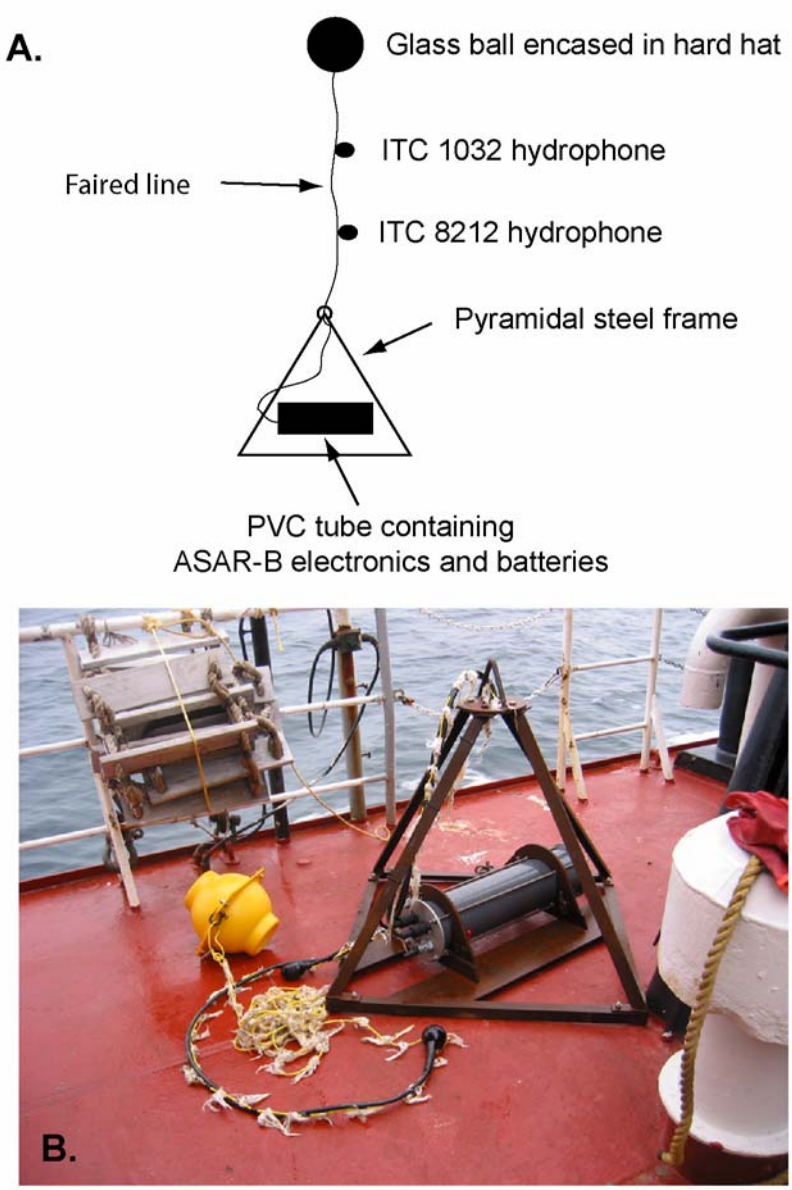

FIGURE 4.1. ASAR-B recorder. ***(A)*** Schematic diagram of the components of the ASAR-B recorder as deployed on the sea floor. Not drawn to scale. ***(B)*** An ASAR-B on the deck of the M/V *Kilabuk* after retrieval. The hydrophones are the black spheres on the cable in the foreground. The yellow sphere to the left of the frame is the hard hat containing the glass ball.

pressure of one micropascal (1 μPa). Both hydrophone types therefore had calibrated responses for the frequency range 5–30,000 Hz, and the ITC 1032 hydrophones were calibrated to 50 kHz.

A Seabird model 19Plus CTD (conductivity-temperature-depth) probe was used at each recording site to obtain a sound velocity profile.

Deployment Procedure

Both ASARs were used in each recording session. The basic layout was the same during measurements of vessel sounds and airgun / shallow-hazards survey sounds and is shown in Figure 4.2. In

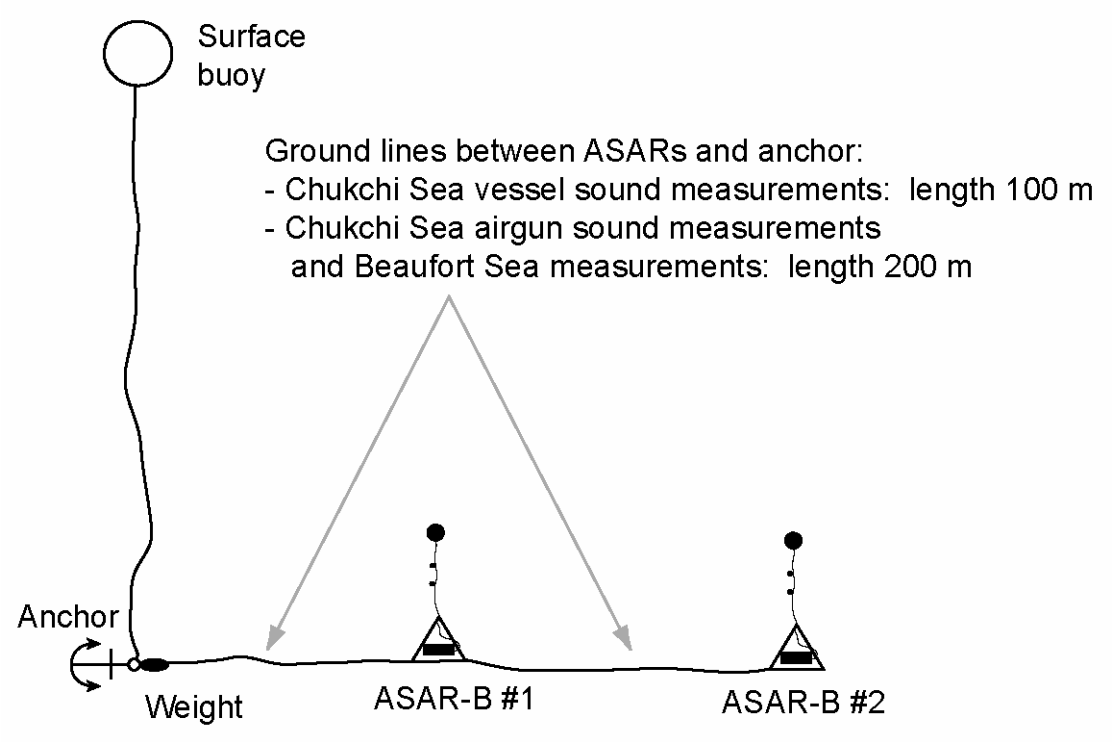

FIGURE 4.2. Deployment layout for ASAR-B recorders. A small weighted anchor is attached to a surface buoy to facilitate retrieval. A ground line connects the anchor to the first ASAR-B, itself connected by a ground line to the second ASAR-B. Anchor and recorders are laid out in a line on the seafloor.

the Chukchi Sea, deployments were done from the *Kilabuk*'s FRC (Fast Rescue Craft) with a crew of four people (boat driver, scientist, and two deck hands). In the Beaufort Sea, deployments were done directly from the deck of the *Henry C.* At the desired deployment location, the anchor and weight were lowered to the bottom with a line connecting them to a surface buoy. A GPS waypoint[7] for the location was obtained. A ground line connecting the anchor to the first ASAR was laid out in a straight line. The length of this line, and of the line between the two ASARs, was 200 m except in the Chukchi vessel sound measurements in which it was 100 m (Fig. 4.2). When the end of the ground line was reached, a "lowering line" was threaded through the "hoop" at the apex of the ASAR's pyramidal cage and the recorder was lowered to the sea floor. A GPS waypoint was obtained at the recorder location. The second length of ground line and the second recorder were deployed in similar fashion.

Deployments in the Chukchi Sea were made on 12 July to record vessel sounds of the *Kilabuk* and *Gilavar*, and on 21 July to record airgun sounds. In the Beaufort Sea the airgun and vessel sound recordings (*Henry C.*) were done concurrently during a single deployment of the ASARs on 8 August. Table 4.1 summarizes information pertaining to these deployments.

[7] A Garmin GPS model 12CX was used during the Chukchi Sea measurements. Deployment positions in the Beaufort Sea were recorded directly by the GPS on the *Henry Christoffersen*.

Recording Procedure

After the ASARs were deployed the sound source — airguns (see specifics below) or vessel — was operated over a dedicated test course referenced to the ASAR positions. There were two main types of recording legs:

- endfire aspect with the sound source opening (stern aspect) or closing (bow aspect) range from the ASARs. In the Chukchi Sea measurements, the test course included travel directly over ASAR #2, but not ASAR #1. Therefore, strictly-endfire data were only available from ASAR #2, even though at farther distances ASAR #1 was at very close to endfire aspect, and the data recorded by both ASARs were identical. For the endfire aspect, measurements were obtained to ~10 km distance for vessel sound measurements in the Chukchi Sea, ~30 km for airgun sound measurements in the Chukchi Sea, and ~20 km for the Beaufort Sea measurements.
- crossfire aspect (broadside aspect) with the sound source passing laterally at several closest points of approach (e.g., 100 m, 500 m, 1000 m) from the recorders. We restricted broadside data to those collected while the sound source was within ±5° of broadside, i.e., within an ~10° span of angles (Fig. 4.3).

During all recordings, the time and GPS position of the sound source were logged every 4–20 sec, depending on the type of measurements:

- The Chief Positioning Specialist on the *Gilavar* provided source positions. During measurements of vessel sounds, the position of the *Gilavar*'s stern was logged every 10 sec. During measurements of airgun sounds the position of the geometric center of the airgun array was logged at every shot, which took place every 19–20 sec.
- During measurements of the *Kilabuk*'s vessel sounds, a handheld GPS receiver (Garmin GPS model 12CX) logged the *Kilabuk's* position every 16 sec.
- On the *Henry C.*, position information was provided by the Geo LLC navigator for every shot of the airgun cluster, about every 4 sec.

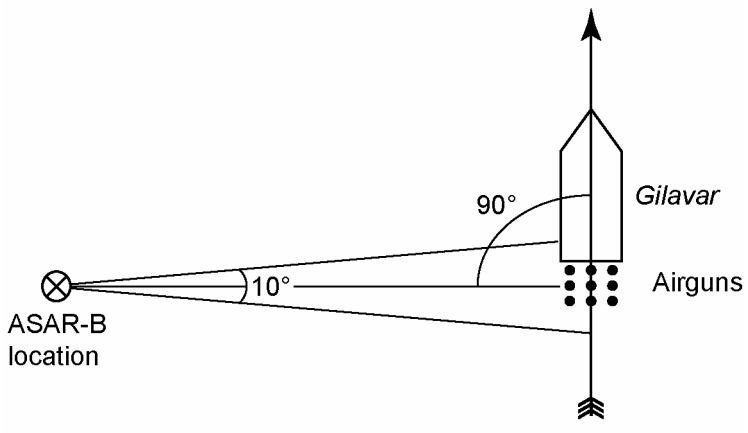

FIGURE 4.3. Circumstances in which data were included in the broadside category (see text).

Sound Sources

The ***Gilavar*** is a seismic research vessel, 84.9 m (279 feet) in length. It has five diesel electric engines, of which four are Bergen KRGB-9 units (2067 brake horse power or BHP each) and one is a Caterpillar 3516B (1855 BHP), for a total of 10,123 BHP. During the Chukchi Sea measurements, the *Gilavar* used two airgun array configurations:

- A three-string array with a total volume of 3147 in^3, with eight airguns per string (i.e., 24 guns total)
- A one-string array with a total volume of 1049 in^3, comprised of eight airguns.

Source depth was 6 m and firing interval was ~19 sec (50 m). Recordings were made using both array configurations consecutively. Although hydrophone streamers are deployed during production operations, they were not deployed during the sound source verification recordings.

The ***Jim Kilabuk*** is an icebreaking tug and supply vessel, 62.5 m (205 feet) in length. It has two turbo-charged diesel engines, for a total of 7200 brake horse power (BHP). The *Kilabuk* was previously (in the 1980s) named the *Canmar Supplier IV*.

The ***Henry Christoffersen*** is a pusher-towing tug, 56.4 m (185 feet) in length. The *Henry C.* has four engines at 1125 HP each for a total of 4500 BHP. The *Henry C.* used five different sound sources for shallow-hazards surveys. These included the following:

- An airgun cluster consisting of four 70 in^3 airguns in a tuned array cluster (total volume 280 in^3), at source depth 2.5 m, with firing interval of ~4 sec (6.25 m)
- A Seabat 8101 bottom mapping sonar operating at 240 kHz
- An SIS 1500 seafloor-imaging sonar operating at 190 kHz
- A chirp sonar (sub-bottom profiler) operating at 2–7 and 8–23 kHz, transducer depth ~1 m, 0.25–5 sec interval
- A bubble pulser operating at frequencies near 400 Hz, 0.5–5 sec interval

The airgun cluster was expected to be the strongest of these sound sources. Since the operational frequencies of the bubble pulser overlapped with those for the airguns, different pulse intervals for the two sources were used: 8 s for the airguns and 6 s for the bubble pulser. The Seabat 8101 bottom mapping

sonar and the SIS 1500 seafloor-imaging sonar both operate at frequencies >180 kHz. That is the highest frequency considered to be of possible influence to any species of marine mammal, including mid- and high-frequency specialists such as toothed whales (Odontocetes) (Miller et al. 2005). No measurements of sounds from these two high-frequency sources were planned since there should be no exclusion zones for seals or whales during their operation.

Retrieval Procedure

When recordings of sound-producing activities were complete, the ASARs were retrieved. In the Chukchi Sea, this was done using the *Kilabuk*'s FRC and a crew of five people (boat driver, scientist, and three deck hands). The surface buoy was retrieved first, followed by the anchor and weight, ASAR #1, and lastly ASAR #2 (see Fig. 4.2). All gear was hauled in by hand. On the *Henry C.*, the gear was hauled in from the port side of the vessel, with help from the vessel's main winch.

Data Analysis

Recorded data were saved as a series of 422.1 MB files which were transferred from the Flash card to laptop computers running MATLAB and custom analysis software. They were then calibrated in units of sound pressure over the data bandwidth (5–20,000 Hz or 5–90,000 Hz depending on sampling rate).

Broadband Analysis

For ***vessel sound measurements*** the data were partitioned into non-overlapping segments of 1 sec each and a broadband (10–20,000 Hz) sound pressure level was obtained for each 1-s segment.

For ***airgun sound measurements*** the sound pressure time series (see Fig. 4.5, later) was used for selecting samples for analysis. Four parameters were determined for each selected pulse (see McCauley et al. 1998, 2000a,b; Burgess and Greene 1999):

- **peak pressure**, i.e. the instantaneous maximum of the absolute sound pressure, in dB re 1 μPa;
- pulse **duration**, defined as the time interval between the arrival of 5% and 95% of the total pulse energy;
- pulse **sound pressure level** (SPL), squared pressure averaged over the pulse duration, in dB re 1 μPa;
- pulse **sound exposure level** (SEL), defined as the squared instantaneous sound pressure integrated over the pulse duration, in dB re 1 $\mu Pa^2 \cdot s$. This measure is related to the total physical energy conveyed in each pulse, and was calculated excluding the contributions of background sound as characterized by measurements between pulses.

SPL and pulse duration are highly interdependent. For example, low-level reverberation that extends the pulse length can result in a longer averaging time and thus a lower SPL. The SEL is not influenced by the duration, as it is a measure of the total energy in the pulse regardless of the pulse duration.

One of two propagation models was fitted by the least squares method to broadband levels of vessel sounds, or to the peak, SPL, and SEL values for seismic pulses, in order to characterize propagation loss underwater. These models were based on logarithmic spreading loss:

$$\text{Received Level } (\mathbf{RL}) = A + B \cdot \log(R) \quad (1)$$

$$\text{Received Level } (\mathbf{RL}) = A + B \cdot \log(R) + C \cdot R \quad (2)$$

In these equations, R is the range to the source in m and the units for **RL** are dB re 1 μPa or 1 $\mu Pa^2 \cdot s$. The constant term (A) is the hypothetical level 1 m from the source, extrapolated back to 1 m range based on far-field measurements. This hypothetical value would equal the actual level at 1 m only if the source were a point source and if loss rates were consistent at all distances from 1 m to the maximum measurement distance, neither of which is the case. The estimated A value is useful mainly as a basis for comparison with other sources operating in the same region. The spreading loss term (B), which is negative, varies with the dominant frequency in the pulse, water depth, bottom topography, and bottom composition. C (in dB/m) is the coefficient describing losses due to scattering and absorption; like B it is negative. The composition and topography of the seabed and sea surface roughness will affect such losses.

The choice of one model over the other is generally determined by the range and water depth over which the measurements were made. In our measurements, water depths were all similar, so our choice was determined by range. When the maximum measurement distance was less than ~10 km, Eq. (1) was used. When measurements extended to greater distances, as for most of the airgun sound measurements, the $C \cdot R$ term was expected to become significant, and Eq. (2) was used. C is a small number except in very shallow water and therefore its effect is difficult to measure until R becomes large.

Spectral Analysis

The spectral composition of each vessel's sound and of the airgun pulses was obtained from data recorded at short ranges (at or close to the CPA). Spectral processing yielded both one-third octave band levels and sound spectral density levels. The one-third octave band levels represent the amount of sound in parts of the frequency spectrum (bands) whose lower and upper frequencies differ by a factor of 1.26×. Spectral density levels represent the amount of sound in 1-Hz bands and are expressed in dB re 1 $\mu Pa^2/Hz$.

M-weighting

Hearing abilities differ among different types of marine mammals, with some marine mammals being more sensitive to low frequencies (e.g., baleen whales) while others are more sensitive to high frequencies (e.g., porpoises). In assessing the effects of sound on different types of marine mammals it is useful to weight the sounds reaching the animal by de-emphasizing frequencies which the animal of concern cannot hear, or hears only weakly. Ideally there should be a specific weighting function for each species of marine mammal, but audiograms are not available for most species. In the interim, all marine mammal species have been placed into one of five groups, based on their hearing function (Miller et al. 2005; Southall et al., submitted). These five groups are low-, mid-, and high-frequency cetaceans, pinnipeds in water, and pinnipeds in air. Three of these groups are of interest in this report: mid-frequency cetaceans (including beluga whales), pinnipeds in water (seals and walruses), and low-frequency cetaceans (bowhead and gray whales). The different M-weighting functions are determined by the variables f_{low} and f_{high}, which are conservative estimates of the lower and upper boundaries of effective hearing for each group:

- mid-frequency cetaceans: f_{low} = 150 Hz, f_{high} = 160 kHz;
- pinnipeds in water: f_{low} = 75 Hz, f_{high} = 75 kHz;
- low-frequency cetaceans: f_{low} = 7 Hz, f_{high} = 22 kHz;

The M-weighting functions have been defined primarily for applications involving exposure to strong sounds, including pulsed sounds (Miller et al. 2005; Southall et al., submitted). These functions are analogous to the C-weighting function that is widely used in characterizing effective levels of strong pulsed sounds insofar as they affect humans. Annex 4.3 shows the M-weighting functions in relation to frequency.

To assess the effect of *M*-weighting on broadband SPLs and SELs, a subset of seismic pulses was analyzed after being weighted according to the three types of *M*-weighting functions described above.

RESULTS

Seismic and Sonar Sound Measurements

Broadband Levels for Seismic Vessel Gilavar *(Chukchi Sea)*

On 21 July 2006 both ASARs were deployed in the locations given in Table 4.1. To maximize recording time, the ASAR start times were offset by 6 h (11:00 for ASAR #2 and 17:00 for ASAR #1). The *Gilavar* followed a predetermined course over and away from the ASAR locations, to provide recordings of airgun sounds from different distances and different aspects (bow, stern, broadside). The *Gilavar*'s course is shown in Figure 4.4. During these recordings the *Gilavar* traveled at a speed of ~5.5 knots (10.2 km/h or 6.3 mph).

Sound pressure time series of airgun sounds (three-string array), as recorded by ASAR #2 (hydrophone ITC 1032), are shown in Figure 4.5. Data recorded with the more sensitive hydrophone (model ITC 8212) were saturated for most of the obtained pulses, so we only present data obtained with the less sensitive hydrophone.

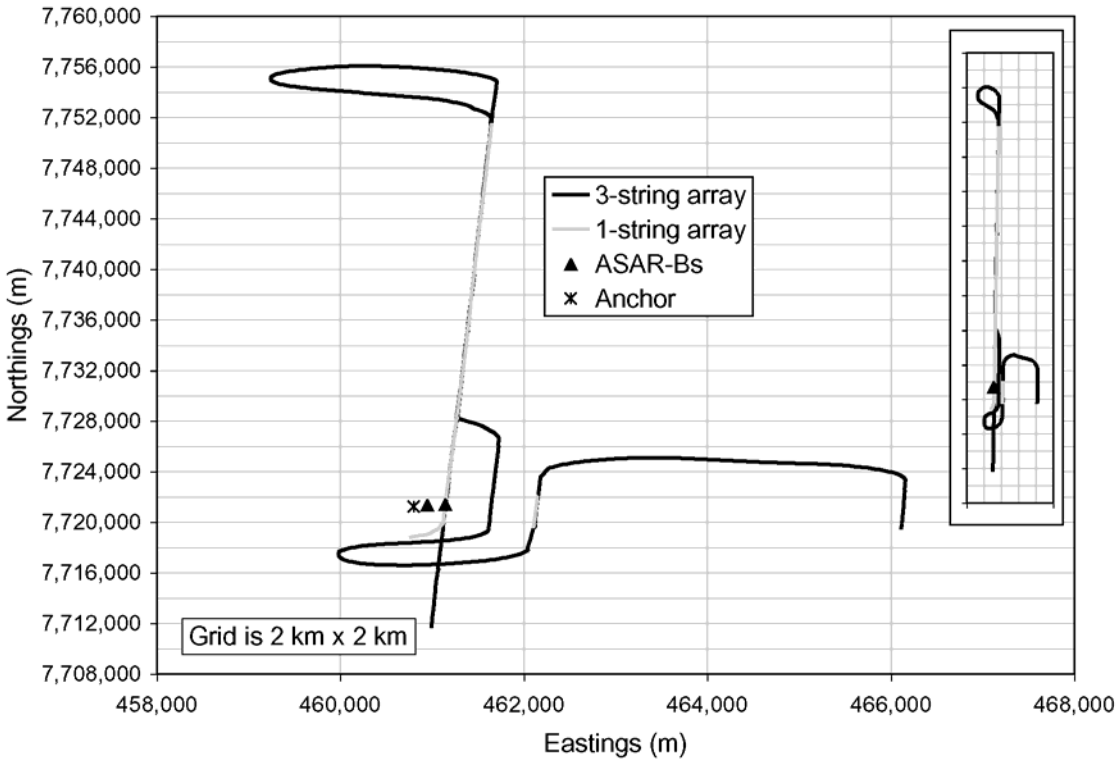

FIGURE 4.4. Track of the M/V *Gilavar* during airgun sound measurements, while towing a three-string airgun array (black) and a one-string array (gray), 21 July 2006, Chukchi Sea. The grid squares are 2 km × 2 km; the main map has been extended in the E–W direction to better show the ship track but the inset map shows the track to scale. Filled triangles show the ASAR locations.

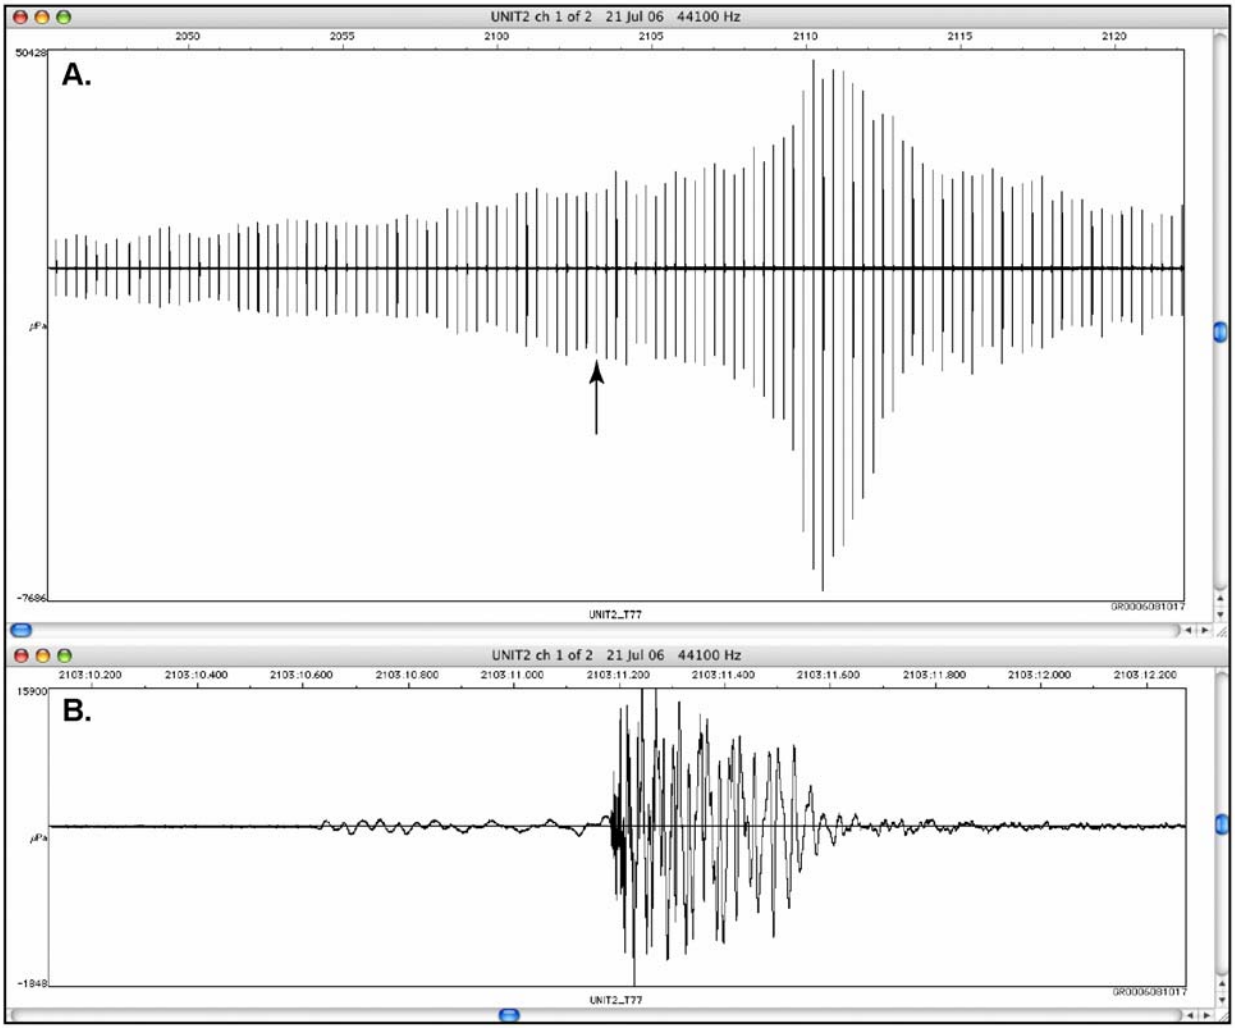

FIGURE 4.5. Sound pressure time series (SPTS) of airgun sounds as recorded on 21 July 2006 by ASAR #2, ITC 1032 hydrophone. ***(A)*** About 37 min of recording while the *Gilavar* passed by ASAR #2 at a distance of 1 km. Calculated distance from ASAR #2 to the center of the airgun array was 3880 m at the time of the first pulse shown, 1008 m at the CPA, and 2007 m at the time of the last pulse shown. ***(B)*** Detail of pulse shown by arrow in plot (A).

Three-String Array Configuration (3147 in^3).—Broadband levels of airgun sounds for the three-string array configuration are shown in Figures 4.6–4.9. Figure 4.6 shows bow aspect data for four pulse parameters as a function of distance from the airguns: peak level, SPL, SEL, and pulse duration. For peak, SPL, and SEL values Eq. (2) was fitted to the data. The resulting equations and correlation coefficients (R or r, as appropriate) are shown in Table 4.2.

Figures 4.7 and 4.8 show the same types of data as Figure 4.6, but for the stern and broadside aspects. Broadside data were only collected to a distance of ~5 km. Therefore Eq. (1) was fitted to the data, instead of the more complex model [Eq. (2)] which takes scattering and absorption losses into account but requires measurements over a larger span of distances.

Propagation effects, such as geometric dispersion, predictably lengthen pulse durations with increasing distance from the sound source (see Greene and Burgess 2000). This can be seen in Figures 4.6–4.8 for all three aspects.

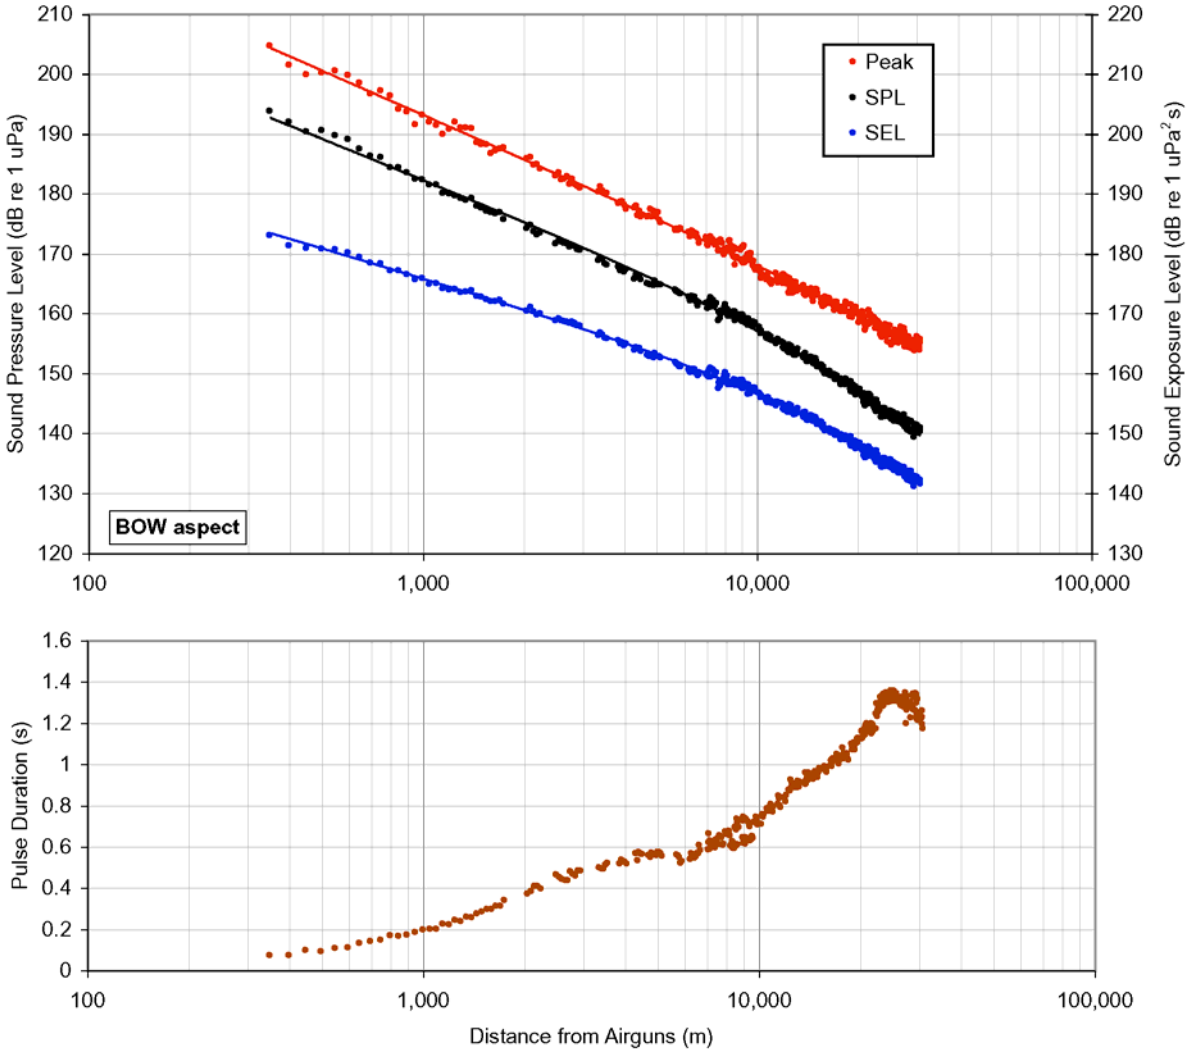

FIGURE 4.6. Received broadband levels of sound with *Gilavar*'s three-string array (3147 in^3) for **bow** aspect, as a function of distance from the airguns, 21 July 2006, Chukchi Sea. The top plot shows peak levels and SPLs, with values to be read on the left y-axis (dB re 1 μPa), and SELs with values to be read on the right y-axis (dB re 1 $\mu Pa^2 \cdot s$). Note that to avoid overlap, values on the two y-axes are offset by 10 dB. Equations for the regressions are given in Table 4.2. The bottom plot shows pulse duration as a function of distance from the airguns.

Figure 4.9 compares the fitted regression lines from Figures 4.6–4.8 in order to illustrate the effect of aspect (bow, stern, and broadside). For bow and stern aspects, the SPL and SEL regressions have been extrapolated beyond the maximum distances of our measurements to the range where the received level has diminished to 120 dB. These extrapolations are for purposes of comparison only, due to uncertainties in the propagation model and the effects of measurement variability on the regressions. However, for SEL, the consistency of the results for the 3 aspects suggests that—for this acoustic measure—measurement variability was small. Figure 4.9 shows that, for the *Gilavar*'s 3-string array, aspect dependence was relatively small, at least out to the maximum distance (5 km) at which broadside-aspect data were acquired.

TABLE 4.2. Values for variables *A*, *B*, and *C* [Eq. (1) and (2)] in the regressions shown in Figures 4.6–4.9; data were collected using the three-string airgun array in the Chukchi Sea. Values are shown for peak level, sound pressure level (SPL), and sound exposure level (SEL) for all three aspects (bow, stern, broadside). The multiple-*R* or *r*-value is also shown for each equation, as well as the range of distances over which the measurements were made and the sample size (number of pulses analyzed).

	A	*B*	*C*	*R* (or *r*)	Range of distances (km)	Sample size
BOW					0.35–30.6	391
Peak	266.4	–24.34	$-9.45\ 10^{-5}$	–0.997		
SPL	249.5	–22.26	$-3.25\ 10^{-4}$	–0.998		
SEL	224.6	–16.11	$-3.54\ 10^{-4}$	–0.998		
STERN					0.30–33.9	232
Peak	249.8	–19.90	$-2.24\ 10^{-4}$	–0.997		
SPL	247.2	–22.40	$-2.05\ 10^{-4}$	–0.997		
SEL	221.0	–15.44	$-3.55\ 10^{-4}$	–0.998		
BROADSIDE					0.52–5.16	54
Peak	253.5	–19.71	N.A.	(–0.986)		
SPL	239.7	–18.96	N.A.	(–0.994)		
SEL	222.9	–15.41	N.A.	(–0.994)		

One-String Array Configuration (1049 in^3).—Broadband levels of airgun sounds for the one-string array configuration are shown in Figures 4.10–4.12. Figure 4.10 shows stern aspect data for peak level, SPL, SEL and pulse duration, as a function of distance from the airguns. For all sound level parameters Eq. (2) was fitted to the data. The resulting equations and multiple-R values are shown in Table 4.3. The equivalent bow and broadside data are shown in Figure 4.11. Bow and broadside data were only collected to a distance of less than 2 km; therefore Eq. (1) was fitted to the data. The resulting equations and *r*-values are shown in Table 4.3.

Figure 4.12 compares the fitted regressions lines from Figures 4.10 and 4.11 in order to illustrate the effect of aspect. For the stern aspect, the regression has been extrapolated beyond the maximum distance of our measurements to the distance where the received level was 120 dB. (Data for bow and broadside aspects were not collected over a large enough range to justify extrapolation.) As predicted by the pre-field-season modeling (Chapter 3), aspect dependence was more marked for data collected with the one-string array, compared to the three-string array (*cf.* Fig. 4.9).

Relationship Between SPL, SEL, and Range.—Figure 4.13 summarizes the relationship between SPL, SEL, and the distance from the hydrophone to the airguns. The difference between SPL and SEL is mathematically related to pulse duration and is shown in Fig. 4.13A (i.e., if the actual data were plotted they would fall on the shown line and *r* would equal 1.0). Since we define pulse duration as the time interval between the arrival of 5% and 95% of the total pulse energy (see Methods section), SPL and SEL are equal (i.e., their difference is 0) when pulse duration = 0.9 sec. When x = 0.9, y = – 0.4576 – 10·log(0.9) = 0, as

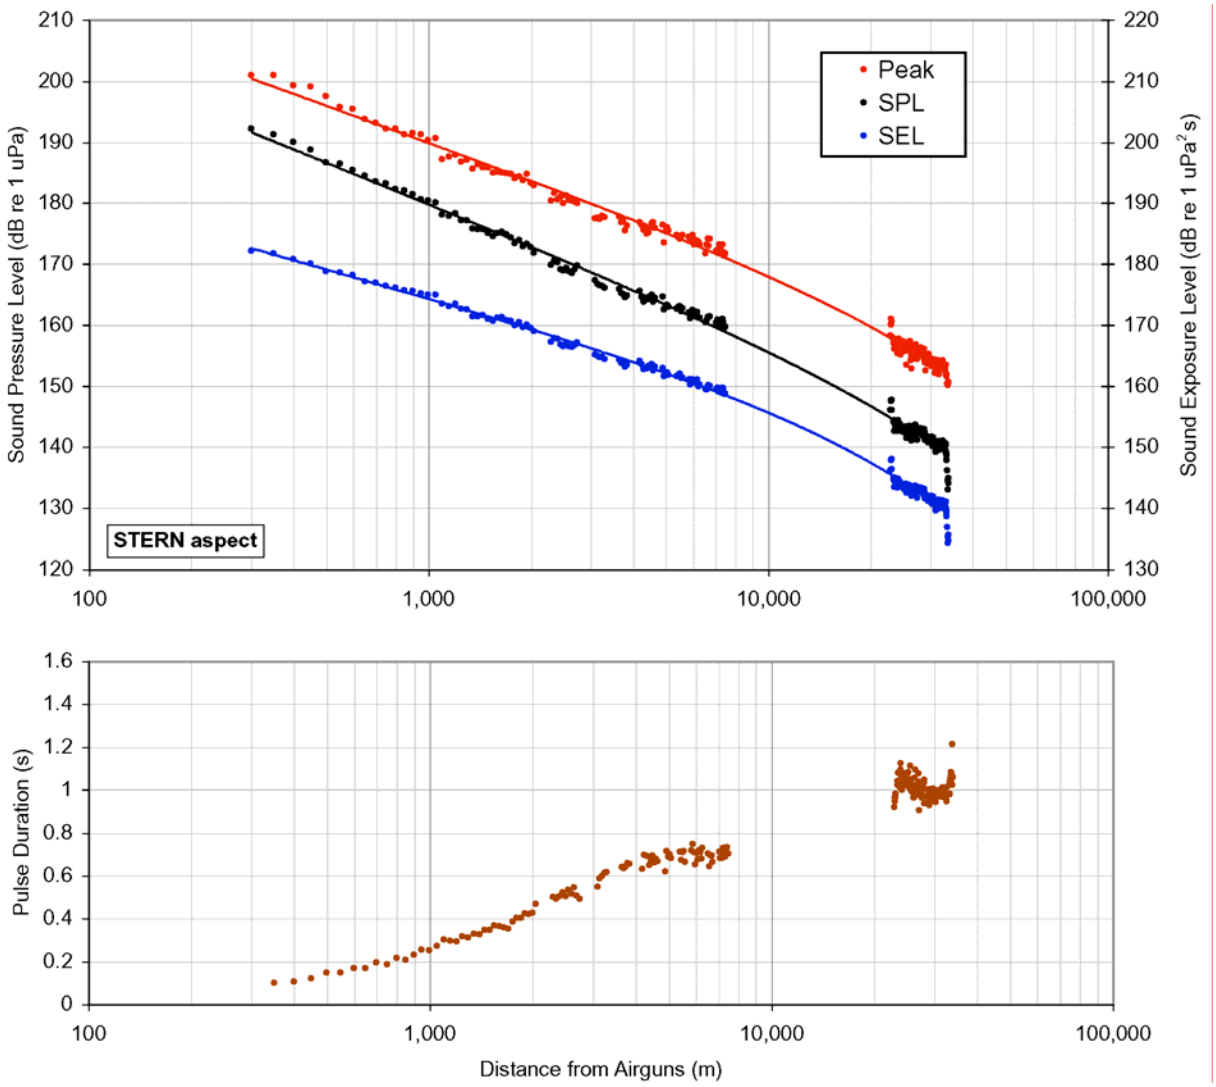

FIGURE 4.7. Received broadband levels of sound with *Gilavar*'s three-string array (3147 in^3) for **stern** aspect, as a function of distance from the airguns, 21 July 2006, Chukchi Sea. Plotted as in Figure 4.6.

10·log(0.9) = –0.4576 (see Fig. 4.13A). Figures 4.13B and C illustrate how the difference between SPL and SEL changes with distance from the airguns for data collected with the three- and one-string arrays, respectively. The difference between SPL and SEL values was highest closest to the sound source, with SPLs about 10 dB higher than SELs ~300 m from the airguns. Out to ~3 km the difference between SPL and SEL decreased by about 8.5 dB / tenfold change in distance. Beyond 10–16 km the difference becomes negative, i.e., SEL values are larger than SPL values. This reflects the fact that most pulse durations had been "stretched" by propagation phenomena to 1 sec or greater at distances beyond 10–16 km (Fig. 4.6, 4.7, 4.10).

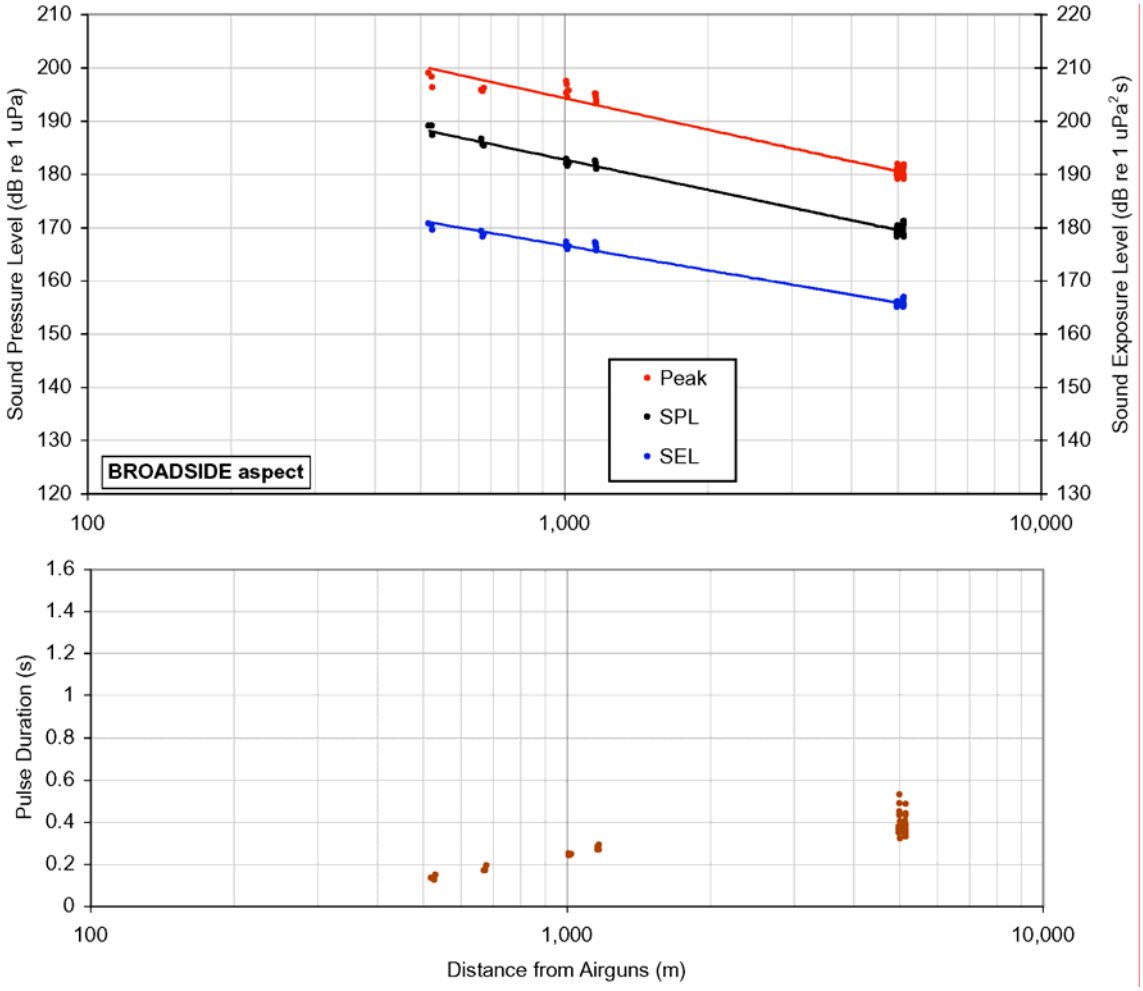

FIGURE 4.8. Received broadband levels of sound with *Gilavar*'s three-string array (3147 in^3) for **broadside** aspect, as a function of distance from the airguns, 21 July 2006, Chukchi Sea. Plotted as in Figure 4.6.

Comparison of Empirical and Modeled Radii for Airgun Sounds.—Table 4.4 summarizes the distances to a set of specified SELs and SPLs, as determined using the field measurements presented above for the one-string and three-string airgun arrays. These empirical distances are compared to distances predicted by sound propagation modeling (see Chapter 3). JASCO used their MONM acoustic model to generate SEL contours, from which SPLs were derived by Fourier synthesis analysis (see Chapter 3, Jensen et al. 2000). Because the contours produced by the MONM model are anisotropic (i.e., not distributed evenly in all directions), the predicted distances given in Table 4.4 are the radii encompassing 95% of the locations where the predicted SEL or SPL equals or exceeds the criterion value. For each array type, metric (SEL vs SPL), received level, and aspect (bow, stern, broadside) an "empirical : predicted" (E:P) ratio was calculated and is shown in Table 4.4.

Considering the SPL values (which are the ones used for mitigation purposes under current NMFS guidance), the empirical distances exceeded predicted distances in most (but not all) situations. For the *3-string array*, the E:P ratios for the 190-dB distance ranged from 1.5× to 2.0×, depending on aspect (Table 4.4A). The E:P ratios for the 180-dB distance around that array ranged from 1.2× to 1.7×. The ratios for the 160-dB distance ranged 1.5× to 1.8× (considering bow and stern aspect only). E:P ratios for the 120 dB

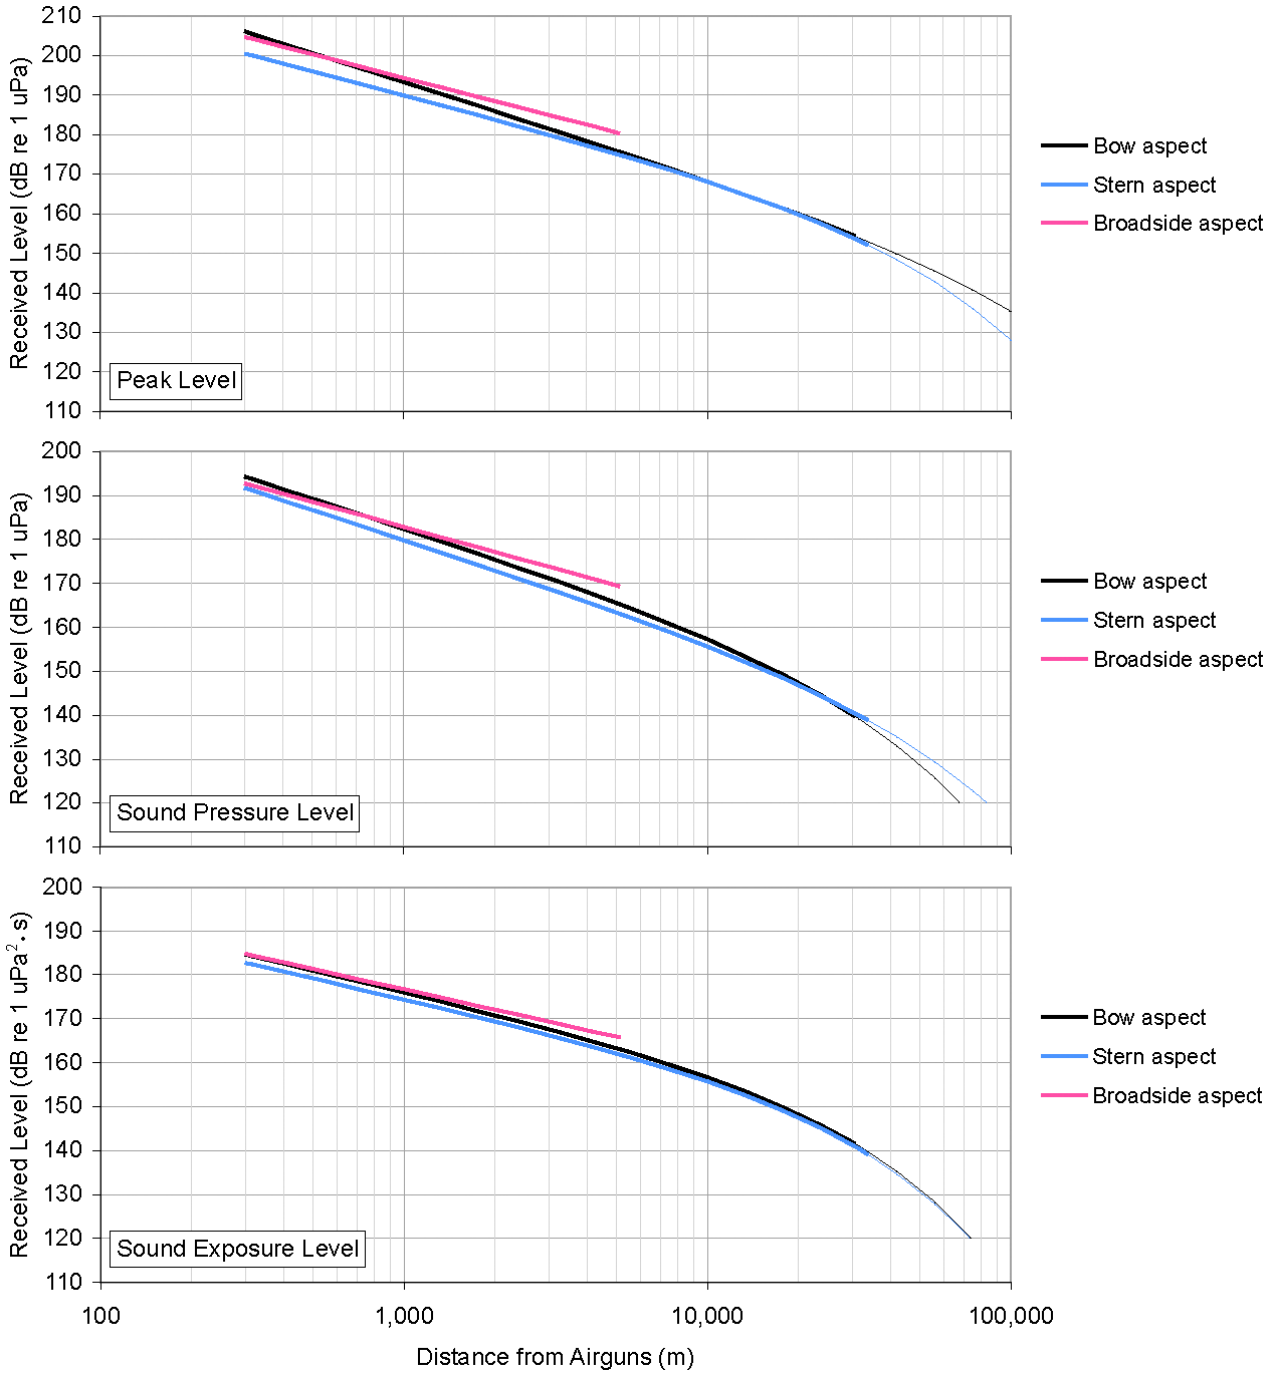

FIGURE 4.9. Summary of broadband levels for *Gilavar*'s three-string array configuration, 21 July 2006, Chukchi Sea. Data for all aspects are shown for peak (top plot), sound pressure (center plot), and sound exposure levels (bottom plot). Received levels which were obtained by extrapolating the regressions beyond the range of distances within which the measurements were made are indicated with a thinner line. Farthest measurement distances were 30.6 km, 33.9 km, and 5.2 km for bow, stern, and broadside data, respectively.

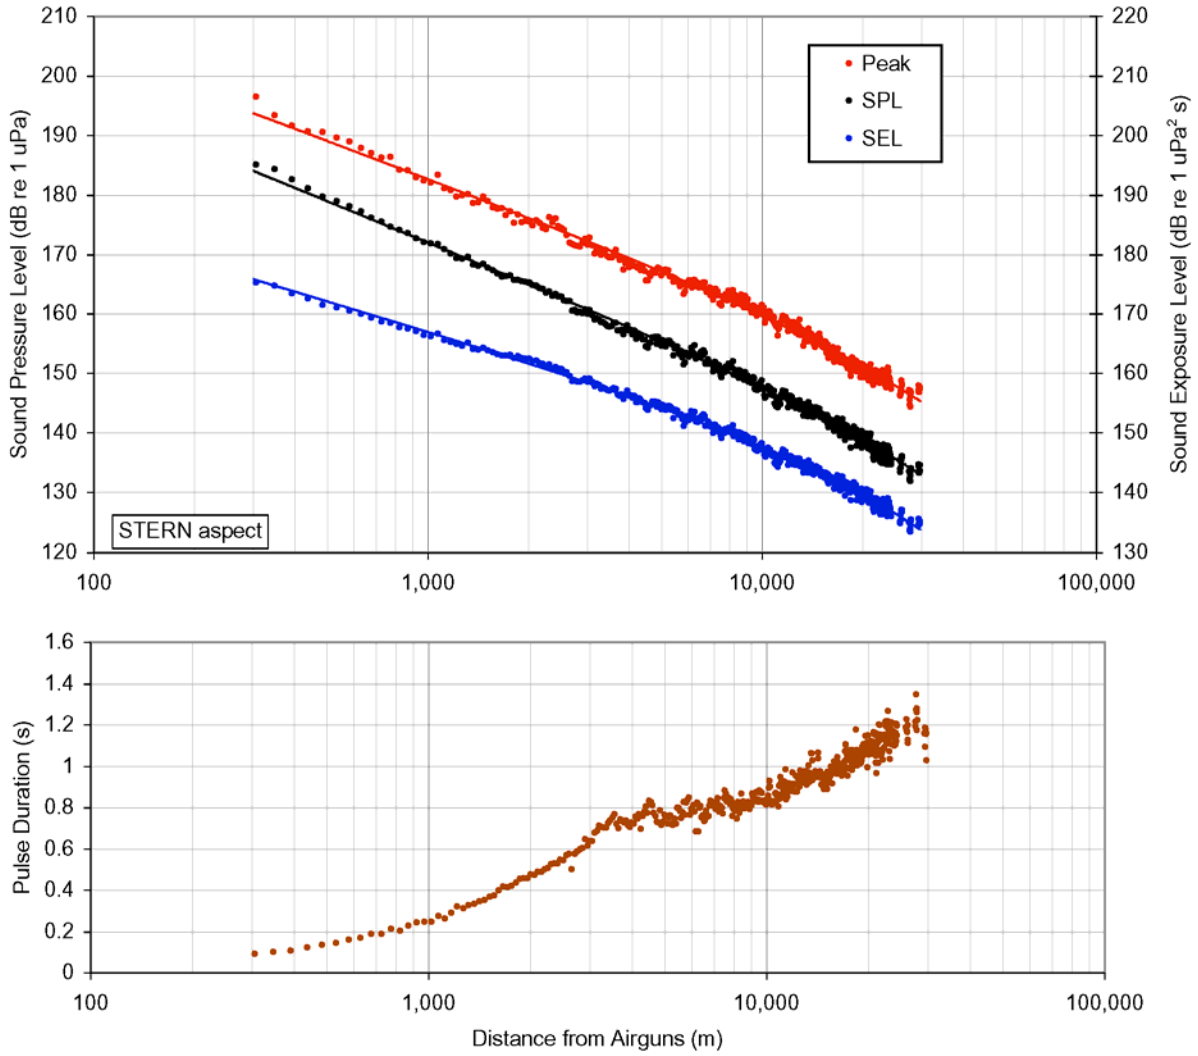

FIGURE 4.10. Received broadband levels of sound with *Gilavar*'s one-string array (1049 in^3) for **stern** aspect, as a function of distance from the airguns, 21 July 2006, Chukchi Sea. Equations for the regressions are given in Table 4.3. Otherwise plotted as in Figure 4.6.

distance were higher: 2.6× to 3.2× (again considering only bow and stern aspect). For the *single-string array*, the results also showed a tendency for higher E:P ratios when dealing with the 190 dB and 120 dB distances than when dealing with 160–180 dB distances. However, for the single-string array, the empirical distances were in fact less than the predicted distances (E:P < 1.0) in some cases (Table 4.4B). It should be noted that, because of ice conditions, the empirical measurements were taken at a location about 127 km from the C_1 site considered in JASCO's modeling. Differences in environmental conditions between those two sites probably accounted for some of the difference between empirical and predicted distances; the model would be expected to perform better if run for the actual site where the empirical measurements were acquired (D. Hannay, JASCO, pers. comm.).

Considering the SEL (energy) measure, the E:P ratios were higher than those for the SPL measure for almost all combinations of criterion level and aspect (Table 4.4). The underestimation of SEL levels by the model was particularly severe at the closer distances, i.e., those where the SEL value was 180–190

TABLE 4.3. Values for variables *A*, *B*, and *C* [Eq. (1) and (2)] in the regressions shown in Figures 4.10–4.12. Data were collected using the one-string airgun array in the Chukchi Sea. Values are shown for peak level, sound pressure level (SPL), and sound exposure level (SEL) for all three aspects (bow, stern, broadside). The multiple-*R* or *r*-value is also shown for each equation as well as the range of distances over which the measurements were made and the sample size (number of pulses analyzed).

	A	*B*	*C*	*R* (or *r*)	Range of distances (km)	Sample size
BOW					0.28–1.48	25
Peak	260.4	–24.94	N.A.	–0.992		
SPL	253.1	–25.99	N.A.	–0.992		
SEL	222.2	–17.87	N.A.	–0.991		
STERN					0.30–29.8	509
Peak	245.7	–20.94	$-2.25\ 10^{-4}$	–0.996		
SPL	240.6	–22.78	$-1.87\ 10^{-4}$	–0.997		
SEL	216.9	–16.54	$-3.06\ 10^{-4}$	–0.997		
BROADSIDE					0.17–1.16	7
Peak	247.2	–17.71	N.A.	(–0.998)		
SPL	242.2	–19.85	N.A.	(–0.999)		
SEL	210.7	–11.57	N.A.	(–0.997)		

dB re $(1\ \mu Pa)^2 \cdot s$. The SEL metric is not currently used for mitigation purposes, but would be used under the new procedures proposed by Southall et al. (submitted).

The fitted regressions resulting from Eq. (1) and (2) are based on a standard least-squares fit to the measured data, which means that about 50% of the empirical measurements fall above the line and 50% fall below (Fig. 4.6–4.8, 4.10, 4.11). Increasing the intercept value of each regression by 2 dB "elevates" each fitted curve by 2 dB, and nearly all the empirical measurements then are along or below the curves. Using these adjusted curves to determine mitigation radii results in protective radii that provide some margin for the inevitable variability in received levels. Table 4.5 is based on the same data as is Table 4.4, but the empirical distances are based on the curves with 2 dB added to all intercept values. The "E:P" ratios are larger in this case, as was to be expected when a protective factor was added to the empirical estimates but not to the model predictions.

Effect of M-weighting on Broadband SPLs and SELs.—Figure 4.14 illustrates the effects of *M*-weighting (as defined for mid-frequency cetaceans M_{mf}, pinnipeds in water M_{pw}, and low-frequency cetaceans M_{lf}) on SPLs (Fig. 4.14A) and SELs (Fig. 4.14B) for data collected in the Chukchi Sea. The amount (in dB) by which broadband (10–20,000 Hz) levels decreased as a result of being *M*-weighted is shown as a function of distance from the airguns. As expected given the varying low-frequency inflection points (f_{low}) for the three weighting functions, M_{lf} with $f_{low} = 7$ Hz had almost no effect on broadband SPLs or SELs, while M_{mf} with $f_{low} = 150$ Hz had the highest effect, and M_{pw} with $f_{low} = 75$ Hz had an intermediate effect. At close distances (400–650 m) pulse SPLs and SELs dropped by about 10 dB and 11 dB, respectively, for M_{mf}. At the same distance pulse SPLs and SELs dropped by about 5.5 dB and 6 dB,

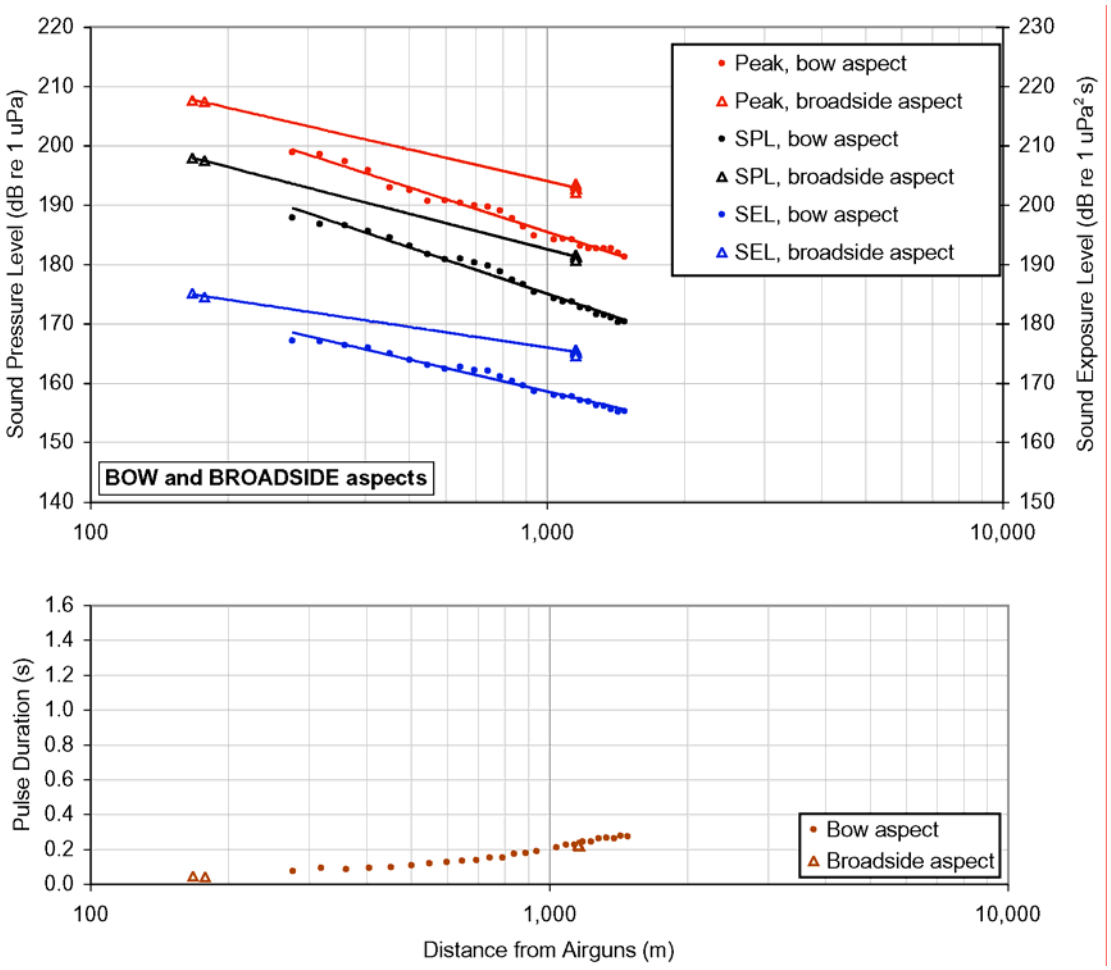

FIGURE 4.11. Received broadband levels of sound with *Gilavar*'s one-string array (1049 in^3) for **bow** (filled circles) and **broadside** (open triangles) aspects, as a function of distance from the airguns, 21 July 2006, Chukchi Sea. Plotted as in Figure 4.10.

respectively, for $M_{pw,}$. The effect of *M*-weighting decreased with distance from the sound source. At the farthest measurement distance, ~34 km, pulse SPLs and SELs dropped by less than 4 dB for M_{mf} and less than 2 dB for $M_{pw,}$. This was a result of the more rapid attenuation of the lower frequency components of the pulses with increasing distance.

To estimate how the 190 dB and 180 dB radii would change if *M*-weighted data were used instead of unweighted data, we fit two regressions to the points in Figure 4.14A, one for mid-frequency cetaceans and one for pinnipeds in water. The regressions were fitted to combined bow and stern aspect data. These represent the amounts (dB) by which SPLs drop as a result of M-weighting the data, as a function of distance from the airguns. For each distance (every m), we then subtracted the resulting decrease in SPL from the SPL regression shown in Figure 4.6 (bow aspect, three-string array) and reassessed the distances at which the 190 and 180 dB levels were reached. With unweighted data the 190 dB and 180 dB radii were 462 m and 1266 m, respectively (Table 4.4). For mid-frequency cetaceans (M_{mf}) these values decrease to 132 m and 455 m, respectively (28% and 36% of their former values, respectively). For pinnipeds in water (M_{pw}) these values decrease to 247 m and 776 m, respectively (53% and 61% of their former values, respectively).

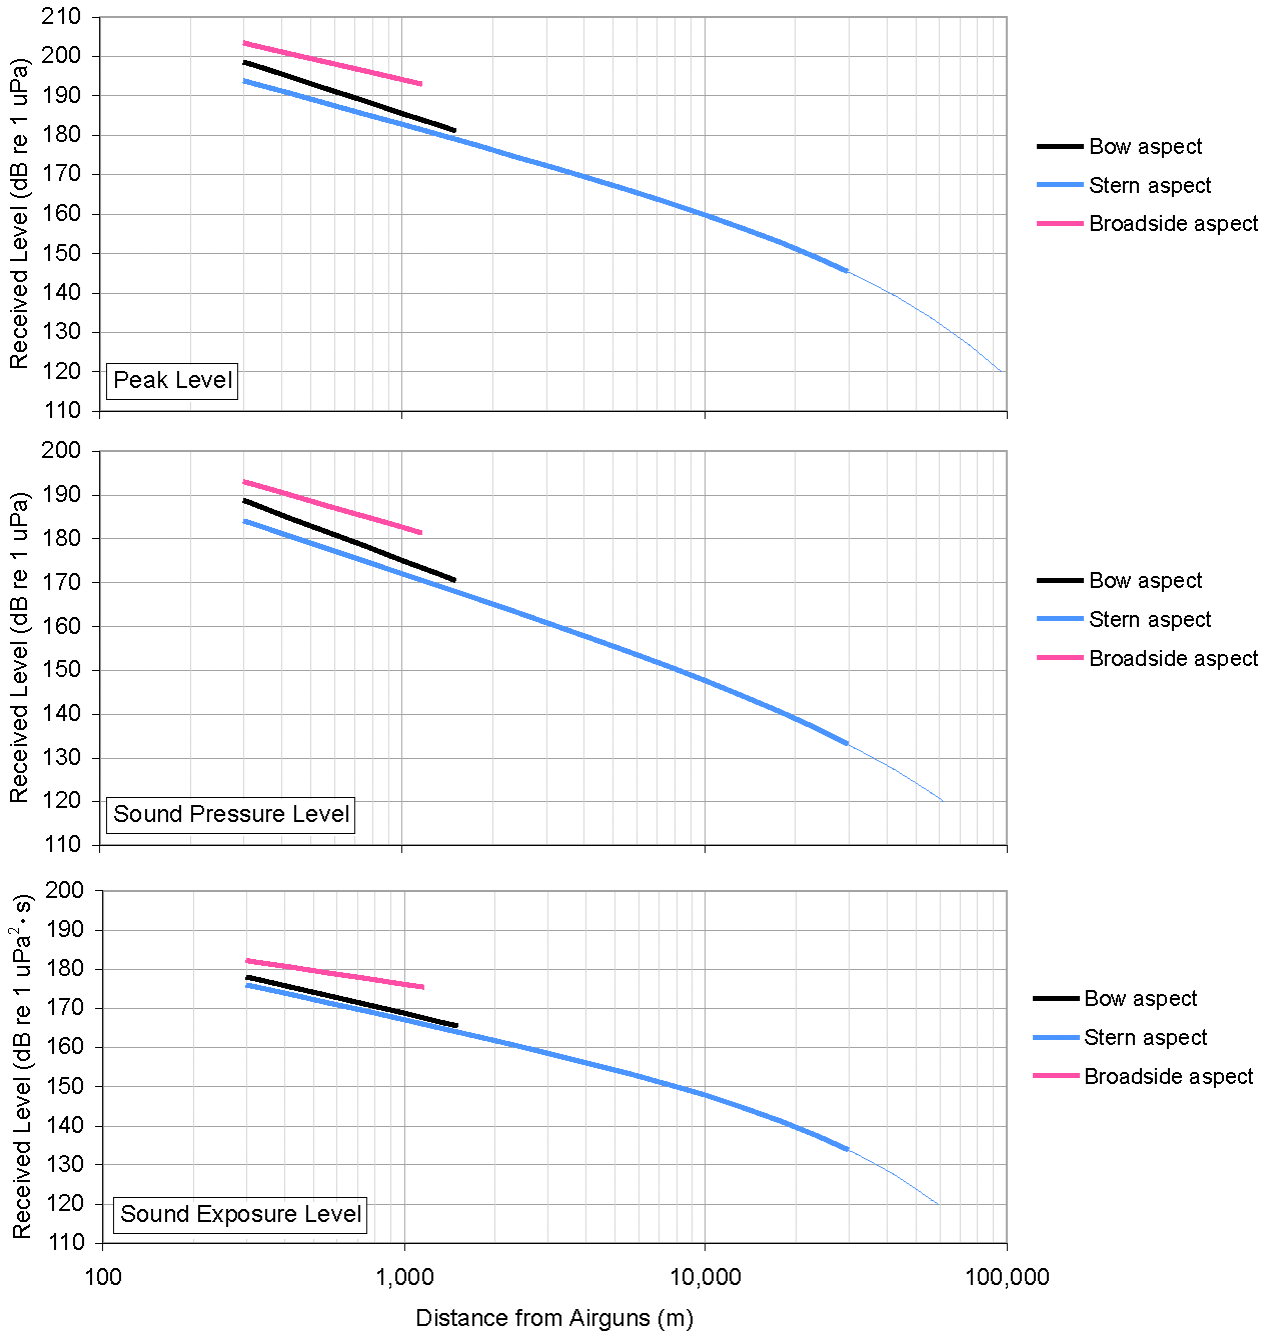

FIGURE 4.12. Summary of broadband levels for *Gilavar*'s one-string array configuration, 21 July 2006, Chukchi Sea. Data for all aspects are shown for peak (top plot), sound pressure (center plot), and sound exposure levels (bottom plot). Received levels which were obtained by extrapolating the regressions beyond the range of distances within which the measurements were made are indicated with a thinner line. Farthest measurement distances were 1.5 km, 29.8 km, and 1.2 km for bow, stern, and broadside data, respectively.

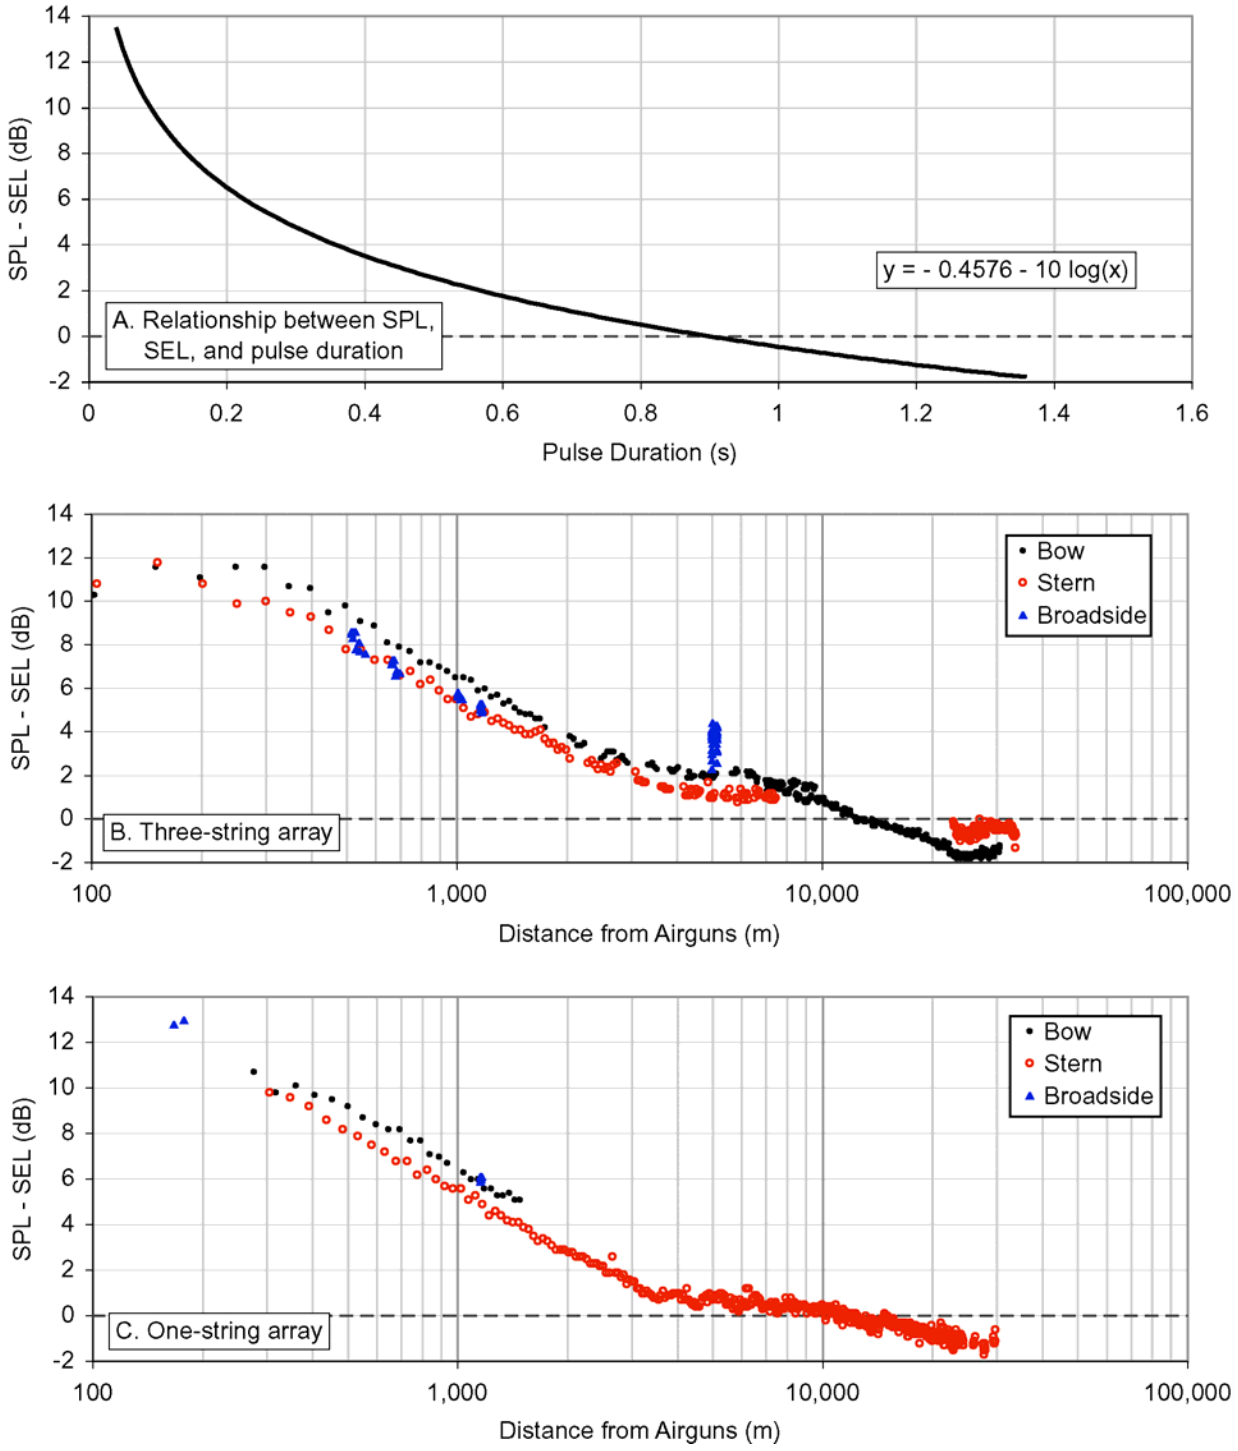

FIGURE 4.13. Relationship between SPL, SEL, pulse duration, and distance from *Gilavar*'s airguns for data collected in the Chukchi Sea. ***(A)*** SPL–SEL (i.e., the difference, for each analyzed pulse, in the received sound pressure level and sound exposure level) as a function of pulse duration. This relationship is defined mathematically as SPL–SEL = –0.4576–10 log(pulse duration). ***(B)*** SPL–SEL as a function of distance from the airguns for the three-string array data. ***(C)*** SPL–SEL as a function of distance from the airguns for the one-string array data.

TABLE 4.4. Distances to specified received sound exposure levels (SEL) and sound pressure levels (SPL) obtained with both array sizes used in the Chukchi Sea, and comparison with modeled values. All distances are in kilometers. C_1 is the site modeled by JASCO that most closely resembled the site where the empirical measurements were made. The "empirical : predicted" ratios were calculated with unrounded distances. For values shown in italics, the empirical distance was based on an extrapolation of the fitted curve beyond the range of the measured data.

	JASCO Predictions (km)	Empirical measurements (km)			"Empirical : Predicted" ratios

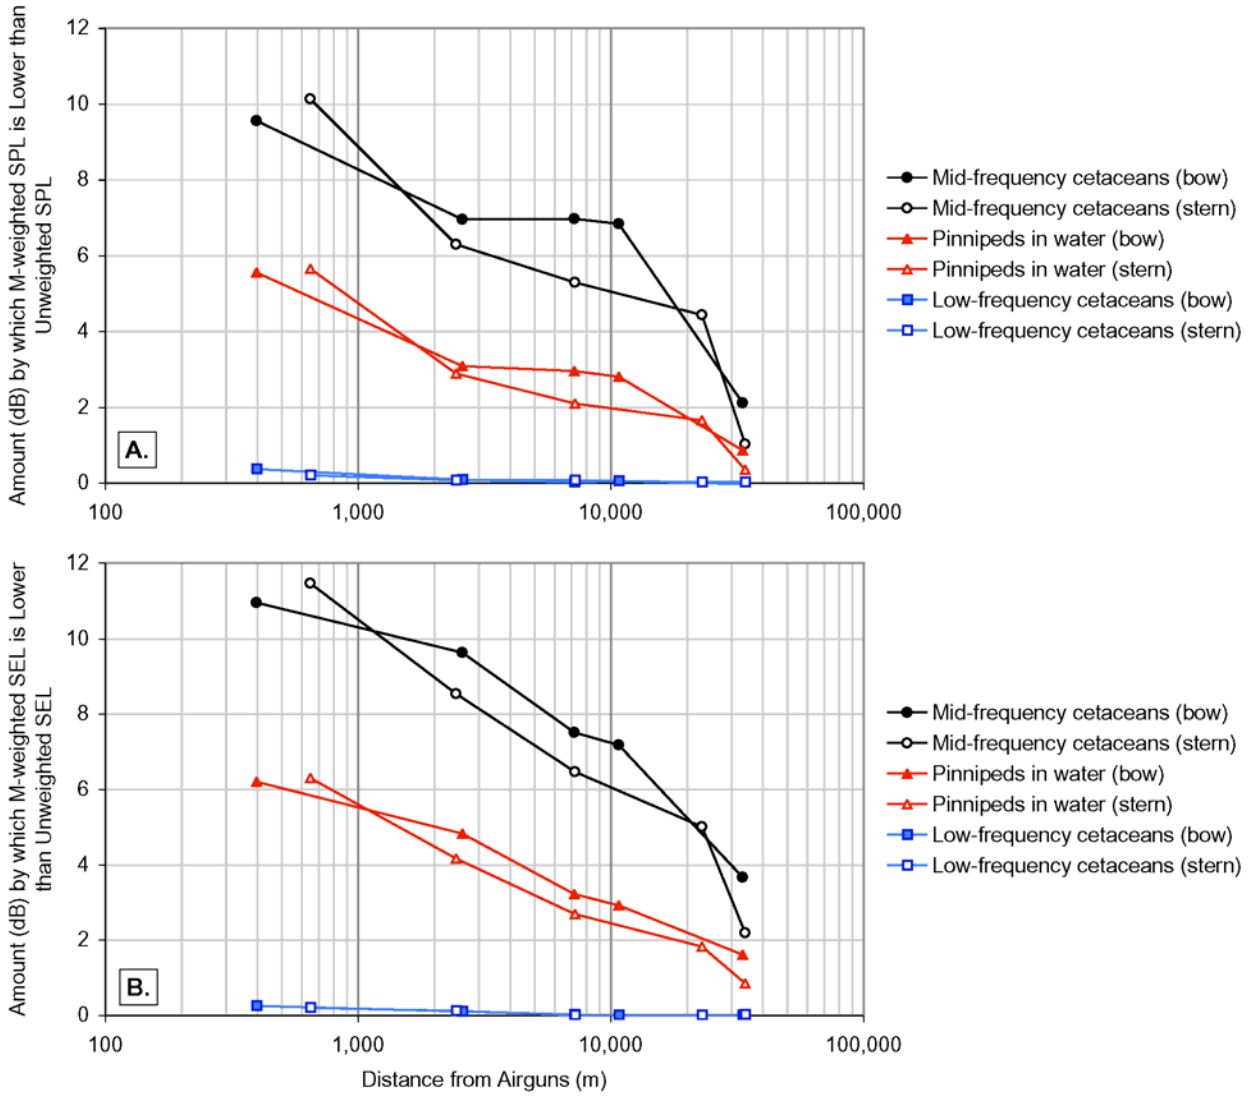

FIGURE 4.14. Effect of *M*-weighting on broadband levels, as a function of distance from the airguns (Chukchi Sea data). Both plots show the amount (dB) by which *M*-weighting decreases (A) pulse sound pressure levels (SPL) and (B) sound exposure levels (SEL). Three different types of *M*-weighting were used: for mid-frequency cetaceans (M_{mf}), pinnipeds in water (M_{pw}), and low-frequency cetaceans (M_{lf}). Each data point is the average of five consecutive pulses. Bow aspect data are distinguished from stern aspect data.

Broadband Levels for Shallow-Hazards Vessel Henry Christoffersen *(Beaufort Sea)*

On 8 August 2006, both ASARs were deployed in the locations given in Table 4.1, about 54 km east of Kaktovik off the north coast of Alaska. ASAR #1 was set to sample at 192 kHz (therefore filling its memory capacity in ~3 hours) and ASAR #2 at 44.1 kHz. Both ASARs started recording at 09:30 local time. The *Henry Christoffersen* followed a predetermined course over and away from the ASAR locations, providing endfire aspect data for various types of seismic sound sources. The *Henry C.*'s track is shown in Figure 4.15. The seismic and sonar sources were all operating simultaneously, but only on the outbound trip (away from the ASARs). While the sources were on, the *Henry C.* traveled at a speed of ~4 knots (7.4 km/h or 4.6 mph), using its two outer engines at reduced power (the two inner engines were turned off).

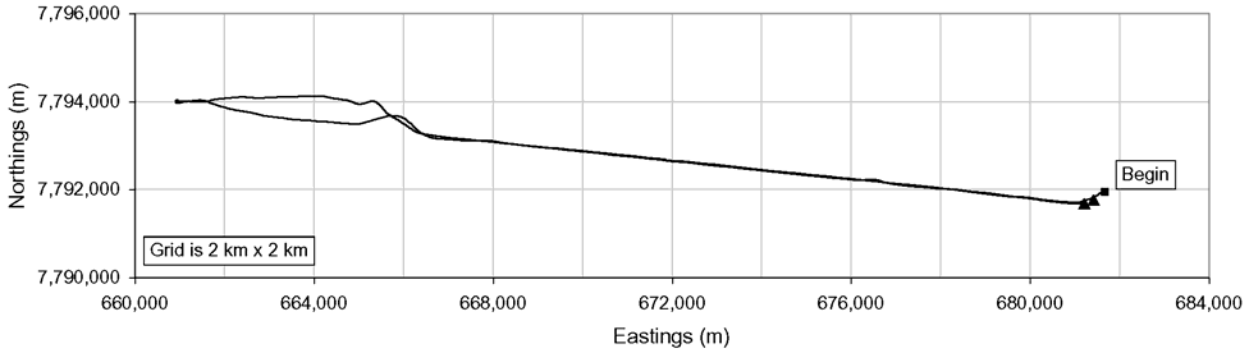

FIGURE 4.15. Track of the *Henry Christoffersen* during seismic, sonar, and vessel sound measurements. The grid squares are 2 km × 2 km. The *Henry C.* started its course at the filled square, steered over the two ASARs, then headed WNW at a speed of ~4 knots while seismic and sonar sound sources were turned on. On its return trip to the ASAR locations the *Henry C.* traveled at ~12 knots without any seismic or sonar sound sources turned on (see text for details). Filled triangles show the ASAR locations.

Airguns.—Figure 4.16 shows broadband levels for four pulse parameters as a function of distance from the Henry C.'s 4-airgun array: peak level, SPL, SEL and pulse duration. All aspects are combined, but the small, symmetric configuration of the four-gun array suggested there would be virtually no aspect dependence. For peak, SPL, and SEL values, Eq. (2) was fitted to the data. The resulting equations and multiple-*R* values are shown in Table 4.6. As expected, the received levels at a given distance were much lower for the small airgun array deployed from the *Henry C* than for the larger airgun arrays deployed from the Gilavar.

Comparison of Empirical and Modeled Radii for Airgun Sounds.—Table 4.7 summarizes the distances to a set of specified SELs and SPLs, as determined using the field measurements presented above for the *Henry Christoffersen*'s airgun array. These empirical distances are compared to distances predicted by sound propagation modeling (see Chapter 3). Note however that the empirical measurements were made with a 4-airgun 280 in^3 array whereas a 4-airgun 240 in^3 array was assumed in the modeling. JASCO used their MONM acoustic model to generate SEL contours, from which SPLs were derived by Fourier synthesis analysis (see Chapter 3, Jensen et al. 2000). Because the contours produced by the MONM model are anisotropic, the predicted distances given in Table 4.7 are the radii encompassing 95% of the locations where the predicted SEL or SPL equals or exceeds the criterion value. An "empirical : predicted" (E:P) ratio was calculated for each metric (SEL and SPL) and received level, as shown in Table 4.7. The E:P ratio was in general better (lower) for the Beaufort Sea measurements in Table 4.7 than the Chukchi Sea measurements in Table 4.4.

TABLE 4.6. Values for variables *A*, *B*, and *C* [Eq. (2)] in the regressions shown in Figure 4.16 for sounds from the airgun array towed by the *Henry Christoffersen*. Values are shown for peak level, sound pressure level (SPL), and sound exposure level (SEL) for all three aspects combined. The multiple-*R* value is shown for each equation as well as the range of distances over which the measurements were made and the sample size (number of pulses analyzed).

	A	*B*	*C*	Mult.-*R* value	Range of distances (km)	Sample size
					0.06–20.53	15
Peak	242.7	–21.70	$-6.31\ 10^{-4}$	–0.996		
SPL	233.4	–22.21	$-7.58\ 10^{-4}$	–0.993		
SEL	203.9	–15.72	$-7.47\ 10^{-4}$	–0.986		

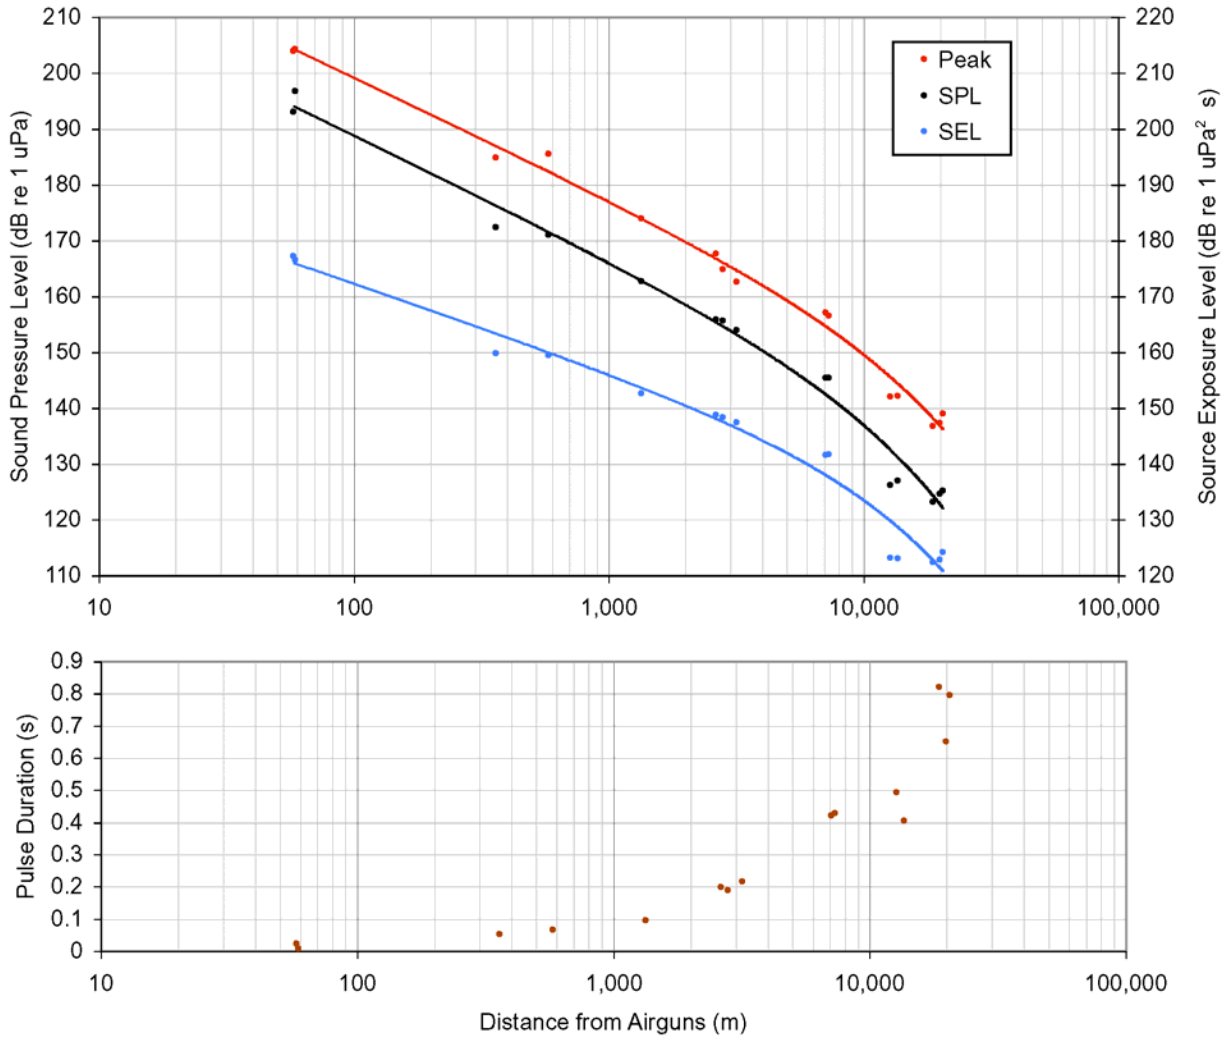

FIGURE 4.16. Received broadband levels of sound from airguns towed by the *Henry Christoffersen*, as a function of distance from the source (all aspects combined). The top plot shows peak levels and SPLs, with values to be read on the left y-axis (dB re 1 μPa), and SELs with values to be read on the right y-axis (dB re 1 $\mu Pa^2 \cdot s$). Note that to avoid overlap, values on the two y-axes are offset by 10 dB. Equations for the regressions are given in Table 4.5. The bottom plot shows pulse duration as a function of distance from the airguns.

The equations (Table 4.6) that resulted from fitting Eq. (2) to the empirical data were derived via a standard least-squares procedure, which means that about 50% of the empirical measurements fall above the line and 50% fall below. As for the Chukchi Sea, we calculated an alternate set of mitigation radii by increasing the intercept value of each regression in Table 4.6 so that almost all empirical data fall below the regression line. In the Chukchi data set, intercept values were increased by 2 dB. For the Beaufort measurements, we adjusted by 3 dB because of the somewhat greater variability in received levels at a given distance. These conservative radii and their comparison with the modeled ones are also shown in Table 4.7.

Chirp Sonar.—Received peak levels, SPLs, and SELs are shown in Figure 4.17 as a function of distance from the chirp sonar (sample size 73 pulses). Eq. (1) was fitted to the data for each parameter.

TABLE 4.7. Distances to specified received sound exposure levels (SEL) and sound pressure levels (SPL) obtained with 4-airgun array used in the Beaufort Sea, and comparison with modeled values. All distances are in kilometers. B_1 is the site modeled by JASCO that most closely resembled the site where the empirical measurements were made. However, modeling assumed a 240 in^3 array whereas the one used in the field was a 280 in^3 array. The "empirical : predicted" (E:P) ratios were calculated with unrounded distances. For values shown in italics, the empirical distance was based on an extrapolation of the fitted curve beyond the range of the measured data.

	JASCO Predictions (km)	Empirical Measure-ments (km)	E : P ratios
	B_1, 240 in^3		
SEL			
190 dB	0.005	*0.008*	*1.5*
180 dB	0.020	*0.033*	*1.6*
170 dB	0.055	0.14	2.6
160 dB	0.54	0.58	1.1
